a. *Ignore the missing value during analysis* – This approach ignores missing values in the analysis. This approach can, however, introduce inaccuracies in the results.
b. *Delete cases with missing values* – This approach eliminates the cases with missing values. It can however lead to bias in the analysis.
c. *Delete variables with lots of missing data* – This approach eliminates the variables with missing values. However, if those variables are deemed critical to the analysis, this approach many not be feasible.
d. *Estimate the missing values* – Sometimes missing values can be estimated. Common simple methods for estimation include mean and median substitution. Other more complex methods have been developed to estimate missing data. These methods are generally difficult to implement.

The Process of Data Cleaning

As a process, data cleaning consists of two main steps (Han & Kamber, 2006). The first step is *discrepancy detection*. Knowledge about the data or metadata is

crucial for this step. This knowledge could include the domain and data type of each variable, acceptable values, range of length of values, data dependencies, and so on. Summary statistics becomes very useful in understanding data trends and identifying any anomalies.

There are a number of automated tools that can aid in this step. They include *data scrubbing tools* which use simple domain knowledge to identify errors and make corrections in the data. They also include *data auditing tools* that find discrepancies by analyzing the data to discover rules and relationships, and identifying data that violates those rules and relationships.

The second step in data cleaning is *data transformation*, which defines and applies a series of transformations to correct the discrepancies identified in the first step. Data transformation is discussed in the next section. Automated tools can assist in the data transformation step. For example, *Data migration tools* allow simple transformations to be specified while *ETL (Extraction/Transformation/Loading) tools* allow users to specify data transformations using easy-to-use graphical user interface. Custom scripts need to be written for more complex transformations.

Data Transformation

Data transformation is the process of eliminating discrepancies and transforming the data into forms that are best suited for data mining (Osborne, 2002). Data transformation can involve the following operations:

a. *Data recoding* – Data recoding involves transforming the data type of a variable, for example, from alphanumeric to numeric.
b. *Smoothing* – Smoothing is used to remove noise from the data and reduce the effect of outliers. Smoothing techniques include binning, regression, and clustering.
c. *Grouping values* – Grouping values involves creating new variables with fewer categories by grouping together, or binning, values of existing variable.
d. *Aggregation* – Aggregation performs summary operations to the data.
e. *Generalization* – Generalization replaces low-level data with higher-level concepts.
f. *Functional transformation* – A functional transformation transforms distributions that skewed with a function, such as the natural log, to make it more regular and symmetrical.
g. *Normalization* – Normalization scales the values of a variable so that they fall with a small specified range, such as 0.0 to 1.0.
h. *Feature construction* – New fields are created and added to the data set to help the mining process.
i. *Feature selection* – Feature selection reduces the number of variables in the analysis for easier interpretation of the results.

FUTURE TRENDS

New approaches to data cleaning emphasize strong user involvement and interactivity. These approaches combine discrepancy detection and transformation into powerful automated tools (Raman & Hellertein, 2001). Using these tools, users build a series of transformations by creating individual transformations, one step at a time, using a graphical user interface. Results can be shown immediately on the data being manipulated on the screen. Users can elect to accept or undo the transformations. The tool can perform discrepancy checking automatically on the latest transformed view of the data. Users can develop and refine transformations as discrepancies are found, leading to a more effective and efficient data cleaning.

Another future trend for data cleaning is the development of declarative languages for the specification of data transformation operators (Galhardas, Florescu, Shasha, Simon, & Sita, 2001). These languages could be defined through powerful extensions to SQL and related algorithms to enable user to express data cleaning rules and specifications in an efficient manner.

CONCLUSION

Data preparation is a very important prerequisite to data mining as real-world data tend to suffer from inconsistencies, noise, errors and other problems. It is a broad area and consists of different approaches and techniques that are interrelated in complex ways. Data preparation can even answer some of the questions typically revealed by data mining. For example, patterns can sometimes be found, through visual inspection of data. Additionally, some of the techniques used in data

exploration can aid in understanding and interpreting data mining results.

KEY TERMS

Data Cleaning: The detection and correction of data quality problems.

Data Exploration: The preliminary investigation of data in order to better understand its characteristics.

Data Preparation: The steps that should be applied to make data more suitable for data mining.

Data Reorganization: The process of reorganizing data into a different case basis.

Data Selection: The task of extracting smaller representative data sets from larger data sources.

Data Transformation: The process of transforming data into forms that are best suited for data mining.

Data Visualization: The display of data in tabular or graphic format.

Data Provenance

INTRODUCTION

In recent years, our sensing capability has increased manifold. The developments in sensor technology, telecommunication, computer networking and distributed computing domain have created strong grounds for building sensor networks that are now reaching global scales (Balazinska et al., 2007). As data sources are increasing, the task of processing and analysis has gone beyond the capabilities of conventional desktop data processing tools. For quite a long time, data was assumed to be available on the single user-desktop; and handling, processing as well as analysis was carried out single-handedly. With proliferation of streaming data-sources and near real-time applications, it has become important to make provisions of automated identification and attribution of data-sets derived from such diverse sources. Considering the sharing and reuse of such diverse data-sets, the information about: the source of data, ownership, time-stamps, accuracy related details, processes and transformations subjected to it etc. have become essential. The piece of data that provide such information about the given data-set is known as *Metadata*.

The need is recognized for creating and handling of metadata as an integrated part of large-scale systems. Considering the information requirements of scientific and research community, the efforts towards the building global data commons have came into existence (Onsrud & Campbell, 2007). A special type of service is required that can address the issues like: explication of licensing & Intellectual Property Rights, standards based automated generation of metadata, data provenance, archival and peer-review. While each of these terms is being addressed as individual research topics, the present article is focused only on Data Provenance.

BACKGROUND

In present scenario, data-sets are created, processed and shared at ever increasing quantities sometimes approaching gigabyte or terabyte scales. The given data-set is merely a useless series of characters, unless proper information is provided about it's content and quality. A good analogy provided to understand the importance of such metadata; a data-set can be compared with a piece of art. The art collectors and scholars are able to appreciate given object only based on authentic documented history that reveals the information like the artist, the era of creation, related events and any special treatments it was subjected to. Similarly, a given data-set may be a raw and uncorrected sensor log, or it can be derived after subjecting it to a series of careful statistical and analytical operations, making it useful for decision making.

Any kind of information provided about the data-set is therefore helpful in determining its true value for potential users. But a general record of information about given data-set; which also qualifies to be a Metadata, renders only a limited value to the user by providing simple housekeeping and ownership related information. It is only through a systematic documented history about source, intermediate stages and processing subjected to the given data-set captured in the metadata content, that provides due recognition of the quality and characteristic of the given data-set. This special type of metadata content is known as "Data Provenance" or "Pedigree" or "Lineage" or "Audit Trail". It is now being recognized (Jagadish et al., 2007) that apart from the data models, Data Provenance has critical role in improving usability of the data.

MAIN FOCUS

Provenance is used in art, science, technology and many other fields for a long time. With the recent developments

of database management systems (DBMS) responding to increasingly complex utilization scenarios, the importance of data provenance has become evident. In simplest from, data provenance in DBMS can be utilized to hold information about how, when any why the Views are created. Sensor networks, enterprise systems and collaborative applications involve more complex data provenance approaches required to handle large data stores (Ledlie, Ng, & Holland, 2005).

The purpose of this article is to introduce only the important terms and approaches involved in Data Provenance to the Data Mining and Data Warehousing community. For the detailed account of the subject including historical development, taxonomy of approaches, recent research and application trends, the readers are advised to refer (Bose & Frew, 2005) and (Simmhan, Plale, & Gannon, 2005).

Characteristics of Provenance

Data Provenance is a general umbrella term under which many flavors can be identified based on how it is created and what specific information it provides. In a simple way (Buneman, Khanna, & Tan, 2001) it is classified it in two terms: *Where Provenance* and *Why provenance*. Where provenance refers to the data that provides information about location at which the source of data can be found. Why provenance provide information about the reason due to which the data is in current state. Later, (Braun, Garfinkel, Holland, Muniswamy-Reddy, & Seltzer, 2006) identified more flavors of data provenance based on the handling approach. A manual entry of provenance information is identified as *Manual Provenance* or Annotation. The approach that relies on the observation by the system is called *Observed Provenance*. In case of observed provenance, the observing system may not be configured to record all possible intermediate stages that the given dataset may pass through. Hence, resulting provenance, holding only partial information due to incomplete information flow analysis is classified as *False Provenanc*e. When participating entities provide explicit provenance to the third-party provenance handling system, it is known as *Disclosed Provenance*. When a participating system directs the desired structure and content about the object, it is classified as *Specified Provenance*. Many other provenance characteristics are studied for the detail classification of data provenance in (Simmhan, Plale, & Gannon, 2005). It mentions the reference to "*Phantom Linage"*-a special status of provenance when the data-set that is being described in given provenance record is deleted from the source.

Provenance System Requirements

Comprehensive application scenario followed by detailed use cases analysis has been documented to reveal the requirements for building provenance systems (Miles, Groth, Branco, & Moreau, 2007). It is recommended that a system targeted to handle data provenance, must support some general features apart from any specific that can be identified based on the application domain. A core functional requirement is the activity of *Provenance Record* that requires the recording the provenance using manual or automated mechanism. The collected record must be stored and shared for the utilization - which leads to the requirement for a *Storage Service*. The recorded provenance is accessed by the end-users or systems by issuing appropriately formed queries. The support for query is an important feature that allows retrieval of provenance. Handling provenance is an event-driven methodology for tracking, executing and reporting series of execution steps or processes collected as a workflow. To support the execution of a workflow enactment service is required. A processing component is required that is responsible for creation and handling, validating and inference of provenance data. Any special Domain Specific information that is beyond the scope of general purpose provenance system, and must be provided with special provisions. *Actor side recording* is a functional requirement that allows recording of provenance data from actor side that cannot be observed or recorded by an automated system. Presentation functionality is required that can allow rendering of search-results in user-friendly manner that reveals the historical process hierarchy and source information.

Some Provenance Systems

Over a period of time, many provenance systems are proposed that realize one or more functionalities identified above. In Data Warehousing and Data Mining domain, it is conventional that the users themselves assume the responsibility for collecting, encoding and handling of the required data-sets from multiple sources and maintenance the provenance information. Such manually curated data provenance poses a challenge

due to heterogeneity in collaborative environment. A "copy-paste database" approach (Buneman, Chapman, Cheney, & Vansummeren, 2006) is proposed as a solution to this problem that emulates a human curator adding individual items in the provenance. A formal treatment towards building a data provenance system, covering tasks from modeling to implementation and storage is discussed in (Lawabni, Hong, Du, & Tewfik, 2005). Considering the information needs of users in bio-informatics and remote sensing data sources, an Update Propagation Module is proposed focusing on Sensitivity analysis, Confidence level and Complexity in handling provenance data. Considering the interoperability issues in handling multiple heterogeneous systems, various designs are proposed that provides implementation of grid (Wootten, Rajbhandari, Rana, & Pahwa, 2006), semantics (Frey et al., 2006) and workflow (Barga & Digiampietri, 2006) based provenance systems.

Automation in Provenance

Apart from manual and observed provenance, it is possible to automate the process of provenance handling if some automation related issues are duly addressed in the design. (Braun, Garfinkel, Holland, Muniswamy-Reddy, & Seltzer, 2006) pointed out issues like, predicting granularity of observed provenance to match the user needs, the possibility of cyclic ancestry and determination of a new version based on a unit activity. In case of workflow, the workflow enactment engine is made responsible for automated handling of provenance (Barga & Digiampietri, 2006). A multi-layered model employed for handling different levels of workflow details in representation, thereby allowing multiple granularity of data provenance to suit the user needs.

Provenance in SOA and Grid

Service Oriented Architecture (SOA) paradigm advocates the strategy to expose unit functionality as a standard based service. (Tsai et al., 2007) provides special challenges for creating and handling of Data Provenance following SOA paradigm, with identification of additional features like dynamic composition, data routing and data classification. It is further claimed that complete recording of the provenance is not required and based on the needs, in place of full provenance record, it can be restricted only as: actor provenance, time-based provenance, event-based provenance, actor related provenance and scenario-based provenance. In SOA domain, Grid Computing is a special branch focused on ensuring non-trivial quality of service in providing access to services and resources that can be used for both storing and processing data. Utility of Grid in e-science projects have been successfully demonstrated by many projects. Data provenance in Grid environment poses unique requirements that are identified (Groth, Luck, & Moreau, 2004) by introduction of SOA specific flavors of the data provenance. The information about service invocations and interactions that resulted the data to its current form is introduced as *Interaction Provenance*.

It is likely that certain experiments have data processing needs that cannot be met by single service invocation. Therefore more than one service must be integrated to create a workflow that realizes the complete process. Such experiment-specific information about the process that can only be provided by a specific actor, and that can not be verifiable by any other means is identified as *Actor Provenance*. Up on building such composition, a service-based workflow encompassing a complete multi-stage business or scientific process can be achieved. (Szomszor & Moreau, 2003) provides a provenance architecture that offers a Provenance Service that exposes record and query operation in Grid Environment. During the execution of the workflow, for each unit service, the record operation is invoked. This approach results in a workflow trace, that consists of the provenance detail of each invocation during the workflow.

Provenance in Applications

The field of bio-informatics is claimed to be a field of Knowledge Management, where data from various sources are passed through series of processes resulting in important bio-informatics resource. Therefore, in this domain, the activity of knowledge management for *In Silico* experiments is considered as a task of managing Data Provenance. Addressing this challenge (Stevens, Zhao, & Goble, 2007) proposed an approach identifying four levels or data provenance information namely: Process level, data level, organization level and knowledge level in a provenance pyramid. Provenance handling using such approach provided capability for verification and validation of experiments.

In field of astronomy a virtual observatory effort provides access to established astronomy data to multiple users. Astronomy Distributed Annotation System was demonstrated (Bose, Mann, & Prina-Ricotti, 2006) that allows assertion of entity mappings that can be shared and integrated with existing query mechanisms for better performance in distributed environment.

Recently, wide acceptance of Web 2.0 application has resulted in proliferation of user-created data contributed by numerous users acting as data sources. When such data-sources are utilized for the determination of ranking and evaluation of products and services, authenticity of the content becomes important challenge. (Golbeck, 2006) proposed an approach that captures trust annotation and provenance for inference of trust relationships. It demonstrated a case for calculating personalized movie recommendations and ordering reviews based on computed trust values. Other interesting case based on the same principle, demonstrated how intelligence professionals assign the trust value to the provider of information and analysis to ascertain the quality of the information content.

In Healthcare domain, management of the patient data is a challenging task as such data is available in the form of islands of information created by one or many health professionals (Kifor et al., 2006). Agent based technology was found useful in efforts towards the automation, but face challenges due to heterogeneity of systems and models employed by individual professionals. As a solution to this problem, a Provenance based approach is proposed that requires the professional to assert the treatment related information encoded in process calculus and semantics. A case of organ transplant management application demonstrated how multiple agents collaborate for handling the data provenance so that, consistent health records can be generated.

Apart from social applications and project specific research problems, recent efforts of grid computing research community have contributed general-purpose systems that provide higher computational, storage and processing capability exposed through open general purpose standards. The resulting grid technology is found ideal for execution and handling of large-scale e-science experiments in distributed environments. While, by virtue of the capabilities of such systems, computation and resource management for generating experimental processes became considerably easy task, it introduced a novel requirement for evaluation of completed experiments for their validity. A provenance based approach is demonstrated (Miles, Wong, et al., 2007), that enables the verification of documented scientific experiment, by evaluating: input arguments to the scientific processes, the source of data, verification against Ontology, conformance to the plans and patent related details.

FUTURE TRENDS

As data sources continues to proliferate, data sharing and processing capabilities continue to grow and as the end-users continue to utilize them, the issue of data provenance will continue to become more complex. The piling up of the raw data and multiple copies or derived data-sets for each of them, calls for investigation of optimal engineering approaches that can provide low-cost, standards-based, reliable handling for error-free data provenance. Apart from automation achieved using semantics or workflow based strategy, the future research efforts will focus on machine learning techniques and similar approaches that will enable machine processable handling, storage, dissemination and purging of the data provenance.

CONCLUSION

As monitoring capabilities are increasing, it is become possible to capture, handle and share large amounts of data. The data collected initially for specific purpose can later be useful to many other users in their decision-making process. From initial collection phase up to the phase in which data is used for decision-making, data undergoes various transformations. It therefore becomes a challenging problem to identify and determine true identity and quality of given data-set extracted out of large amount of data shared in huge repositories. Data Provenance- a special type of metadata, is introduced as a solution for this problem. With increasing acceptance of service-oriented approaches for data sharing and processing, the resulting loosely coupled systems provide very little support for consistent management of provenance. Once published data is subjected to unplanned used and further processed by many intermediate users, the maintenance of change-log of the data becomes a challenging issue. This article provided various methods, protocols and system architectures

relating to data provenance in specific domain and application scenarios.

KEY TERMS

Actor Provenance: A special provenance strategy utilized in SOA realizing a scientific workflow for which a domain specific information can be collected only by the actors and by no other automated mechanisms.

Data Provenance: Data provenance is a historical record of processes executed over the raw data that resulted in to its current form. It is a special kind of Metadata that is also known as "Lineage", "Audit trail" or "Pedigree".

Interaction Provenance: A Provenance Strategy utilized in SOA environment that captures every method call in data provenance.

Phantom Linage: A special kind of provenance data that describes the data that is missing or deleted from the sources.

Provenance Architecture: A system architecture that is capable to satisfy all the functional and non-functional requirements identified for a provenance in given problem.

Provenance Collection: Activity of collecting provenance from single or multiple data sources and processing systems by employing manual or automated methods.

Provenance Granularity: The detail of provenance information collected and recorded. The high granularity contains every small intermediate process step (or method call) where as coarse granularity provenance provides only major changes experienced by the dataset.

Observed Provenance: Presentation of data in human understandable graphics, images, or animation.

Data Quality in Data Warehouses

William E. Winkler
U.S. Bureau of the Census, USA

INTRODUCTION

Fayyad and Uthursamy (2002) have stated that the majority of the work (representing months or years) in creating a data warehouse is in cleaning up duplicates and resolving other anomalies. This paper provides an overview of two methods for improving quality. The first is record linkage for finding duplicates within files or across files. The second is edit/imputation for maintaining business rules and for filling-in missing data. The fastest record linkage methods are suitable for files with hundreds of millions of records (Winkler, 2004a, 2008). The fastest edit/imputation methods are suitable for files with millions of records (Winkler, 2004b, 2007a).

BACKGROUND

When data from several sources are successfully combined in a data warehouse, many new analyses can be done that might not be done on individual files. If duplicates are present within a file or across a set of files, then the duplicates might be identified. Record linkage uses name, address and other information such as income ranges, type of industry, and medical treatment category to determine whether two or more records should be associated with the same entity. Related types of files might be combined. In the health area, a file of medical treatments and related information might be combined with a national death index. Sets of files from medical centers and health organization might be combined over a period of years to evaluate the health of individuals and discover new effects of different types of treatments. Linking files is an alternative to exceptionally expensive follow-up studies.

The uses of the data are affected by *lack of quality* due to duplication of records and missing or erroneous values of variables. Duplication can waste money and yield error. If a hospital has a patient incorrectly represented in two different accounts, then the hospital might repeatedly bill the patient. Duplicate records may inflate the numbers and amounts in overdue billing categories. If the quantitative amounts associated with some accounts are missing, then the totals may be biased low. If values associated with variables such as billing amounts are erroneous because they do not satisfy edit or business rules, then totals may be biased low or high. Imputation rules can supply replacement values for erroneous or missing values that are consistent with the edit rules and preserve joint probability distributions. Files without error can be effectively data mined.

MAIN THRUST OF THE CHAPTER

This section provides an overview of record linkage and of statistical data editing and imputation. The cleaning-up and homogenizing of the files are preprocessing steps prior to data mining.

Record Linkage

Record linkage is also referred to as *entity resolution* or *object identification*. Record linkage was given a formal mathematical framework by Fellegi and Sunter (1969). Notation is needed. Two files A and B are matched. The idea is to classify pairs in a product space **A ´ B** from two files A and B into M, the set of true matches, and U, the set of true nonmatches. Fellegi and Sunter considered ratios of conditional probabilities of the form:

$$R = P(\gamma \in \Gamma \mid M) / P(\gamma \in \Gamma \mid U) \quad (1)$$

where γ is an arbitrary agreement pattern in a comparison space Γ over all the pairs in **A ´ B**. For instance, Γ might consist of eight patterns representing simple agreement or not on the largest name component, street name, and street number. The distinct patterns in Γ partition the entire set of pairs in **A ´ B**. Alternatively, each $\gamma \in \Gamma$ might additionally account for the relative frequency with which specific values of name components such as “Smith”, “Zabrinsky”, “AAA”, and “Capitol” oc-

cur. Ratio R or any monotonely increasing function of it such as the natural log is referred to as a *matching weight (or score).*

The decision rule is given by:

If $R > T_{\mu}$, then designate pair as a match.

If $T_{\lambda} \leq R \leq T_{\mu}$, then designate pair as a possible match and hold for clerical review. (2)

If $R < T_{\lambda}$, then designate pair as a nonmatch.

The cutoff thresholds T_{μ} and T_{λ} are determined by a priori error bounds on false matches and false nonmatches. Rule (2) agrees with intuition. If $\gamma \in \Gamma$ consists primarily of agreements, then it is intuitive that $\gamma \in \Gamma$ would be more likely to occur among matches than nonmatches and ratio (1) would be large. On the other hand, if $\gamma \in \Gamma$ consists primarily of disagreements, then ratio (1) would be small. Rule (2) partitions the set $\gamma \in \Gamma$ into three disjoint subregions. The region $T_{\lambda} \leq R \leq T_{\mu}$ is referred to as the no-decision region or clerical review region. In some situations, resources are available to review pairs clerically.

Linkages can be error-prone in the absence of *unique identifiers* such as a verified social security number that identifies an individual record or entity. *Quasi identifiers* such as name, address and other non-uniquely identifying information are used. The combination of quasi identifiers can determine whether a pair of records represents the same entity. If there are errors or differences in the representations of names and addresses, then many duplicates can erroneously be added to a warehouse. For instance, a business may have its name 'John K Smith and Company' in one file and 'J K Smith, Inc' in another file. Without additional corroborating information such as address, it is difficult to determine whether the two names correspond to the same entity. With three addresses such as '123 E. Main Street,' '123 East Main St' and 'P O Box 456' and the two names, the linkage can still be quite difficult. With suitable pre-processing methods, it may be possible to represent the names in forms in which the different components can be compared. To use addresses of the forms '123 E. Main Street' and 'P O Box 456,' it may be necessary to use an auxiliary file or expensive follow-up that indicates that the addresses have at some time been associated with the same entity.

If there is minor typographical error in individual fields, then string comparators that account for typographical error can allow effective comparisons (Winkler, 2004b; Cohen, Ravikumar, & Fienberg, 2003). Individual fields might be first name, last name, and street name that are delineated by extraction and standardization software. Rule-based methods of standardization are available in commercial software for addresses and in other software for names (Winkler, 2008). The probabilities in equations (1) and (2) are referred to as *matching parameters*. If training data consisting of matched and unmatched pairs is available, then a *supervised method* that requires training data can be used for estimation matching parameters. Optimal matching parameters can sometimes be estimated via unsupervised learning methods such as the EM algorithm under a conditional independence assumption (also known as *naïve Bayes* in machine learning). The parameters vary significantly across files (Winkler, 2008). They can even vary significantly within a single file for subsets representing an urban area and an adjacent suburban area. If two files each contain 10,000 or more records, than it is impractical to bring together all pairs from two files. This is because of the small number of potential matches within the total set of pairs. *Blocking* is the method of only considering pairs that agree exactly (character-by-character) on subsets of fields. For instance, a set of blocking criteria may be to only consider pairs that agree on U.S. Postal ZIP code and first character of the last name. Additional blocking passes may be needed to obtain matching pairs that are missed by earlier blocking passes (Winkler, 2004a).

Statistical Data Editing and Imputation

Correcting inconsistent information and filling-in missing information needs to be efficient and cost-effective. For single fields, edits are straightforward. A look-up table may show that a given value in not in an acceptable set of values. For multiple fields, an edit might require that an individual of less than 15 years of age must have marital status of unmarried. If a record fails this edit, then a subsequent procedure would need to change either the age or the marital status. Alternatively, an edit might require than the ratio of the total payroll divided by the number of employees at a company within a particular industrial

classification fall within lower and upper bounds. In each situation, the 'errors' in values in fields may be due to typographical error or misunderstanding of the information that was requested.

Editing has been done extensively in statistical agencies since the 1950s. Early work was clerical. Later computer programs applied if-then-else rules with logic similar to the clerical review. The main disadvantage was that edits that did not fail for a record initially would fail as values in fields associated with edit failures were changed. Fellegi and Holt (1976, hereafter FH) provided a theoretical model. In providing their model, they had three goals:

1. The data in each record should be made to satisfy all edits by changing the fewest possible variables (fields).
2. Imputation rules should derive automatically from edit rules.
3. When imputation is necessary, it should maintain the joint distribution of variables.

FH (Theorem 1) proved that implicit edits are needed for solving the problem of goal 1. Implicit edits are those that can be logically derived from explicitly defined edits. Implicit edits provide information about edits that do not fail initially for a record but may fail as values in fields associated with failing edits are changed. The following example illustrates some of the computational issues. An edit can be considered as a set of points. Let edit E = {married & age ≤ 15}. Let *r* be a data record. Then $r \in E \Rightarrow r$ fails edit. This formulation is equivalent to 'If age ≤15, then not married.' If a record *r* fails a set of edits, then one field in each of the failing edits must be changed. An implicit edit E_3 can be implied from two explicitly defined edits E_1 and E_2; i.e., E_1 & $E_2 \Rightarrow E_3$.

E_1 = {age ≤ 15, married, . }
E_2 = { . , not married, spouse}
E_3 = {age ≤ 15, . , spouse}

The edits restrict the fields *age*, *marital-status* and *relationship-to-head-of- household*. Implicit edit E_3 is derived from E_1 and E_2. If E_3 fails for a record *r* = {age ≤ 15, not married, spouse}, then necessarily either E_1 or E_2 fail. Assume that the implicit edit E_3 is unobserved. If edit E_2 fails for record *r*, then one possible correction is to change the marital status field in record *r* to married to obtain a new record r_1. Record r_1 does not fail for E_2 but now fails for E_1. The additional information from edit E_3 assures that record *r* satisfies all edits after changing one additional field. For larger data situations having more edits and more fields, the number of possibilities increases at a very high exponential rate.

In data-warehouse situations, the ease of implementing FH ideas using generalized edit software is dramatic. An analyst who has knowledge of the edit situations might put together the edit tables in a relatively short time. In a direct comparison, Statistics Canada and the U.S. Census Bureau (Herzog, Scheuren & Winkler, 2007) compared two edit systems on the same sets of economic data. Both were installed and run in less than one day. Both were able to produce data files that were as good as the manually edited files that were used as a reference. For many business and data warehouse situations, only a few simple edit rules might be needed. In a dramatic demonstration, researchers at the Census Bureau (Herzog et al., 2007) showed that a FH system was able to edit/impute a large file of financial information in less than 24 hours. For the same data, twelve analysts needed six months and changed three times as many fields.

FUTURE TRENDS

Various methods represent the most recent advances in areas that still need further extensions to improve speed significantly, make methods applicable in a variety of data types or reduce error. First, some research considers better search strategies to compensate for typographical error. Winkler (2008, 2004a) applies efficient blocking strategies for bringing together pairs except in the extreme situations where some truly matching pairs have no 3-grams in common (i.e., no consecutive three characters in one record are in its matching record). Although extremely fast, the methods are not sufficiently fast for the largest situations (larger than 10^{17} pairs). Second, another research area investigates methods to standardize and parse general names and address fields into components that can be more easily compared. Cohen and Sarawagi (2004) and Agichtein and Ganti (2004) have Hidden Markov methods that work as well or better than some of the rule-based methods. Although the Hidden Markov methods require training data, straightforward methods quickly create

additional training data for new applications. Third, in the typical situations with no training data, optimal matching parameters are needed for separating matches and nonmatches even in the case when error rates are not estimated. Ravikumar and Cohen (2004) have unsupervised learning methods that improve over EM methods under the conditional independence assumption. With some types of data, their methods are even competitive with supervised learning methods. Bhattacharya and Getoor (2006) introduced unsupervised learning techniques based on latent Dirichlet models that may be more suitable than predecessor unsupervised methods. Fourth, other research considers methods of (nearly) automatic error rate estimation with little or no training data. Winkler (2002) considers semi-supervised methods that use *unlabeled* data and very small subsets of *labeled* data (training data). Winkler (2006) provides methods for estimating false match rates without training data. The methods are primarily useful in situations with matches and nonmatches can be separated reasonably well. Fifth, some research considers methods for adjusting statistical and other types of analyses for matching error. Lahiri and Larsen (2004) have methods for improving the accuracy of statistical analyses in the presence of matching error in a very narrow range of situations. The methods need to be extended to situations with moderate false match rates (0.10+), with more than two files, with sets of matched pairs that are unrepresentative of the pairs in one or more of the files being matches, and with complex relationships of the variables.

There are two trends for edit/imputation research. The first is faster ways of determining the minimum number of variables containing values that contradict the edit rules. Using satisfiability, Bruni (2005) provides very fast methods for editing discrete data. Riera-Ledesma and Salazar-Gonzalez (2007) apply clever heuristics in the set-up of the problems that allow direct integer programming methods for continuous data to perform far faster. Although these methods are considerably faster than predecessor methods with large test decks (of sometimes simulated data), the methods need further testing with large, real-world data sets. The second is methods that preserve both statistical distributions and edit constraints in the pre-processed data. Winkler (2003) connects the generalized imputation methods of Little and Rubin (2002) with generalized edit methods. For arbitrary discrete data and restraint relationships, Winkler (2007a) provides fast methods of edit/imputation that generalize the methods of imputation based on Bayesian networks introduced by Di Zio, Scanu, Coppola, Luzi and Ponti (2004) and the statistical matching methods of D'Orazio, Di Zio and Scanu (2006). The methods use convex constraints that cause the overall data to better conform to external and other controls. Statistical matching is sometimes used in situations where there are insufficient quasi-identifying fields for record linkage. As a special case (Winkler, 2007b), the methods can be used for generating synthetic or partially synthetic data that preserve analytic properties while significantly reducing the risk of re-identification and assuring the privacy of information associated with individuals. These methods assure, in a principled manner, the statistical properties needed for privacy-preserving data mining. Methods for general data (discrete and continuous) need to be developed.

CONCLUSION

To data mine effectively, data need to be pre-processed in a variety of steps that remove duplicates, perform statistical data editing and imputation, and do other clean-up and regularization of the data. If there are moderate errors in the data, data mining may waste computational and analytic resources with little gain in knowledge.

KEY TERMS

Edit Restraints: Logical restraints such as business rules that assure that an employee's listed salary in a job category is not too high or too low or that certain contradictory conditions such as a male hysterectomy do not occur.

Imputation: The method of filling in missing data that sometimes preserves statistical distributions and satisfies edit restraints.

Quasi Identifiers: Fields such as name, address, and date-of-birth that by themselves do not uniquely identify an individual but in combination may uniquely identify.

Pre-Processed Data: In preparation for data mining, data that have been through consistent coding of fields, record linkage or edit/imputation.

Privacy-Preserving Data Mining: Mining files in which obvious identifiers have been removed and combinations of quasi-identifiers have been altered to both assure privacy for individuals and still maintain certain aggregate data characteristics for mining and statistical algorithms.

Record Linkage: The methodology of identifying duplicates in a single file or across a set of files using name, address, and other information.

Rule Induction: Process of learning, from cases or instances, if-then rule relationships consisting of an antecedent (if-part, defining the preconditions or coverage of the rule) and a consequent (then-part, stating a classification, prediction, or other expression of a property that holds for cases defined in the antecedent).

Training Data: A representative subset of records for which the truth of classifications and relationships is known and that can be used for rule induction in machine learning models.

Data Reduction with Rough Sets

INTRODUCTION

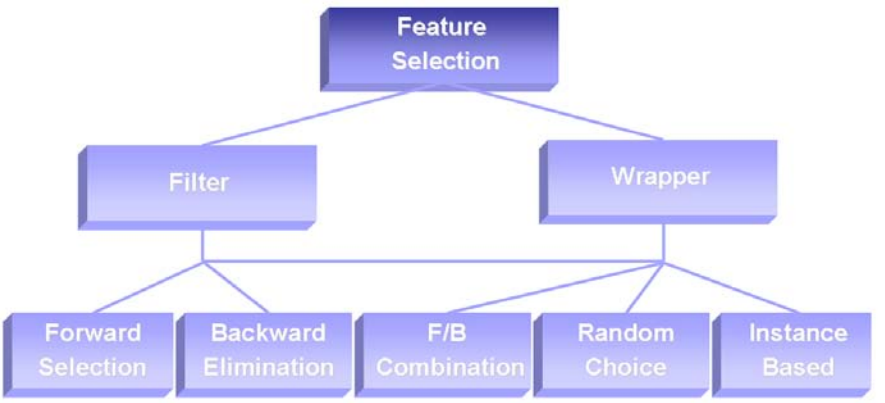
Data reduction is an important step in knowledge discovery from data. The high dimensionality of databases can be reduced using suitable techniques, depending on the requirements of the data mining processes. These techniques fall in to one of the following categories: those that transform the underlying meaning of the data features and those that are semantics-preserving. Feature selection (FS) methods belong to the latter category, where a smaller set of the original features is chosen based on a subset evaluation function. The process aims to determine a minimal feature subset from a problem domain while retaining a suitably high accuracy in representing the original features. In knowledge discovery, feature selection methods are particularly desirable as they facilitate the interpretability of the resulting knowledge. For this, rough set theory has been successfully used as a tool that enables the discovery of data dependencies and the reduction of the number of features contained in a dataset using the data alone, while requiring no additional information.

BACKGROUND

The main aim of feature selection is to determine a minimal feature subset from a problem domain while retaining a suitably high accuracy in representing the original features. In many real world problems FS is a must due to the abundance of noisy, irrelevant or misleading features. A detailed review of feature selection techniques devised for classification tasks can be found in (Dash & Liu, 1997).

The usefulness of a feature or feature subset is determined by both its relevancy and its redundancy. A feature is said to be relevant if it is predictive of the decision feature(s) (i.e. dependent variable(s)), otherwise it is irrelevant. A feature is considered to be redundant if it is highly correlated with other features. Hence, the

Figure 1. Feature selection taxonomy



search for a good feature subset involves finding those features that are highly correlated with the decision feature(s), but are uncorrelated with each other.

A taxonomy of feature selection approaches can be seen in Figure 1. Given a feature set of size n, the task of any FS method can be seen as a search for an ''optimal'' feature subset through the competing 2^n candidate subsets. The definition of what an optimal subset is may vary depending on the problem to be solved. Although an exhaustive method may be used for this purpose in theory, this is quite impractical for most datasets. Usually FS algorithms involve heuristic or random search strategies in an attempt to avoid this prohibitive complexity.

Determining subset optimality is a challenging problem. There is always a trade-off in non-exhaustive techniques between subset minimality and subset suitability - the task is to decide which of these must suffer in order to benefit the other. For some domains (particularly where it is costly or impractical to monitor many features, such as complex systems monitoring (Shen & Jensen, 2004)), it is much more desirable to have a smaller, less accurate feature subset. In other areas it may be the case that the modeling accuracy (e.g. the classification rate) using the selected features must be extremely high, at the expense of a non-minimal set of features, such as web content categorization (Jensen & Shen, 2004b).

MAIN FOCUS

The work on rough set theory offers an alternative, and formal, methodology that can be employed to reduce the dimensionality of datasets, as a preprocessing step to assist any chosen method for learning from data. It helps select the most information rich features in a dataset, without transforming the data, while attempting to minimize information loss during the selection process. Computationally, the approach is highly efficient, relying on simple set operations, which makes it suitable as a preprocessor for techniques that are much more complex. Unlike statistical correlation reducing approaches, it requires no human input or intervention. Most importantly, it also retains the semantics of the data, which makes the resulting models more transparent to human scrutiny. Combined with an automated intelligent modeler, say a fuzzy system or a neural network, the feature selection approach based on rough set theory can not only retain the descriptive power of the learned models, but also allow simpler system structures to reach the knowledge engineer and field operator. This helps enhance the interoperability and understandability of the resultant models and their reasoning.

Rough Set Theory

Rough set theory (RST) has been used as a tool to discover data dependencies and to reduce the number of attributes contained in a dataset using the data alone, requiring no additional information (Pawlak, 1991; Polkowski, 2002; Skowron et al., 2002). Over the past ten years, RST has become a topic of great interest to researchers and has been applied to many domains. Indeed, since its invention, this theory has been successfully utilized to devise mathematically sound and often, computationally efficient techniques for addressing problems such as hidden pattern discovery from data, data reduction, data significance evaluation, decision rule generation, and data-driven inference interpretation (Pawlak, 2003). Given a dataset with discretized attribute values, it is possible to find a subset (termed a *reduct*) of the original attributes using RST that are the most informative; all other attributes can be removed from the dataset with minimal information loss.

The rough set itself is the approximation of a vague concept (set) by a pair of precise concepts, called lower and upper approximations, which are a classification of the domain of interest into disjoint categories. The lower approximation is a description of the domain objects which are known with certainty to belong to the subset of interest, whereas the upper approximation is a description of the objects which possibly belong to the subset. The approximations are constructed with regard to a particular subset of features.

Rough set theory possesses many features in common (to a certain extent) with the Dempster-Shafer theory of evidence (Skowron & Grzymala-Busse, 1994) and fuzzy set theory (Wygralak, 1989). It works by making use of the granularity structure of the data only. This is a major difference when compared with Dempster-Shafer theory and fuzzy set theory, which require probability assignments and membership values, respectively. However, this does not mean that no model assumptions are made. In fact, by using only the given

information, the theory assumes that the data is a true and accurate reflection of the real world (which may not be the case). The numerical and other contextual aspects of the data are ignored which may seem to be a significant omission, but keeps model assumptions to a minimum.

Dependency Function-Based Reduction

By considering the union of the lower approximations of all concepts in a dataset with respect to a feature subset, a measure of the quality of the subset can be obtained. Dividing the union of lower approximations by the total number of objects in the dataset produces a value in the range [0,1] that indicates how well this feature subset represents the original full feature set. This measure is termed the dependency degree in rough set theory and it is used as the evaluation function within feature selectors to perform data reduction (Jensen & Shen, 2004a; Swiniarski & Skowron, 2003).

Discernibility Matrix-Based Reduction

Many applications of rough sets to feature selection make use of discernibility matrices for finding reducts; for example, pattern recognition (Swiniarski & Skowron, 2003). A discernibility matrix is generated by comparing each object *i* with every other object *j* in a dataset and recording in entry (*i*,*j*) those features that differ. For finding reducts, the decision-relative discernibility matrix is of more interest. This only considers those object discernibilities that occur when the corresponding decision features differ. From this, the discernibility function can be defined - a concise notation of how each object within the dataset may be distinguished from the others. By finding the set of all prime implicants (i.e. minimal coverings) of the discernibility function, all the reducts of a system may be determined (Skowron & Rauszer, 1992).

Extensions

Variable precision rough sets (VPRS) (Ziarko, 1993) extends rough set theory by the relaxation of the subset operator. It was proposed to analyze and identify data patterns which represent statistical trends rather than functional. The main idea of VPRS is to allow objects to be classified with an error smaller than a certain predefined level. This introduced threshold relaxes the rough set notion of requiring no information outside the dataset itself, but facilitates extra flexibility when considering noisy data.

The reliance on discrete data for the successful operation of RST can be seen as a significant drawback of the approach. Indeed, this requirement of RST implies an objectivity in the data that is simply not present. For example, in a medical dataset, values such as *Yes* or *No* cannot be considered objective for a *Headache* attribute as it may not be straightforward to decide whether a person has a headache or not to a high degree of accuracy. Again, consider an attribute *Blood Pressure*. In the real world, this is a real-valued measurement but for the purposes of RST must be discretized into a small set of labels such as *Normal*, *High*, etc. Subjective judgments are required for establishing boundaries for objective measurements.

In the rough set literature, there are two main ways of handling continuous attributes – through fuzzy-rough sets and tolerance rough sets. Both approaches replace the traditional equivalence classes of crisp rough set theory with alternatives that are better suited to dealing with this type of data.

In the fuzzy-rough case, fuzzy equivalence classes are employed within a fuzzy extension of rough set theory, resulting in a hybrid approach (Jensen & Shen, 2007). Subjective judgments are not entirely removed as fuzzy set membership functions still need to be defined. However, the method offers a high degree of flexibility when dealing with real-valued data, enabling the vagueness and imprecision present to be modeled effectively (Dubois & Prade, 1992; De Cock et al., 2007; Yao, 1998). Data reduction methods based on this have been investigated with some success (Jensen & Shen, 2004a; Shen & Jensen, 2004; Yeung et al., 2005).

In the tolerance case, a measure of feature value similarity is employed and the lower and upper approximations defined based on these similarity measures. Such lower and upper approximations define tolerance rough sets (Skowron & Stepaniuk, 1996). By relaxing the transitivity constraint of equivalence classes, a further degree of flexibility (with regard to indiscernibility) is introduced. In traditional rough sets, objects are grouped into equivalence classes if their attribute values are equal. This requirement might be too strict for real-world data, where values might differ only as a result of noise. Methods based on tolerance rough

sets provide more flexibility than traditional rough set approaches, but are not as useful as fuzzy-rough set methods due to the dependency on crisp granulations

FUTURE TRENDS

Rough set theory will continue to be applied to data reduction as it possesses many essential characteristics for the field. For example, it requires no additional information other than the data itself and provides constructions and techniques for the effective removal of redundant or irrelevant features. In particular, developments of its extensions will be applied to this area in order to provide better tools for dealing with high-dimensional noisy, continuous-valued data. Such data is becoming increasingly common in areas as diverse as bioinformatics, visualization, microbiology, and geology.

CONCLUSION

This chapter has provided an overview of rough set-based approaches to data reduction. Current methods tend to concentrate on alternative evaluation functions, employing rough set concepts to gauge subset suitability. These methods can be categorized into two distinct approaches: those that incorporate the degree of dependency measure (or extensions), and those that apply heuristic methods to generated discernibility matrices.

Methods based on traditional rough set theory do not have the ability to effectively manipulate continuous data. For these methods to operate, a discretization step must be carried out beforehand, which can often result in a loss of information. There are two main extensions to RST that handle this and avoid information loss: tolerance rough sets and fuzzy-rough sets. Both approaches replace crisp equivalence classes with alternatives that allow greater flexibility in handling object similarity.

KEY TERMS

Core: The intersection of all reducts (i.e. those features that appear in all reducts). The core contains those features that cannot be removed from the data without introducing inconsistencies.

Data Reduction: The process of reducing data dimensionality. This may result in the loss of the semantics of the features through transformation of the underlying values, or, as in feature selection, may preserve their meaning. This step is usually carried out in order to visualize data trends, make data more manageable, or to simplify the resulting extracted knowledge.

Dependency Degree: The extent to which the decision feature depends on a given subset of features, measured by the number of discernible objects divided by the total number of objects.

Discernibility Matrix: Matrix indexed by pairs of object number, whose entries are sets of features that differ between objects.

Feature Selection: The task of automatically determining a minimal feature subset from a problem domain while retaining a suitably high accuracy in representing the original features, and preserving their meaning.

Fuzzy-Rough Sets: An extension of RST that employs fuzzy set extensions of rough set concepts to determine object similarities. Data reduction is achieved through use of fuzzy lower and upper approximations.

Lower Approximation: The set of objects that definitely belong to a concept, for a given subset of features.

Reduct: A subset of features that results in the maximum dependency degree for a dataset, such that no feature can be removed without producing a decrease in this value. A dataset may be reduced to those features occurring in a reduct with no loss of information according to RST.

Rough Set: An approximation of a vague concept, through the use of two sets – the lower and upper approximations.

Tolerance Rough Sets: An extension of RST that employs object similarity as opposed to object equality (for a given subset of features) to determine lower and upper approximations.

Upper Approximation: The set of objects that possibly belong to a concept, for a given subset of features.

Variable Precision Rough Sets: An extension of RST that relaxes the notion of rough set lower and upper approximations by introducing a threshold of permissible error.

Data Streams

INTRODUCTION

Nowadays, data bases are required to store massive amounts of data that are continuously inserted, and queried. Organizations use decision support systems to identify potential useful patterns in data. Data analysis is complex, interactive, and exploratory over very large volumes of historic data, eventually stored in distributed environments.

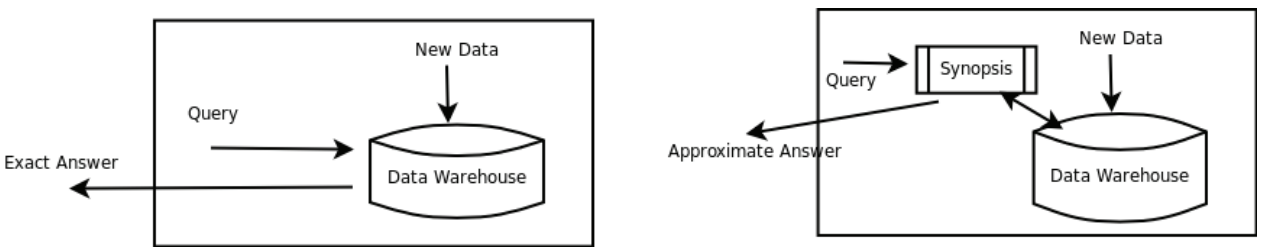
What distinguishes current data sources from earlier ones are the continuous flow of data and the automatic data feeds. We do not just have people who are entering information into a computer. Instead, we have computers entering data into each other (Muthukrishnan, 2005). Some illustrative examples of the magnitude of today data include: 3 billion telephone calls per day, 4 Giga Bytes of data from radio telescopes every night, 30 billion emails per day, 1 billion SMS, 5 Giga Bytes of Satellite Data per day, 70 billion IP Network Traffic per day. In these applications, data is modelled best not as persistent tables but rather as transient data streams. In some applications it is not feasible to load the arriving data into a traditional Data Base Management Systems (DBMS), and traditional DBMS are not designed to directly support the continuous queries required in these applications (Alon et al., 1996; Babcock et al. 2002; Cormode & Muthukrishnan, 2003). These sources of data are called *Data Streams*.

Computers play a much more active role in the current trends in decision support and data analysis. Data mining algorithms search for hypothesis, evaluate and suggest patterns. The pattern discovery process requires online ad-hoc queries, not previously defined, that are successively refined. Due to the exploratory nature of these queries, an exact answer may be not required: a user may prefer a fast but approximate answer to a exact but slow answer. Processing queries in streams require radically different type of algorithms. Range queries and selectivity estimation (the proportion of tuples that satisfy a query) are two illustrative examples where fast but approximate answers are more useful than slow and exact ones. Approximate answers are obtained from small data structures (synopsis) attached to data base that summarize information and can be updated incrementally. The general schema is presented in Figure 1.

An Illustrative Problem

A problem that clear illustrates the issues in streaming process (Datar, 2002), is the problem of finding the

Figure 1. Querying schemas: slow and exact answer vs fast but approximate answer using synopsis



maximum value (MAX) or the minimum value (MIN) in a sliding window over a sequence of numbers. When we can store in memory all the elements of the sliding window, the problem is trivial and we can find the exact solution. When the size of the sliding window is greater than the available memory, there is no exact solution. For example, suppose that the sequence is monotonically decreasing and the aggregation function is MAX. Whatever the window size, the first element in the window is always the maximum. As the sliding window moves, the exact answer requires maintaining all the elements in memory.

BACKGROUND

What makes Data Streams different from the conventional relational model? A key idea is that operating in the data stream model does not preclude the use of data in conventional stored relations. Some relevant differences (Babcock et al., 2002) include:

- The data elements in the stream arrive online.
- The system has no control over the order in which data elements arrive, either within a data stream or across data streams.
- Data streams are potentially unbound in size.
- Once an element from a data stream has been processed it is discarded or archived. It cannot be retrieved easily unless it is explicitly stored in memory, which is small relative to the size of the data streams.

In the streaming model (Muthukrishnan, 2005) the input elements $\mathbf{a_1}$, $\mathbf{a_2}$, **...** arrive sequentially, item by item, and describe an underlying function **A**. Streaming models differ on how $\mathbf{a_i}$ describe **A**. Three different models are:

- *Time Series Model*: once an element $\mathbf{a_i}$ is seen, it can not be changed.
- *Turnstile Model:* each $\mathbf{a_i}$ is an update to **A(j)**.
- *Cash Register Model:* each $\mathbf{a_i}$ is an increment **to** $\mathbf{A(j) = A(j)+a_i}$.

Research Issues in Data Streams Management Systems

Data streams are unbounded in length. However, this is not the only problem. The domain of the possible values of an attribute is also very large. A typical example is the domain of all pairs of IP addresses on the Internet. It is so huge, that makes exact storage intractable, as it is impractical to store all data to execute queries that reference past data. *Iceberg queries* process relative large amount of data to find aggregated values above some specific threshold, producing results that are often very small in number (the tip of the iceberg). Some query operators are unable to produce the first tuple of the output before they have seen the entire input. They are referred as *blocking query operators* (Babcock et al., 2002). Examples of blocking query operators are aggregating operators, like SORT, SUM, COUNT, MAX, MIN, join between multiple streams, etc. In the stream setting, continuous queries using block operators are problematic. Their semantics in the stream context is an active research area.

There are two basic approaches: sliding windows (Datar & Motwani, 2007) and summaries (Aggarwal & Yu, 2007. In the sliding windows approach a *time stamp* is associated with each tuple. The time stamp defines when a specific tuple is valid (e.g. inside the sliding window) or not. Queries run over the tuples inside the window. In the case of join multiple streams the semantics of timestamps is much less clear. For example, what is the time stamp of an output tuple?

In the latter, queries are executed over a summary, a compact data-structure that captures the distribution of the data. This approach requires techniques for storing summaries or synopsis information about previously seen data. Large summaries provide more precise answers. There is a trade-off between the size of summaries and the overhead to update summaries and the ability to provide precise answers. Histograms and wavelets are the most common used summaries, and are discussed later in this chapter.

From the point of view of a Data Stream Management System several research issues emerge. Illustrative problems (Babcock et al., 2002; Datar et al., 2002) include:

- Approximate query processing techniques to evaluate queries that require unbounded amount of memory.

Table 1. The following table summarizes the main differences between traditional and stream data processing

	Traditional	Stream
Number of passes	Multiple	Single
Processing Time	Unlimited	Restricted
Used Memory	Unlimited	Restricted
Result	Accurate	Approximate

- Sliding window query processing both as an approximation technique and as an option in the query language.
- Sampling to handle situations where the flow rate of the input stream is faster than the query processor.
- The meaning and implementation of blocking operators (e.g. aggregation and sorting) in the presence of unending streams.

MAIN FOCUS

The basic general bounds on the tail probability of a random variable include the Markov, Chebyshev and Chernoff inequalities (Motwani & Raghavan, 1997) that give the probability that a random variable deviates greatly from its expectation. The challenge consists of using sub-linear space, obtaining approximate answers with error guaranties. One of the most used approximate schemas is the so-called (ε, δ): Given two small positive numbers, ε, δ, compute an estimate that with probability 1- δ, is within a relative error less than ε.

A useful mathematical tool used elsewhere in solving the above problems is the so called **frequency moments**. A frequency moment is a number F^K, defined as

$$F^K = \sum_{i=1}^{v} m_i^K$$

where **v** is the domain size, $\mathbf{m}_i$ is the frequency of **i** in the sequence, and k>= 0. $\mathbf{F^0}$ is the number of distinct values in the sequence, $\mathbf{F^1}$ is the length of the sequence, $\mathbf{F^2}$ is known as the self-join size (the repeat rate or Gini's index of homogeneity). The frequency moments provide useful information about the data and can be used in query optimizing. In (Alon et al., 1996) the authors present an unexpected result that the second frequency moment of a stream of values can be approximated using logarithmic space. The authors also show that no analogous result holds for higher frequency moments.

Hash functions are another powerful tool in streaming process. They are used to project attributes with huge domains into lower space dimensions. One of the earlier results is the **Hash sketches** for **distinct-value counting** (aka **FM**) introduced by Flajolet & Martin (1983). The basic assumption is the existence of a hash function h(x) that maps incoming values x in (0,…, N-1) *uniformly* across (0,…, 2^L-1), where L = O(logN). The FM sketches are used for estimating the number of distinct items in a database (or stream) in one pass while using only a small amount of space.

Data Synopsis

With new data constantly arriving even as old data is being processed, the amount of computation time per data element must be low. Furthermore, since we are limited to bound amount of memory, it may not be possible to produce exact answers. High-quality approximate answers can be an acceptable solution. Two types of techniques can be used: data reduction and sliding windows. In both cases, they must use data structures that can be maintained incrementally. The most common used techniques for data reduction involve: sampling, synopsis and histograms, and wavelets.

Sampling

Instead of dealing with an entire data stream, we can sample instances at periodic intervals. The **reservoir sampling** technique (Vitter, 1985) is the classic algorithm to maintain an online random sample. The basic idea consists of maintaining a sample of size **s**, called the *reservoir*. As the stream flows, every new element

has a certain probability of replacing an old element in the reservoir. Extensions to maintain a sample of size *k* over a count-based sliding window of the *n* most recent data items from data streams appear in (Babcock et al., 2002a).

Synopsis and Histograms

Synopsis and Histograms are summarization techniques that can be used to approximate the frequency distribution of element values in a data stream. They are commonly used to capture attribute value distribution statistics for query optimizers (like range queries). A histogram is defined by a set of non-overlapping intervals. Each interval is defined by the boundaries and a frequency count. The reference technique is the V-Optimal histogram (Guha et al., 2004). It defines intervals that minimize the frequency variance within each interval. Sketches are special case of synopsis, which provide probabilistic guarantees on the quality of the approximate answer (e.g. the answer is 10±2 with probability 95%). Sketches have been used to solve the **k-hot items** (Cormode & Muthukrishnan 2003).

Wavelets

Wavelet transforms are mathematical techniques, in which signals are represented as a weighted sum of waveforms that attempt to capture trends in numerical functions. Wavelet analysis (Gilbert et al. 2003) is popular in several streaming applications, because most signals can be represented using a small set of coefficients. The simplest and most common transformation is the Haar wavelet (Jawerth & Sweldens, 1994). Any sequence (x_0, x_1,..., x_{2n}, x_{2n+1}) of even length is transformed into a sequence of two-component-vectors ((s_0, d_0 ,..., (s_n, d_n)). One stage of the Fast Haar-Wavelet Transform consists of:

$$\begin{bmatrix} s_i \\ d_i \end{bmatrix} = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \mathrm{x} \begin{bmatrix} \mathrm{x_i} \\ x_{i+1} \end{bmatrix}$$

The process continues, by separating the sequences **s** and **d** and transforming the sequence **s**.

FUTURE TRENDS

Emerging topics in data stream research involve the semantics of block-operators in the stream scenario; join over multi-streams, and processing distributed streams with privacy preserving concerns. The inductive machine learning community study computer programs able to extract rules and patterns from massive data sets (Hulten & Domingos, 2001). Some decision models (decision trees, decision rules, etc.) can provide concise, compact, and interpretable description of massive data sets. Moreover, the summaries and synopsis generated from massive flows of data used in DSMS are relevant for the Data Mining community. Future research points to a symbiosis between research in DSMS and Machine Learning.

CONCLUSION

Data Stream Management Systems development is an emergent topic in the computer science community, as they present solutions to process and query massive and continuous flow of data. Algorithms that process data streams deliver approximate solutions, providing a fast answer using few memory resources. In some applications, mostly database oriented, an approximate answer should be within an admissible error margin. In general, as the range of the error decreases the space of computational resources goes up. The challenge is to find sub-linear space data-structures that provide approximate answers to queries with narrow error bounds.

KEY TERMS

Blocking Query Operators: Query operators that only produce the first output tuple after seeing the entire input.

Data Mining: Process of extraction of useful information in large Data Bases.

Data Stream: Continuous flow of data eventually at high speed

Histograms: Graphical display of tabulated frequencies.

Iceberg Queries: Queries that compute aggregate functions over an attribute to find aggregate values over some specific threshold.

Machine Learning: Programming computers to optimize a performance criterion using example data or past experience.

Wavelet: Representation of a signal in terms of a finite length or fast decaying oscillating waveform (known as the *mother wavelet*).

Sampling: Subset of observations about a population.

Summaries: Compact data-structure that capture the distribution of data. (see Histograms, Wavelets, Synopsis).

Synopsis: Summarization technique that can be used to approximate the frequency distribution of element values in a data stream.

Data Transformation for Normalization

Amitava Mitra
Auburn University, USA

INTRODUCTION

As the abundance of collected data on products, processes and service-related operations continues to grow with technology that facilitates the ease of data collection, it becomes important to use the data adequately for decision making. The ultimate value of the data is realized once it can be used to derive information on product and process parameters and make appropriate inferences.

Inferential statistics, where information contained in a sample is used to make inferences on unknown but appropriate population parameters, has existed for quite some time (Mendenhall, Reinmuth, & Beaver, 1993; Kutner, Nachtsheim, & Neter, 2004). Applications of inferential statistics to a wide variety of fields exist (Dupont, 2002; Mitra, 2006; Riffenburgh, 2006).

In data mining, a judicious choice has to be made to extract observations from large databases and derive meaningful conclusions. Often, decision making using statistical analyses requires the assumption of normality. This chapter focuses on methods to transform variables, which may not necessarily be normal, to conform to normality.

BACKGROUND

With the normality assumption being used in many statistical inferential applications, it is appropriate to define the normal distribution, situations under which non-normality may arise, and concepts of data stratification that may lead to a better understanding and inference-making. Consequently, statistical procedures to test for normality are stated.

Normal Distribution

A continuous random variable, Y, is said to have a normal distribution, if its probability density function is given by the equation

$$f(y) = \frac{1}{\sqrt{2\pi}\sigma} \exp[-(y-\mu)^2 / 2\sigma^2], \quad (1)$$

where μ and σ denote the mean and standard deviation, respectively, of the normal distribution. When plotted, equation (1) resembles a bell-shaped curve that is symmetric about the mean (μ). A cumulative distribution function (cdf), F(y), represents the probability $P[Y \leq y]$, and is found by integrating the density function given by equation (1) over the range $(-\infty, y)$. So, we have the cdf for a normal random variable as

$$F(y) = \int_{-\infty}^{y} \frac{1}{\sqrt{2\pi}\sigma} \exp[-(x-\mu)^2 / 2\sigma^2]dx. \quad (2)$$

In general, $P[a \leq Y \leq b] = F(b) - F(a)$.

A standard normal random variable, Z, is obtained through a transformation of the original normal random variable, Y, as follows:

$$Z = (Y - \mu)/\sigma . \quad (3)$$

The standard normal variable has a mean of 0 and a standard deviation of 1 with its cumulative distribution function given by F(z).

Non-Normality of Data

Prior to analysis of data, careful consideration of the manner in which the data is collected is necessary. The following are some considerations that data analysts should explore as they deal with the challenge of whether the data satisfies the normality assumption.

Data Entry Errors

Depending on the manner in which data is collected and recorded, data entry errors may highly distort the distribution. For instance, a misplaced decimal point on an observation may lead that observation to become an outlier, on the low or the high side. **Outliers** are observations that are "very large" or "very small"

compared to the majority of the data points and have a significant impact on the **skewness** of the distribution. Extremely large observations will create a distribution that is right-skewed, whereas outliers on the lower side will create a negatively-skewed distribution. Both of these distributions, obviously, will deviate from normality. If outliers can be justified to be data entry errors, they can be deleted prior to subsequent analysis, which may lead the distribution of the remaining observations to conform to normality.

Grouping of Multiple Populations

Often times, the distribution of the data does not resemble any of the commonly used statistical distributions let alone normality. This may happen based on the nature of what data is collected and how it is grouped. Aggregating data that come from different populations into one dataset to analyze, and thus creating one "superficial" population, may not be conducive to statistical analysis where normality is an associated assumption. Consider, for example, the completion time of a certain task by operators who are chosen from three shifts in a plant. Suppose there are inherent differences between operators of the three shifts, whereas within a shift the performance of the operators is homogeneous. Looking at the aggregate data and testing for normality may not be the right approach. Here, we may use the concept of **data stratification** and subdivide the aggregate data into three groups or populations corresponding to each shift.

Parametric versus Nonparametric Tests

While data from many populations may not necessarily be normal, one approach for dealing with this problem, when conducting parametric tests, is to determine a suitable transformation such that the transformed variable satisfies the normality assumption. Alternatively, one may consider using nonparametric statistical tests (Conover, 1999; Daniel, 1990) for making inferences. The major advantage of nonparametric tests is that they do not make any assumption on the form of the distribution. Hence, such tests could be used for data that are not from normal distributions. There are some disadvantages to nonparametric tests however. One significant disadvantage deals with the **power** of the test. The power of a statistical test is its ability to identify and reject a null hypothesis when the null is false. If the assumptions associated with a parametric test are satisfied, the power of the parametric test is usually larger than that of its equivalent nonparametric test. This is the main reason for the preference of a parametric test over an equivalent nonparametric test.

Validation of Normality Assumption

Statistical procedures known as **goodness-of-fit tests** make use of the empirical cumulative distribution function (cdf) obtained from the sample versus the theoretical cumulative distribution function, based on the hypothesized distribution. Moreover, parameters of the hypothesized distribution may be specified or estimated from the data. The test statistic could be a function of the difference between the observed frequency, and the expected frequency, as determined on the basis of the distribution that is hypothesized. Goodness-of-fit tests may include chi-squared tests (Duncan, 1986), Kolmogorov-Smirnov tests (Massey, 1951), or the Anderson-Darling test (Stephens, 1974), among others. Along with such tests, graphical methods such as **probability plotting** may also be used.

Probability Plotting

In probability plotting, the sample observations are ranked in ascending order from smallest to largest. Thus, the observations $x_1, x_2, \ldots, x_n$ are ordered as $x_{(1)}, x_{(2)}, \ldots, x_{(n)}$, where $x_{(1)}$ denotes the smallest observation and so forth. The **empirical cumulative distribution function (cdf)** of the ith ranked observation, $x_{(i)}$, is given by

$$F_i = \frac{i - 0.5}{n}. \tag{4}$$

The **theoretical cdf**, based on the hypothesized distribution, at $x_{(i)}$, is given by $G(x_{(i)})$, where $G(\cdot)$ is calculated using specified parameters or estimates from the sample. A probability plot displays the plot of $x_{(i)}$, on the horizontal axis, versus F_i and $G(x_{(i)})$ on the vertical axis. The **vertical axis** is **so scaled** such that if the data is from the hypothesized distribution, say normal, the plot of $x_{(i)}$ versus $G(x_{(i)})$ will be a straight line. Thus, departures of $F(\cdot)$ from $G(\cdot)$ are visually easy to detect. The closer the plotted values of $F(\cdot)$ are to the fitted line, $G(\cdot)$, the stronger the support for the null hypothesis. A test statistic is calculated where large

deviations between F(·) and G(·) lead to large values of the test statistic, or alternatively small **p-values**. Hence, if the observed **p-value** is less than α, the chosen level of significance, the null hypothesis representing the hypothesized distribution is rejected.

In a **normal probability plot**, suppose we are testing the null hypothesis that the data is from a normal distribution, with mean and standard deviation not specified. Then, $G(x_{(i)})$ will be $\Phi((x_{(i)} - \bar{x})/s)$, $\Phi(\cdot)$ represents the cdf of a standard normal distribution and $\bar{x}$ and s are sample estimates of the mean and standard deviation respectively.

The software, Minitab (Minitab, 2007), allows probability plotting based on a variety of chosen distributions such as normal, lognormal, exponential, gamma, or Weibull. A common test statistic used for such tests is the Anderson-Darling statistic which measures the area between the fitted line (based on the hypothesized distribution) and the empirical cdf. This statistic is a squared distance that is weighted more heavily in the tails of the distribution. Smaller values of this statistic lead to the non-rejection of the null hypothesis and confirm validity of the observations being likely from the hypothesized distribution. Alternative tests for normality also exist (Shapiro & Wilk, 1965).

MAIN FOCUS

In this section we describe possible ways to transform the original variable such that the transformed variable may satisfy the assumption of normality. There is, of course, no assurance that any variable can always be transformed to a normal random variable.

Discrete Variables

Let us first consider some discrete random variables and their associated transformations to normality. Such variables could represent attribute information, for example, the number of acceptable parts in a batch. Alternatively, it could represent a count of the number of events, for instance, the number of bacterial count per unit volume.

Binomial Random Variable

A Binomial random variable is one where each outcome could be one of two types, i.e., a part acceptable or not. The random variable represents the total number of outcomes of a certain type, say acceptable parts. Thus, in an automatic inspection station, where parts are produced in batches of size 500, the Binomial random variable could be the number of acceptable parts (Y) in each batch. Alternatively, this could be re-expressed as the proportion of acceptable parts (p) in each batch, whose estimate is given by $\hat{p} = y/n$, where n represents the batch size.

It is known that when p is not close to 0.5, or in other words when p is very small (near 0) or very large (close to 1), the distribution of the estimated proportion of acceptable parts is quite asymmetric and highly skewed and will not resemble normality. A possible transformation for Binomial data is the following:

$$Y_T = \text{arc sine}\left(\sqrt{\hat{p}}\right) \tag{5}$$

or

$$Y_T = \ell n\left[\frac{\hat{p}}{1-\hat{p}}\right] \tag{6}$$

The distribution of the transformed variable, Y_T, may approach normality.

Poisson Random Variable

A Poisson random variable represents the number of events (Y) that happen within a product unit, space or volume, or time period, where it is assumed that the events happen randomly and independently. Examples are the number of customer complaints on a monthly basis in a department store, or the number of people entering the intensive care unit in a hospital per week. A possible transformation in this context is the square root transformation given by

$$Y_T = \sqrt{Y} \tag{7}$$

Continuous Variables

Data on most physical variables are measured on a continuum scale. Conceptually, continuous variables can take on an infinite number of values within a given range. Examples are dimensional measurements, temperature, pressure, density, viscosity, and strength.

In transforming continuous variables, the shape of the distribution, as determined by its skewness, may provide an indication of the type of transformation. Let us first consider right-skewed distributions and identify modifications in this context.

Square Root Transformation

Such a transformation applies to data values that are positive. So, if there are negative values, a constant must be added to move the minimum value of the distribution above zero, preferably to 1. The rational for this being that for numbers of 1 and above, the square root transformation behaves differently than for numbers between 0 and 1. This transformation has the effect of reducing the length of the right tail and so is used to bring a right-tailed distribution closer to normality. The form of the transformation is given by

$$Y_T = \sqrt{Y + c} \qquad (8)$$

where c is a constant and such that min (Y + c) ≥ 1.

Log Transformation

Logarithmic transformations are also used for right-skewed distributions. Their impact is somewhat stronger than the square root transformation in terms of reducing the length of the right tail. They represent a class of transformations where the base of the logarithm can vary. Since the logarithm of a negative number is undefined, a translation must be made to the original variable if it has negative values. Similar to the square root transformation, it is desirable to shift the original variable such that the minimum is at 1 or above.

Some general guidelines for choosing the base of the logarithmic transformation exist. Usually, the base of 10, 2, and e should be considered as a minimum, where e = 2.7183 represents the base of natural logarithm. In considering the dataset, for a large range of the values, a base of 10 is desirable. Higher bases tend to pull extreme values in more drastically relative to lower bases. Hence, when the range of values is small, a base of e or 2 could be desirable. The logarithmic transformation is given by

$$Y_T = \log_a(Y + b) \ , \qquad (9)$$

where *a* represents a choice of the base of the logarithm and *b* is a constant such that

min (Y + b) ≥ 1.

Inverse Transformation

The inverse transformation is also used for a right-skewed distribution. Relative to the square root and logarithmic transformation, it has the strongest impact in terms of reducing the length of the right tail.

Taking the inverse makes very large numbers very small and very small numbers very large. It thus has the effect of reversing the order of the data values. So, in order to maintain the same ordering as the original values, the transformed values are multiplied by -1. The inverse transformed variable is given by

$$Y_T = -\frac{1}{Y} \qquad (10)$$

Since equation (10) is not defined for y = 0, a translation in the data could be made prior to the transformation in such a situation.

Power Transformations

We now consider the more general form of power transformations (Box & Cox, 1964; Sakia, 1992) where the original variable (Y) is raised to a certain power (p). The general power transformed variable (Y_T) is given by

$$\begin{aligned} Y_T &= Y^P, \ p > 0 \\ &= -(Y^P), \ p < 0 \\ &= \ell n\,(Y), \ p = 0 \end{aligned} \qquad (11)$$

The impact of the power coefficient, p, is on changing the distributional shape of the original variable. Values of the exponent, p > 1, shift weight to the upper tail of the distribution and reduce negative skewness. The larger the power, the stronger the effect. A parametric family of power transformations is known as a Box-Cox transformation (Box & Cox, 1964).

The three previously considered square root, logarithm, and inverse transformations are special cases of the general power transformation given by equation (11). Selection of the power coefficient (p) will be influenced by the type of data and its degree of skewness. Some guidelines are provided in a separate chapter.

Exponential Transformation

While the transformations given by equation (11) are used for positive values of the observations, another alternative (Manly, 1976) could be used in the presence of negative observations. This transformation is effective for a skewed unimodal distribution to be shifted to a symmetric normal-like distribution and is given by:

$$Y_T = [\exp(pY) - 1] / p, \text{ for } p \neq 0$$
$$= Y \quad , p = 0 \qquad (12)$$

FUTURE TRENDS

Testing hypothesis on population parameters through hypothesis testing or developing confidence intervals on these parameters will continue a trend of expanded usage. Applications of inferential statistics will continue to grow in virtually all areas in which decision making is based on data analysis. Thus, the importance of data transformations to meet the assumption of normality cannot be overemphasized.

CONCLUSION

The need for transformations when conducting data analyses is influenced by the assumptions pertaining to type of statistical test/analysis. Common assumptions may include independence and identical population distributions from which observations are chosen, common variance of two or more populations, and normality of population distribution. This paper has focused on satisfying the assumption of normality of the population distribution.

Prior to conducting data transformations, one should skim the data for possible recording or input errors or for identifiable special causes caused by circumstances that are not normally part of the process. If these events are identified, the data values can be deleted prior to analysis. However, it is of importance to not automatically delete extreme observations (large or small) unless a justifiable rationale has first been established.

KEY TERMS

Data Stratification: A scheme to partition aggregate data into groups or clusters based on the value of a selected variable(s).

Goodness-of-Fit Tests: A class of statistical tests that includes testing the distributional assumption based on comparing the observed frequency of data to the expected frequency under the hypothesized distribution.

Inferential Statistics: A field of statistics where decisions on unknown population parameters are made from information contained in samples.

Normal Distribution: A distribution, also known as the Gaussian distribution, whose density function is an exponential distribution symmetric about the mean. It has two parameters, the mean which is a measure of location and the standard deviation, a measure of dispersion. The equation of the density function is given by equation (1).

Outliers: Data values that are extremely large or extremely small compared to the majority of the values. Based on the distribution, for example normal distribution, an outlier may be considered as one that is more than three standard deviations away from the mean.

Parametric Tests: Statistical tests that deal with making inferences on parameters of distributions, for example estimation or hypothesis testing of the mean of a population. Such tests usually make assumptions on the distributional form.

Power of a Test: The power of a statistical test of hypothesis is the degree to which the test is able to identify and reject a null hypothesis, when the null hypothesis is false. A large power is desirable.

Probability Value: This refers to the chance of obtaining the data that has been observed, or something more extreme, if the null hypothesis is true. Also known as the p-value, it is used in hypothesis testing for decision making. If the p-value is less than the chosen level of significance, the null hypothesis is rejected.

Skewness of a Distribution: A measure of the degree of asymmetry of the distributional form, typically represented by a skewness coefficient. The degree of concentration of the data values along with the presence of outliers may influence skewness.

Data Warehouse Back-End Tools

Alkis Simitsis
National Technical University of Athens, Greece

Dimitri Theodoratos
New Jersey Institute of Technology, USA

INTRODUCTION

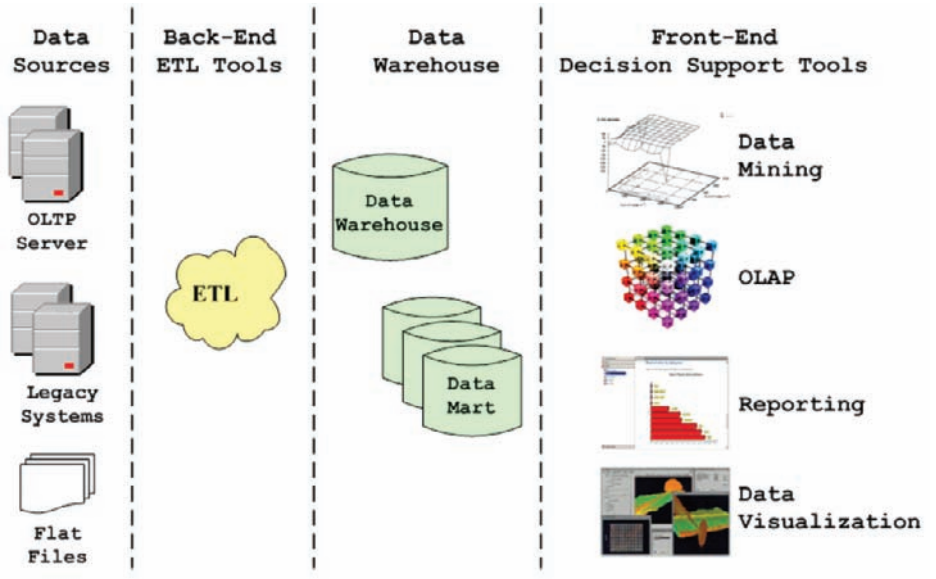
The back-end tools of a data warehouse are pieces of software responsible for the extraction of data from several sources, their cleansing, customization, and insertion into a data warehouse. In general, these tools are known as Extract – Transformation – Load (ETL) tools and the process that describes the population of a data warehouse from its sources is called ETL process. In all the phases of an ETL process (extraction and transportation, transformation and cleaning, and loading), individual issues arise, and, along with the problems and constraints that concern the overall ETL process, make its lifecycle a very complex task.

BACKGROUND

A Data Warehouse (DW) is a collection of technologies aimed at enabling the knowledge worker (executive, manager, analyst, etc.) to make better and faster decisions. The architecture of the data warehouse environment exhibits various layers of data in which data from one layer are derived from data of the previous layer (Figure 1).

The front-end layer concerns end-users who access the data warehouse with decision support tools in order to get insight into their data by using either advanced data mining and/or OLAP (On-Line Analytical Processing) techniques or advanced reports and visualizations. The central data warehouse layer comprises the data warehouse fact and dimension tables along with the

Figure 1. Abstract architecture of a Data Warehouse



appropriate application-specific data marts. The back stage layer includes all the operations needed for the collection, integration, cleaning and transformation of data coming from the sources. Finally, the sources layer consists of all the sources of the data warehouse; these sources can be in any possible format, such as OLTP (On-Line Transaction Processing) servers, legacy systems, flat files, xml files, web pages, and so on.

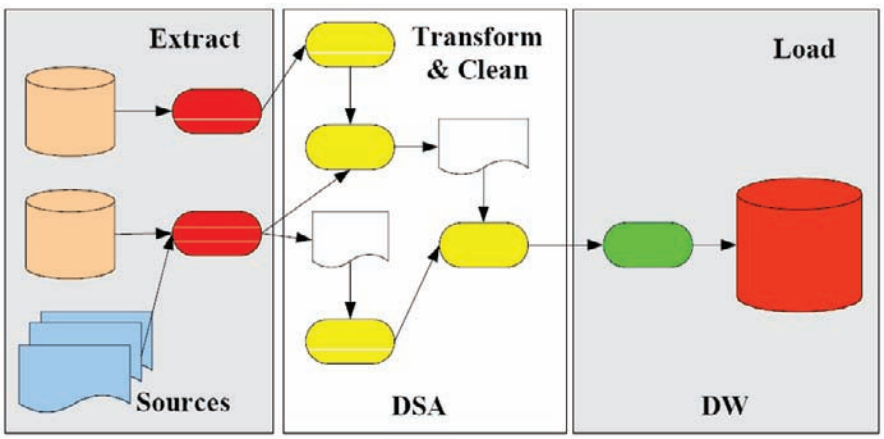
This article deals with the processes, namely ETL processes, which take place in the back stage of the data warehouse environment. The ETL processes are data intensive, complex, and costly (Vassiliadis, 2000). Several reports mention that most of these processes are constructed through an in-house development procedure that can consume up to 70% of the resources for a data warehouse project (Gartner, 2003). The functionality of these processes includes: (a) the identification of relevant information at the source side; (b) the extraction of this information; (c) the transportation of this information from the sources to an intermediate place called Data Staging Area (DSA); (d) the customization and integration of the information coming from multiple sources into a common format; (e) the cleaning of the resulting data set, on the basis of database and business rules; and (f) the propagation of the homogenized and cleansed data to the data warehouse and/or data marts. In the sequel, we will adopt the general acronym ETL for all kinds of in-house or commercial tools, and all the aforementioned categories of tasks.

Figure 2 abstractly describes the general framework for ETL processes. In the left side, the original data providers (Sources) exist. The data from these sources are extracted by extraction routines, which provide either complete snapshots or differentials of the data sources. Next, these data are propagated to the Data Staging Area (DSA) where they are transformed and cleaned before being loaded to the data warehouse. Intermediate results in the form of (mostly) files or relational tables are part of the data staging area. The data warehouse (DW) is depicted in the right part of Fig. 2 and comprises the target data stores, i.e., fact tables for the storage of information and dimension tables with the description and the multidimensional, roll-up hierarchies of the stored facts. The loading of the central warehouse is performed from the loading activities depicted right before the data warehouse data store.

State of the Art

In the past, there have been research efforts towards the design and optimization of ETL tasks. Among them, the following systems are dealing with ETL issues: (a) the AJAX system (Galhardas et al., 2000), (b) the Potter's Wheel system (Raman & Hellerstein, 2001), and (c) Arktos II (Arktos II, 2004). The first two prototypes are based on algebras, which are mostly tailored for the case of homogenizing web data; the latter concerns the modeling and the optimization of ETL processes in a customizable and extensible manner. Additionally, several research efforts have dealt with individual issues and problems of the ETL processes: (a) design and

Figure 2. The environment of Extract-Transform-Load processes



modeling issues (Luján-Mora et al., 2004; Skoutas and Simitsis, 2006; Trujillo J. and Luján-Mora, S., 2003; Vassiliadis et al., 2002), and (b) optimization issues (Simitsis et al., 2005; Tziovara et al., 2007). A first publicly available attempt towards the presentation of a benchmark for ETL Processes is proposed by Vassiliadis et al., 2007.

An extensive review of data quality problems and related literature, along with quality management methodologies can be found in Jarke et al. (2000). Rundensteiner (1999) offers a discussion of various aspects of data transformations. Sarawagi (2000) offers a similar collection of papers in the field of data including a survey (Rahm & Do, 2000) that provides an extensive overview of the field, along with research issues and a review of some commercial tools and solutions on specific problems, e.g., Monge (2000) and Borkar et al. (2000). In a related, but different, context, the IBIS tool (Calì et al., 2003) deals with integration issues following the global-as-view approach to answer queries in a mediated system.

In the market, there is a plethora of commercial ETL tools. Simitsis (2003) and Wikipedia (2007) contain a non-exhaustive list of such tools.

MAIN THRUST OF THE CHAPTER

In this section, we briefly review the problems and constraints that concern the overall ETL process, as well as the individual issues that arise in each phase of an ETL process (extraction and exportation, transformation and cleaning, and loading) separately. Simitsis (2004) offers a detailed study on the problems described in this chapter and presents a framework towards the modeling and the optimization of ETL processes.

Scalzo (2003) mentions that 90% of the problems in data warehouses rise from the nightly batch cycles that load the data. At this period, the administrators have to deal with problems like (a) efficient data loading, and (b) concurrent job mixture and dependencies. Moreover, ETL processes have global time constraints including their initiation time and their completion deadlines. In fact, in most cases, there is a tight 'time window' in the night that can be exploited for the refreshment of the data warehouse, since the source system is off-line or not heavily used during this period. Other general problems include: the scheduling of the overall process, the finding of the right execution order for dependent jobs and job sets on the existing hardware for the permitted time schedule, the maintenance of the information in the data warehouse.

Phase I: Extraction & Transportation

During the ETL process, a first task that must be performed is the extraction of the relevant information that has to be further propagated to the warehouse (Theodoratos et al., 2001). In order to minimize the overall processing time, this involves only a fraction of the source data that has changed since the previous execution of the ETL process, mainly concerning the newly inserted and possibly updated records. Usually, change detection is physically performed by the comparison of two snapshots (one corresponding to the previous extraction and the other to the current one). Efficient algorithms exist for this task, like the snapshot differential algorithms presented in (Labio & Garcia-Molina, 1996). Another technique is log 'sniffing', i.e., the scanning of the log file in order to 'reconstruct' the changes performed since the last scan. In rare cases, change detection can be facilitated by the use of triggers. However, this solution is technically impossible for many of the sources that are legacy systems or plain flat files. In numerous other cases, where relational systems are used at the source side, the usage of triggers is also prohibitive both due to the performance degradation that their usage incurs and the need to intervene in the structure of the database. Moreover, another crucial issue concerns the transportation of data after the extraction, where tasks like ftp, encryption-decryption, compression-decompression, etc., can possibly take place.

Phase II: Transformation & Cleaning

It is possible to determine typical tasks that take place during the transformation and cleaning phase of an ETL process. Rahm & Do (2000) further detail this phase in the following tasks: (a) data analysis; (b) definition of transformation workflow and mapping rules; (c) verification; (d) transformation; and (e) backflow of cleaned data. In terms of the transformation tasks, we distinguish two main classes of problems (Lenzerini, 2002): (a) conflicts and problems at the schema level (e.g., naming and structural conflicts), and, (b) data level transformations (i.e., at the instance level).

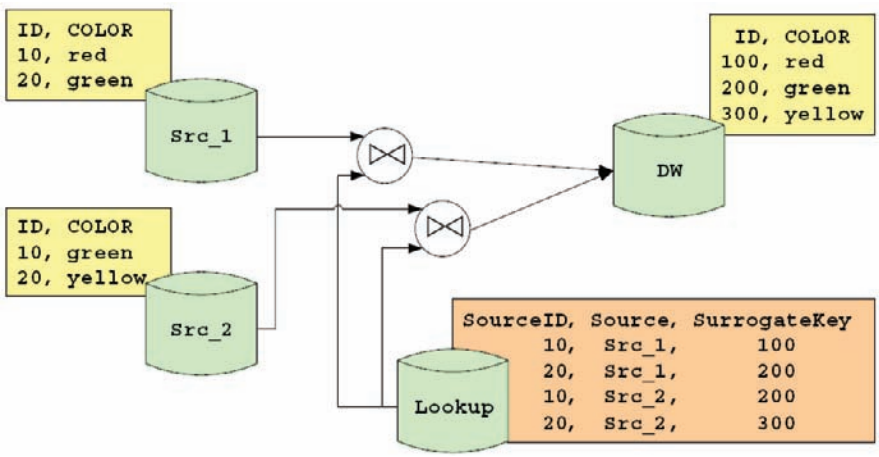
The integration and transformation programs perform a wide variety of functions, such as reformatting data, recalculating data, modifying key structures of data, adding an element of time to data warehouse data, identifying default values of data, supplying logic to choose between multiple sources of data, summarizing data, merging data from multiple sources, etc.

In the sequel, we present four common ETL transformation cases as examples: (a) semantic normalization and denormalization; (b) surrogate key assignment; (c) slowly changing dimensions; and (d) string problems. The research prototypes presented in the previous section and several commercial tools have already done some piece of progress in order to tackle with problems like these four. Still, their presentation in this article aspires to make the reader to understand that the whole process should be discriminated from the way we resolved integration issues until now.

Semantic normalization and denormalization. It is common for source data to be long denormalized records, possibly involving more than a hundred attributes. This is due to the fact that bad database design or classical COBOL tactics led to the gathering of all the necessary information for an application in a single table/file. Frequently, data warehouses are also highly denormalized, in order to answer more quickly certain queries. But, sometimes it is imperative to normalize somehow the input data. Consider, for example, a table of the form `R(KEY,TAX,DISCOUNT,PRICE)`, which we would like to transform to a table of the form `R'(KEY,CODE,AMOUNT)`. For example, the input tuple `t[key,30,60,70]` is transformed into the tuples `t1[key,1,30]; t2[key,2,60]; t3[key,3,70]`. The transformation of the information organized in rows to information organized in columns is called rotation or denormalization (since, frequently, the derived values, e.g., the total income in our case, are also stored as columns, functionally dependent on other attributes). Occasionally, it is possible to apply the reverse transformation, in order to normalize denormalized data before being loaded to the data warehouse.

Surrogate Keys. In a data warehouse project, we usually replace the keys of the production systems with a uniform key, which we call a *surrogate key* (Kimball et al., 1998). The basic reasons for this replacement are performance and semantic homogeneity. Performance is affected by the fact that textual attributes are not the best candidates for indexed keys and need to be replaced by integer keys. More importantly, semantic homogeneity causes reconciliation problems, since different production systems might use different keys for the same object (synonyms), or the same key for different objects (homonyms), resulting in the need for a global replacement of these values in the data warehouse. Observe row (`20,green`) in table `Src_1` of Figure 3. This row has a synonym conflict with row (`10,green`) in table `Src_2`, since they represent the same real-world entity with different `ID`'s, and a homonym conflict with row (`20,yellow`) in table `Src_2`

Figure 3. Surrogate key assignment



(over attribute ID). The *production key* ID is replaced by a *surrogate key* through a lookup table of the form Lookup(SourceID,Source,SurrogateKey). The Source column of this table is required because there can be synonyms in the different sources, which are mapped to different objects in the data warehouse (e.g., value 10 in tables Src_1 and Src_2). At the end of this process, the data warehouse table DW has globally unique, reconciled keys.

Slowly Changing Dimensions. Factual data are not the only data that change. The dimension values change at the sources, too, and there are several policies to apply for their propagation to the data warehouse. (Kimball et al., 1998) present three policies for dealing with this problem: overwrite (*Type* 1), create a new dimensional record (*Type* 2), push down the changed value into an "old" attribute (*Type* 3).

For *Type* 1 processing we only need to issue appropriate update commands in order to overwrite attribute values in existing dimension table records. This policy can be used whenever we do not want to track history in dimension changes and if we want to correct erroneous values. In this case, we use an old version of the dimension data D_{old} as they were received from the source and their current version D_{new}. We discriminate the new and updated rows through the respective operators. The new rows are assigned a new surrogate key, through a function application. The updated rows are assigned a surrogate key (which is the same as the one that their previous version had already being assigned). Then, we can join the updated rows with their old versions from the target table (which will subsequently be deleted) and project only the attributes with the new values.

In the *Type* 2 policy we copy the previous version of the dimension record and create a new one with a new surrogate key. If there is no previous version of the dimension record, we create a new one from scratch; otherwise, we keep them both. This policy can be used whenever we want to track the history of dimension changes.

Last, *Type* 3 processing is also very simple, since again we only have to issue update commands to existing dimension records. For each attribute A of the dimension table, which is checked for updates, we need to have an extra attribute called "old_A". Each time we spot a new value for A, we write the current A value to the old_A field and then write the new value to attribute A. This way we can have both new and old values present at the same dimension record.

String Problems. A major challenge in ETL processes is the cleaning and the homogenization of string data, e.g., data that stands for addresses, acronyms, names etc. Usually, the approaches for the solution of this problem include the application of regular expressions for the normalization of string data to a set of 'reference' values.

Phase III: Loading

The final loading of the data warehouse has its own technical challenges. A major problem is the ability to discriminate between new and existing data at loading time. This problem arises when a set of records has to be classified to (a) the new rows that need to be appended to the warehouse and (b) rows that already exist in the data warehouse, but their value has changed and must be updated (e.g., with an UPDATE command). Modern ETL tools already provide mechanisms towards this problem, mostly through language predicates. Also, simple SQL commands are not sufficient since the open-loop-fetch technique, where records are inserted one by one, is extremely slow for the vast volume of data to be loaded in the warehouse. An extra problem is the simultaneous usage of the rollback segments and log files during the loading process. The option to turn them off contains some risk in the case of a loading failure. So far, the best technique seems to be the usage of the batch loading tools offered by most RDBMS's that avoids these problems. Other techniques that facilitate the loading task involve the creation of tables at the same time with the creation of the respective indexes, the minimization of inter-process wait states, and the maximization of concurrent CPU usage.

FUTURE TRENDS

Currently (as of 2007), the ETL market is a multi-million market. All the major DBMS vendors provide ETL solutions shipped with their data warehouse suites; e.g., IBM with WebSphere Datastage, Microsoft with SQL Server Integration Services, Oracle with Warehouse Builder, and so on. In addition, individual vendors provide a large variety of ETL tools; e.g., Informatica

with PowerCenter, while some open source tools exist as well; e.g., Talend.

Apart from the traditional data warehouse environment, the ETL technology is useful in other modern applications too. Such applications are the mashups applications, which integrate data dynamically obtained via web-service invocations to more than one sources into an integrated experience; e.g., Yahoo Pipes (http://pipes.yahoo.com/), Google Maps (http://maps.google.com/), IBM Damia (http://services.alphaworks.ibm.com/damia/), and Microsoft Popfly (http://www.popfly.com/). The core functionality of those applications is `pure' ETL.

Therefore, the prediction for the future of ETL is very positive. In the same sense, several studies (Giga Information Group, 2002; Gartner, 2003) and a recent chapter (Simitsis et al., 2006) account the ETL as a remaining challenge and pinpoint several topics for future work:

- Integration of ETL with: XML adapters, EAI (Enterprise Application Integration) tools (e.g., MQ-Series), customized data quality tools, and the move towards parallel processing of the ETL workflows,
- Active or real-time ETL (Adzic & Fiore, 2003; Polyzotis et al., 2007), meaning the need to refresh the warehouse with as fresh data as possible (ideally, on-line), and
- Extension of the ETL mechanisms for non-traditional data, like XML/HTML, spatial and biomedical data.

CONCLUSION

ETL tools are pieces of software responsible for the extraction of data from several sources, their cleansing, customization, and insertion into a data warehouse. In all the phases of an ETL process (extraction and exportation, transformation and cleaning, and loading), individual issues arise, and, along with the problems and constraints that concern the overall ETL process, make its lifecycle a very troublesome task. The key factors underlying the main problems of ETL workflows are: (a) vastness of the data volumes; (b) quality problems, since data are not always clean and have to be cleansed; (c) performance, since the whole process has to take place within a specific time window; and (d) evolution of the sources and the data warehouse can eventually lead even to daily maintenance operations. The state of the art in the field of both research and commercial ETL tools indicate significant progress. Still, a lot of work remains to be done, as several issues are technologically open and present interesting research topics in the field of data integration in data warehouse environments.

KEY TERMS

Active Data Warehouse: A data warehouse that continuously is updated. The population of an active data warehouse is realized in a streaming mode. Its main characteristic is the freshness of data; the moment a change occurs in the source site, it should be propagated to the data warehouse immediately. (Similar term: Real-time Data Warehouse.)

Data Mart: A logical subset of the complete data warehouse. We often view the data mart as the restriction of the data warehouse to a single business process or to a group of related business processes targeted towards a particular business group.

Data Staging Area (DSA): An auxiliary area of volatile data employed for the purpose of data transformation, reconciliation and cleaning before the final loading of the data warehouse.

Data Warehouse: A Data Warehouse is a subject-oriented, integrated, time-variant, non-volatile collection of data used to support the strategic decision-making process for the enterprise. It is the central point of data integration for business intelligence and is the source of data for the data marts, delivering a common view of enterprise data (Inmon, 1996).

ETL: Extract, transform, and load (ETL) are data warehousing operations, which extract data from outside sources, transform it to fit business needs, and ultimately load it into the data warehouse. ETL is an important part of data warehousing, as it is the way data actually gets loaded into the warehouse.

On-Line Analytical Processing (OLAP): The general activity of querying and presenting text and number data from data warehouses, as well as a specifically dimensional style of querying and presenting that is exemplified by a number of "OLAP vendors".

Source System: The physical machine(-s) on which raw information is stored. It is an operational system whose semantics capture the transactions of the business.

Target System: The physical machine on which the warehouse's data is organized and is stored for direct querying by end users, report writers, and other applications.

Data Warehouse Performance

INTRODUCTION

A data warehouse is a large electronic repository of information that is generated and updated in a structured manner by an enterprise over time to aid business intelligence and to support decision making. Data stored in a data warehouse is non-volatile and time variant and is organized by subjects in a manner to support decision making (Inmon et al., 2001). Data warehousing has been increasingly adopted by enterprises as the backbone technology for business intelligence reporting and query performance has become the key to the successful implementation of data warehouses. According to a survey of 358 businesses on reporting and end-user query tools, conducted by Appfluent Technology, data warehouse performance significantly affects the Return on Investment (ROI) on Business Intelligence (BI) systems and directly impacts the bottom line of the systems (Appfluent Technology, 2002). Even though in some circumstances it is very difficult to measure the benefits of BI projects in terms of ROI or dollar figures, management teams are still eager to have a "single version of the truth," better information for strategic and tactical decision making, and more efficient business processes by using BI solutions (Eckerson, 2003).

Dramatic increases in data volumes over time and the mixed quality of data can adversely affect the performance of a data warehouse. Some data may become outdated over time and can be mixed with data that are still valid for decision making. In addition, data are often collected to meet potential requirements, but may never be used. Data warehouses also contain external data (e.g. demographic, psychographic, etc.) to support a variety of predictive data mining activities. All these factors contribute to the massive growth of data volume. As a result, even a simple query may become burdensome to process and cause overflowing system indices (Inmon et al., 1998). Thus, exploring the techniques of performance tuning becomes an important subject in data warehouse management.

BACKGROUND

There are inherent differences between a traditional database system and a data warehouse system, though to a certain extent, all databases are similarly designed to serve a basic administrative purpose, e.g., to deliver a quick response to transactional data processes such as entry, update, query and retrieval. For many conventional databases, this objective has been achieved by online transactional processing (OLTP) systems (e.g. Oracle Corp, 2004; Winter and Auerbach, 2004). In contrast, data warehouses deal with a huge volume of data that are more historical in nature. Moreover, data warehouse designs are strongly organized for decision making by subject matter rather than by defined access or system privileges. As a result, a dimension model is usually adopted in a data warehouse to meet these needs, whereas an Entity-Relationship model is commonly used in an OLTP system. Due to these differences, an OLTP query usually requires much shorter processing time than a data warehouse query (Raden, 2003). Performance enhancement techniques are, therefore, especially critical in the arena of data warehousing.

Despite the differences, these two types of database systems share some common characteristics. Some techniques used in a data warehouse to achieve a better performance are similar to those used in OLTP, while some are only developed in relation to data warehousing. For example, as in an OLTP system, an index is also used in a data warehouse system, though a data

warehouse might have different kinds of indexing mechanisms based on its granularity. Partitioning is a technique which can be used in data warehouse systems as well (Silberstein et al., 2003).

On the other hand, some techniques are developed specifically to improve the performance of data warehouses. For example, aggregates can be built to provide a quick response time for summary information (e.g. Eacrett, 2003; Silberstein, 2003). Query parallelism can be implemented to speed up the query when data are queried from several tables (Silberstein et al., 2003). Caching and query statistics are unique for data warehouses since the statistics will help to build a smart cache for better performance. Also, precalculated reports are useful to certain groups of users who are only interested in seeing static reports (Eacrett, 2003). Periodic data compression and archiving helps to cleanse the data warehouse environment. Keeping only the necessary data online will allow faster access (e.g. Kimball, 1996).

MAIN THRUST

As discussed earlier, performance issues play a crucial role in a data warehouse environment. This chapter describes ways to design, build, and manage data warehouses for optimum performance. The techniques of tuning and refining the data warehouse discussed below have been developed in recent years to reduce operating and maintenance costs and to substantially improve the performance of new and existing data warehouses.

Performance Optimization at the Data Model Design Stage

Adopting a good data model design is a proactive way to enhance future performance. In the data warehouse design phase, the following factors should be taken into consideration.

- **Granularity:** Granularity is the main issue that needs to be investigated carefully before the data warehouse is built. For example, does the report need the data at the level of store keeping units (SKUs), or just at the brand level? These are size questions that should be asked of business users before designing the model. Since a data warehouse is a decision support system, rather than a transactional system, the level of detail required is usually not as deep as the latter. For instance, a data warehouse does not need data at the document level such as sales orders, purchase orders, which are usually needed in a transactional system. In such a case, data should be summarized before they are loaded into the system. Defining the data that are needed – no more and no less – will determine the performance in the future. In some cases, the Operational Data Stores (ODS) will be a good place to store the most detailed granular level data and those data can be provided on the jump query basis.
- **Cardinality:** Cardinality means the number of possible entries of the table. By collecting business requirements, the cardinality of the table can be decided. Given a table's cardinality, an appropriate indexing method can then be chosen.
- **Dimensional Models:** Most data warehouse designs use dimensional models, such as Star-Schema, Snow-Flake, and Star-Flake. A star-schema is a dimensional model with fully denormalized hierarchies, whereas a snowflake schema is a dimensional model with fully normalized hierarchies. A star-flake schema represents a combination of a star schema and a snow-flake schema (e.g. Moody and Kortink, 2003). Data warehouse architects should consider the pros and cons of each dimensional model before making a choice.

Aggregates

Aggregates are the subsets of the fact table data (Eacrett, 2003). The data from the fact table are summarized into aggregates and stored physically in a different table than the fact table. Aggregates can significantly increase the performance of the OLAP query since the query will read fewer data from the aggregates than from the fact table. Database read time is the major factor in query execution time. Being able to reduce the database read time will help the query performance a great deal since fewer data are being read. However, the disadvantage of using aggregates is its loading performance. The data loaded into the fact table have to be rolled up to the aggregates, which means any newly updated records will have to be updated in the aggregates as well to make the data in the aggregates

consistent with those in the fact table. Keeping the data as current as possible has presented a real challenge to data warehousing (e.g. Bruckner and Tjoa, 2002). The ratio of the database records transferred to the database records read is a good indicator of whether or not to use the aggregate technique. In practice, if the ratio is 1/10 or less, building aggregates will definitely help performance (Silberstein, 2003).

Database Partitioning

Logical partitioning means using year, planned/actual data, and business regions as criteria to partition the database into smaller data sets. After logical partitioning, a database view is created to include all the partitioned tables. In this case, no extra storage is needed and each partitioned table will be smaller to accelerate the query (Silberstein et al., 2003). Take a multinational company as an example. It is better to put the data from different countries into different data targets, such as cubes or data marts, than to put the data from all the countries into one data target. By logical partitioning (splitting the data into smaller cubes), query can read the smaller cubes instead of large cubes and several parallel processes can read the small cubes at the same time. Another benefit of logical partitioning is that each partitioned cube is less complex to load and easier to perform the administration. Physical partitioning can also reach the same goal as logical partitioning. Physical partitioning means that the database table is cut into smaller chunks of data. The partitioning is transparent to the user. The partitioning will allow parallel processing of the query and each parallel process will read a smaller set of data separately.

Query Parallelism

In business intelligence reporting, the query is usually very complex and it might require the OLAP engine to read the data from different sources. In such case, the technique of query parallelism will significantly improve the query performance. Query parallelism is an approach to split the query into smaller sub-queries and to allow parallel processing of sub-queries. By using this approach, each sub-process takes a shorter time and reduces the risk of system hogging if a single long-running process is used. In contrast, sequential processing definitely requires a longer time to process (Silberstein et al., 2003).

Database Indexing

In a relational database, indexing is a well known technique for reducing database read time. By the same token, in a data warehouse dimensional model, the use of indices in the fact table, dimension table, and master data table will improve the database read time.

- **The Fact Table Index:** By default the fact table will have the primary index on all the dimension keys. However, a secondary index can also be built to fit a different query design (e.g. McDonald et al., 2002). Unlike a primary index, which includes all the dimension keys, the secondary index can be built to include only some dimension keys to improve the performance. By having the right index, the query read time can be dramatically reduced.
- **The Dimension Table Index:** In a dimensional model, the size of the dimension table is the deciding factor affecting query performance. Thus, the index of the dimension table is important to decrease the master data read time, and thus to improve filtering and drill down. Depending on the cardinality of the dimension table, different index methods will be adopted to build the index. For a low cardinality dimension table, Bit-Map index is usually adopted. In contrast, for a high cardinality dimension table, the B-Tree index should be used (e.g. McDonald et al., 2002).
- **The Master Data Table Index:** Since the data warehouse commonly uses dimensional models, the query SQL plan always starts from reading the master data table. Using indices on the master data table will significantly enhance the query performance.

Caching Technology

Caching technology will play a critical role in query performance as the memory size and speed of CPUs increase. After a query runs once, the result is stored in the memory cache. Subsequently, similar query runs will get the data directly from the memory rather than by accessing the database again. In an enterprise server, a certain block of memory is allocated for the caching use. The query results and the navigation status can then be stored in a highly compressed format in that memory block. For example, a background user can

be set up during the off-peak time to mimic the way a real user runs the query. By doing this, a cache is generated that can be used by real business users.

Pre-Calculated Report

Pre-calculation is one of the techniques where the administrator can distribute the workload to off-peak hours and have the result sets ready for faster access (Eacrett, 2003). There are several benefits of using the pre-calculated reports. The user will have faster response time since calculation takes place on the fly. Also, the system workload is balanced and shifted to off-peak hours. Lastly, the reports can be available offline.

Use Statistics to Further Tune Up the System

In a real-world data warehouse system, the statistics data of the OLAP are collected by the system. The statistics provide such information as what the most used queries are and how the data are selected. The statistics can help further tune the system. For example, examining the descriptive statistics of the queries will reveal the most common used drill-down dimensions as well as the combinations of the dimensions. Also, the OLAP statistics will also indicate what the major time component is out of the total query time. It could be database read time or OLAP calculation time. Based on the data, one can build aggregates or offline reports to increase the query performance.

Data Compression

Over time, the dimension table might contain some unnecessary entries or redundant data. For example, when some data has been deleted from the fact table, the corresponding dimension keys will not be used any more. These keys need to be deleted from the dimension table in order to have a faster query time since the query execution plan always start from the dimension table. A smaller dimension table will certainly help the performance.

The data in the fact table need to be compressed as well. From time to time, some entries in the fact table might contain just all zeros and need to be removed. Also, entries with the same dimension key value should be compressed to reduce the size of the fact table.

Kimball (1996) pointed out that data compression might not be a high priority for an OLTP system since the compression will slow down the transaction process. However, compression can improve data warehouse performance significantly. Therefore, in a dimensional model, the data in the dimension table and fact table need to be compressed periodically.

Data Archiving

In the real data warehouse environment, data are being loaded daily or weekly. The volume of the production data will become huge over time. More production data will definitely lengthen the query run time. Sometimes, there are too much unnecessary data sitting in the system. These data may be out-dated and not important to the analysis. In such cases, the data need to be periodically archived to offline storage so that they can be removed from the production system (e.g. Uhle, 2003). For example, three years of production data are usually sufficient for a decision support system. Archived data can still be pulled back to the system if such need arises

FUTURE TRENDS

Although data warehouse applications have been evolving to a relatively mature stage, several challenges remain in developing a high performing data warehouse environment. The major challenges are:

- How to optimize the access to volumes of data based on system workload and user expectations (e.g. Inmon et al., 1998)? Corporate information systems rely more and more on data warehouses that provide one entry point for access to all information for all users. Given this, and because of varying utilization demands, the system should be tuned to reduce the system workload during peak user periods.
- How to design a better OLAP statistics recording system to measure the performance of the data warehouse? As mentioned earlier, query OLAP statistics data is important to identify the trend and the utilization of the queries by different users. Based on the statistics results, several techniques could be used to tune up the performance, such as aggregates, indices and caching.

- How to maintain data integrity and keep the good data warehouse performance at the same time? Information quality and ownership within the data warehouse play an important role in the delivery of accurate processed data results (Ma et al., 2000). Data validation is thus a key step towards improving data reliability and quality. Accelerating the validation process presents a challenge to the performance of the data warehouse.

CONCLUSION

Information technologies have been evolving quickly in recent decades. Engineers have made great strides in developing and improving databases and data warehousing in many aspects, such as hardware; operating systems; user interface and data extraction tools; data mining tools, security, and database structure and management systems.

Many success stories in developing data warehousing applications have been published (Beitler and Leary, 1997; Grim and Thorton, 1997). An undertaking of this scale – creating an effective data warehouse, however, is costly and not risk-free. Weak sponsorship and management support, insufficient funding, inadequate user involvement, and organizational politics have been found to be common factors contributing to failure (Watson et al., 1999). Therefore, data warehouse architects need to first clearly identify the information useful for the specific business process and goals of the organization. The next step is to identify important factors that impact performance of data warehousing implementation in the organization. Finally all the business objectives and factors will be incorporated into the design of the data warehouse system and data models, in order to achieve high-performing data warehousing and business intelligence.

KEY TERMS

Cache: A region of a computer's memory which stores recently or frequently accessed data so that the time of repeated access to the same data can decrease.

Granularity: The level of detail or complexity at which an information resource is described.

Indexing: In data storage and retrieval, the creation and use of a list that inventories and cross-references data. In database operations, a method to find data more efficiently by indexing on primary key fields of the database tables.

ODS (Operational Data Stores): A system with capability of continuous background update that keeps up with individual transactional changes in operational systems versus a data warehouse that applies a large load of updates on an intermittent basis.

OLTP (Online Transaction Processing): A standard, normalized database structure designed for transactions in which inserts, updates, and deletes must be fast.

OLAP (Online Analytical Processing): A category of software tools for collecting, presenting, delivering, processing and managing multidimensional data (i.e., data that has been aggregated into various categories or "dimensions") in order to provide analytical insights for business management.

Service Management: The strategic discipline for identifying, establishing, and maintaining IT services to support the organization's business goal at an appropriate cost.

SQL (Structured Query Language): A standard interactive programming language used to communicate with relational databases in order to retrieve, update, and manage data.

Data Warehousing and Mining in Supply Chains

Richard Mathieu
Saint Louis University, USA

Reuven R. Levary
Saint Louis University, USA

INTRODUCTION

Every finished product has gone through a series of transformations. The process begins when manufacturers purchase the raw materials that will be transformed into the components of the product. The parts are then supplied to a manufacturer, who assembles them into the finished product and ships the completed item to the consumer. The transformation process includes numerous activities (Levary, 2000). Among them are

- Designing the product
- Designing the manufacturing process
- Determining which component parts should be produced in house and which should be purchased from suppliers
- Forecasting customer demand
- Contracting with external suppliers for raw materials or component parts
- Purchasing raw materials or component parts from suppliers
- Establishing distribution channels for raw materials and component parts from suppliers to manufacturer
- Establishing of distribution channels to the suppliers of raw materials and component parts
- Establishing distribution channels from the manufacturer to the wholesalers and from wholesalers to the final customers
- Manufacturing the component parts
- Transporting the component parts to the manufacturer of the final product
- Manufacturing and assembling the final product
- Transporting the final product to the wholesalers, retailers, and final customer

Each individual activity generates various data items that must be stored, analyzed, protected, and transmitted to various units along a supply chain.

A *supply chain* can be defined as a series of activities that are involved in the transformation of raw materials into a final product, which a customer then purchases (Levary, 2000). The flow of materials, component parts, and products is moving downstream (i.e., from the initial supply sources to the end customers). The flow of information regarding the demand for the product and orders to suppliers is moving upstream, while the flow of information regarding product availability, shipment schedules, and invoices is moving downstream. For each organization in the supply chain, its customer is the subsequent organization in the supply chain, and its subcontractor is the prior organization in the chain.

BACKGROUND

Supply chain data can be characterized as either transactional or analytical (Shapiro, 2001). All new data that are acquired, processed, and compiled into reports that are transmitted to various organizations along a supply chain are deemed transactional data (Davis & Spekman, 2004). Increasingly, transactional supply chain data is processed and stored in enterprise resource planning systems, and complementary data warehouses are developed to support decision-making processes (Chen R., Chen, C., & Chang, 2003; Zeng, Chiang, & Yen, 2003). Organizations such as Home Depot, Lowe's, and Volkswagen have developed data warehouses and integrated data-mining methods that complement their supply chain management operations (Dignan, 2003a; Dignan, 2003b; Hofmann, 2004). Data that are used in descriptive and optimization models are considered

analytical data (Shapiro, 2001). Descriptive models include various forecasting models, which are used to forecast demands along supply chains, and managerial accounting models, which are used to manage activities and costs. Optimization models are used to plan resources, capacities, inventories, and product flows along supply chains.

Data collected from consumers are the core data that affect all other data items along supply chains. Information collected from the consumers at the point of sale include data items regarding the sold product (e.g., type, quantity, sale price, and time of sale) as well as information about the consumer (e.g., consumer address and method of payment). These data items are analyzed often. Data-mining techniques are employed to determine the types of items that are appealing to consumers. The items are classified according to consumers' socioeconomic backgrounds and interests, the sale price that consumers are willing to pay, and the location of the point of sale.

Data regarding the return of sold products are used to identify potential problems with the products and their uses. These data include information about product quality, consumer disappointment with the product, and legal consequences. Data-mining techniques can be used to identify patterns in returns so that retailers can better determine which type of product to order in the future and from which supplier it should be purchased. Retailers are also interested in collecting data regarding competitors' sales so that they can better promote their own product and establish a competitive advantage.

Data related to political and economic conditions in supplier countries are of interest to retailers. Data-mining techniques can be used to identify political and economic patterns in countries. Information can help retailers choose suppliers who are situated in countries where the flow of products and funds is expected to be stable for a reasonably long period of time.

Manufacturers collect data regarding a) particular products and their manufacturing process, b) suppliers, and c) the business environment. Data regarding the product and the manufacturing process include the characteristics of products and their component parts obtained from CAD/CAM systems, the quality of products and their components, and trends in theresearch and development (R & D) of relevant technologies. Data-mining techniques can be applied to identify patterns in the defects of products, their components, or the manufacturing process. Data regarding suppliers include availability of raw materials, labor costs, labor skills, technological capability, manufacturing capacity, and lead time of suppliers. Data related to qualified teleimmigrants (e.g., engineers and computer software developers) is valuable to many manufacturers. Data-mining techniques can be used to identify those teleimmigrants having unique knowledge and experience. Data regarding the business environment of manufacturers include information about competitors, potential legal consequences regarding a product or service, and both political and economic conditions in countries where the manufacturer has either facilities or business partners. Data-mining techniques can be used to identify possible liability concerning a product or service as well as trends in political and economic conditions in countries where the manufacturer has business interests.

Retailers, manufacturers, and suppliers are all interested in data regarding transportation companies. These data include transportation capacity, prices, lead time, and reliability for each mode of transportation.

MAIN THRUST

Data Aggregation in Supply Chains

Large amounts of data are being accumulated and stored by companies belonging to supply chains. Data aggregation can improve the effectiveness of using the data for operational, tactical, and strategic planning models. The concept of data aggregation in manufacturing firms is called *group technology (GT).* Nonmanufacturing firms are also aggregating data regarding products, suppliers, customers, and markets.

Group Technology

Group technology is a concept of grouping parts, resources, or data according to similar characteristics. By grouping parts according to similarities in geometry, design features, manufacturing features, materials used, and/or tooling requirements, manufacturing efficiency can be enhanced, and productivity increased. Manufacturing efficiency is enhanced by

- Performing similar activities at the same work center so that setup time can be reduced

- Avoiding duplication of effort both in the design and manufacture of parts
- Avoiding duplication of tools
- Automating information storage and retrieval (Levary, 1993)

Effective implementation of the GT concept necessitates the use of a classification and coding system. Such a system codes the various attributes that identify similarities among parts. Each part is assigned a number or alphanumeric code that uniquely identifies the part's attributes or characteristics. A part's code must include both design and manufacturing attributes.

A classification and coding system must provide an effective way of grouping parts into part families. All parts in a given part family are similar in some aspect of design or manufacture. A part may belong to more than one family.

A part code is typically composed of a large number of characters that allow for identification of all part attributes. The larger the number of attributes included in a part code, the more difficult the establishment of standard procedures for classifying and coding. Although numerous methods of classification and coding have been developed, none has emerged as the standard method. Because different manufacturers have different requirements regarding the type and composition of parts' codes, customized methods of classification and coding are generally required. Some of the better known classification and coding methods are listed by Groover (1987).

After a code is established for each part, the parts are grouped according to similarities and are assigned to part families. Each part family is designed to enhance manufacturing efficiency in a particular way. The information regarding each part is arranged according to part families in a GT database. The GT database is designed in such a way that users can efficiently retrieve desired information by using the appropriate code.

Consider part families that are based on similarities of design features. A GT database enables design engineers to search for existing part designs that have characteristics similar to those of a new part that is to be designed. The search begins when the design engineer describes the main characteristics of the needed part with the help of a partial code. The computer then searches the GT database for all the items with the same code. The results of the search are listed on the computer screen, and the designer can then select or modify an existing part design after reviewing its specifications. Selected designs can easily be retrieved. When design modifications are needed, the file of the selected part is transferred to a CAD system. Such a system enables the design engineer to effectively modify the part's characteristics in a short period of time. In this way, efforts are not duplicated when designing parts.

The creation of a GT database helps reduce redundancy in the purchasing of parts as well. The database enables manufacturers to identify similar parts produced by different companies. It also helps manufacturers to identify components that can serve more than a single function. In such ways, GT enables manufacturers to reduce both the number of parts and the number of suppliers. Manufacturers that can purchase large quantities of a few items rather than small quantities of many items are able to take advantage of quantity discounts.

Aggregation of Data Regarding Retailing Products

Retailers may carry thousands of products in their stores. To effectively manage the logistics of so many products, product aggregation is highly desirable. Products are aggregated into families that have some similar characteristics. Examples of product families include the following:

- Products belonging to the same supplier
- Products requiring special handling, transportation, or storage
- Products intended to be used or consumed by a specific group of customers
- Products intended to be used or consumed in a specific season of the year
- Volume and speed of product movement
- The methods of the transportation of the products from the suppliers to the retailers
- The geographical location of suppliers
- Method of transaction handling with suppliers; for example, EDI, Internet, off-line

As in the case of GT, retailing products may belong to more than one family.

Aggregation of Data Regarding Customers of Finished Products

To effectively market finished products to customers, it is helpful to aggregate customers with similar characteristics into families. Examples of customers of finished product families include

- Customers residing in a specific geographical region
- Customers belonging to a specific socioeconomic group
- Customers belonging to a specific age group
- Customers having certain levels of education
- Customers having similar product preferences
- Customers of the same gender
- Customers with the same household size

Similar to both GT and retailing products, customers of finished products may belong to more than one family.

FUTURE TRENDS

Supply Chain Decision Databases

The enterprise database systems that support supply chain management are repositories for large amounts of transaction-based data. These systems are said to be data rich but information poor. The tremendous amount of data that are collected and stored in large, distributed database systems has far exceeded the human ability for comprehension without analytic tools. Shapiro estimates that 80% of the data in a transactional database that supports supply chain management is irrelevant to decision making and that data aggregations and other analyses are needed to transform the other 20% into useful information (2001). Data warehousing and online analytical processing (OLAP) technologies combined with tools for data mining and knowledge discovery have allowed the creation of systems to support organizational decision making.

The supply chain management (SCM) data warehouse must maintain a significant amount of data for decision making. Historical and current data are required from supply chain partners and from various functional areas within the firm in order to support decision making in regard to planning, sourcing, production, and product delivery. Supply chains are dynamic in nature. In a supply chain environment, it may be desirable to learn from an archived history of temporal data that often contains some information that is less than optimal. In particular, SCM environments are typically characterized by variable changes in product demand, supply levels, product attributes, machine characteristics, and production plans. As these characteristics change over time, so does the data in the data warehouses that support SCM decision making. We should note that Kimball and Ross (2002) use a *supply value chain* and a *demand supply chain* as the framework for developing the data model for all business data warehouses.

The data warehouses provide the foundation for decision support systems (DSS) for supply chain management. Analytical tools (simulation, optimization, & data mining) and presentation tools (geographic information systems and graphical user interface displays) are coupled with the input data provided by the data warehouse (Marakas, 2003). Simchi-Levi, D., Kaminsky, and Simchi-Levi, E. (2000) describe three DSS examples: logistics network design, supply chain planning and vehicle routing, and scheduling. Each DSS requires different data elements, has specific goals and constraints, and utilizes special graphical user interface (GUI) tools.

The Role of Radio Frequency Identification (RFID) in Supply Chains Data Warehousing

The emerging RFID technology will generate large amounts of data that need to be warehoused and mined. *Radio frequency identification (RFID)* is a wireless technology that identifies objects without having either contact or sight of them. RFID tags can be read despite environmentally difficult conditions such as fog, ice, snow, paint, and widely fluctuating temperatures. Optically read technologies, such as bar codes, cannot be used in such environments. RFID can also identify objects that are moving.

Passive RFID tags have no external power source. Rather, they have operating power generated from a reader device. The passive RFID tags are very small and inexpensive. Further, they have a virtually unlimited operational life. The characteristics of these passive RFID tags make them ideal for tracking materials through supply chains. Wal-Mart has required manufacturers,

suppliers, distributors, and carriers to incorporate RFID tags into both products and operations. Other large retailers are following Wal-Mart's lead in requesting RFID tags to be installed in goods along their supply chain. The tags follow products from the point of manufacture to the store shelf. RFID technology will significantly increase the effectiveness of tracking materials along supply chains and will also substantially reduce the loss that retailers accrue from thefts. Nonetheless, civil liberty organizations are trying to stop RFID tagging of consumer goods, because this technology has the potential of affecting consumer privacy. RFID tags can be hidden inside objects without customer knowledge. So RFID tagging would make it possible for individuals to read the tags without the consumers even having knowledge of the tags' existence.

Sun Microsystems has designed RFID technology to reduce or eliminate drug counterfeiting in pharmaceutical supply chains (Jaques, 2004). This technology will make the copying of drugs extremely difficult and unprofitable. Delta Air Lines has successfully used RFID tags to track pieces of luggage from check-in to planes (Brewin, 2003). The luggage-tracking success rate of RFID was much better than that provided by bar code scanners.

Active RFID tags, unlike passive tags, have an internal battery. The tags have the ability to be rewritten and/or modified. The read/write capability of active RFID tags is useful in interactive applications such as tracking work in process or maintenance processes. Active RFID tags are larger and more expensive than passive RFID tags. Both the passive and active tags have a large, diverse spectrum of applications and have become the standard technologies for automated identification, data collection, and tracking. A vast amount of data will be recorded by RFID tags. The storage and analysis of this data will pose new challenges to the design, management, and maintenance of databases as well as to the development of data-mining techniques.

CONCLUSION

A large amount of data is likely to be gathered from the many activities along supply chains. This data must be warehoused and mined to identify patterns that can lead to better management and control of supply chains. The more RFID tags installed along supply chains, the easier data collection becomes. As the tags become more popular, the data collected by them will grow significantly. The increased popularity of the tags will bring with it new possibilities for data analysis as well as new warehousing and mining challenges.

KEY TERMS

Analytical Data: All data that are obtained from optimization, forecasting, and decision support models.

Computer Aided Design (CAD): An interactive computer graphics system used for engineering design.

Computer Aided Manufacturing (CAM): The use of computers to improve both the effectiveness and efficiency of manufacturing activities.

Decision Support System (DSS): Computer-based systems designed to assist in managing activities and information in organizations.

Graphical User Interface (GUI): A software interface that relies on icons, bars, buttons, boxes, and other images to initiate computer-based tasks for users.

Group Technology (GP): The concept of grouping parts, resources, or data according to similar characteristics.

Online Analytical Processing (OLAP): A form of data presentation in which data are summarized, aggregated, deaggregated, and viewed in the frame of a table or cube.

Supply Chain: A series of activities that are involved in the transformation of raw materials into a final product that is purchased by a customer.

Transactional Data: All data that are acquired, processed, and compiled into reports, which are transmitted to various organizations along a supply chain.

Data Warehousing for Association Mining

Yuefeng Li
Queensland University of Technology, Australia

INTRODUCTION

With the phenomenal growth of electronic data and information, there are many demands for developments of efficient and effective systems (tools) to address the issue of performing data mining tasks on data warehouses or multidimensional databases. Association rules describe associations between itemsets (i.e., sets of data items) (or granules). Association mining (or called association rule mining) finds interesting or useful association rules in databases, which is the crucial technique for the development of data mining. Association mining can be used in many application areas, for example, the discovery of associations between customers' locations and shopping behaviours in market basket analysis.

Association mining includes two phases. The first phase is called pattern mining that is the discovery of frequent patterns. The second phase is called rule generation that is the discovery of the interesting and useful association rules in the discovered patterns. The first phase, however, often takes a long time to find all frequent patterns that also include much noise as well (Pei and Han, 2002). The second phase is also a time consuming activity (Han and Kamber, 2000) and can generate many redundant rules (Zaki, 2004) (Xu and Li, 2007). To reduce search spaces, user constraint-based techniques attempt to find knowledge that meet some sorts of constraints. There are two interesting concepts that have been used in user constraint-based techniques: meta-rules (Han and Kamber, 2000) and granule mining (Li et al., 2006).

The aim of this chapter is to present the latest research results about data warehousing techniques that can be used for improving the performance of association mining. The chapter will introduce two important approaches based on user constraint-based techniques. The first approach requests users to inputs their meta-rules that describe their desires for certain data dimensions. It then creates data cubes based these meta-rules and then provides interesting association rules.

The second approach firstly requests users to provide condition and decision attributes that used to describe the antecedent and consequence of rules, respectively. It then finds all possible data granules based condition attributes and decision attributes. It also creates a multi-tier structure to store the associations between granules, and association mappings to provide interesting rules.

BACKGROUND

Data warehouse mainly aims to make data easily accessible, present data consistently and be adaptive and resilient to change (Kimball and Ross, 2002). A data warehouse is an application that contains a collection of data, which is subject-oriented, integrated, non-volatile and time-variant, supporting management's decisions (Inmon, 2005). Data warehousing focuses on constructing and using data warehouses. The construction includes data cleaning, data integration and data consolidation. After these steps, a collection of data in a specific form can be stored in a data warehouse.

Data warehouses can also provide clean, integrated and complete data to improve the process of data mining (Han and Kamber, 2000). Han and Kamber also defined different levels of the integration of data mining and data warehouse. At the loosest level the data warehouse only acts as a normal data source of data mining. While at the tightest level both the data warehouse and data mining are sub-components that cooperate with each other. In a data mining oriented data warehouse, the data warehouse not only cleans and integrates data, but also tailors data to meet user constraints for knowledge discovery in databases. Thus, data mining can return what users want in order to improve the quality of discovered knowledge.

It is painful when we review the two steps in association mining: both take a long time and contain uncertain information for determining useful knowledge. Data mining oriented data warehousing is a promising direction for solving this problem. It refers

to constructing systems, in which both the data mining and data warehouse are a sub-component cooperating with each other. Using these systems, the data warehouse not only cleans and integrates data, but tailors data to fit the requirements of data mining. Thus, data mining becomes more efficient and accurate. In this chapter we discuss how data warehousing techniques are useful for association mining.

MAIN FOCUS

Based on the above introduction, we understand that data warehousing techniques can be helpful for improving the quality of data mining. We will focus on two areas in this chapter: mining patterns and meta-rules through data cubes and mining granules and decision rules through multi-tier structures.

Mining Patterns and Meta Rules through Data Cubes

There are many studies that discuss the research issue of performing data mining tasks on a data warehouse. The main research point is that pattern mining and rule generation can be used together with OLAP (On-Line Analytical Processing) to find interesting knowledge from data cubes (Han and Kamber, 2000) (Imielinski et al., 2002) (Messaoud et al., 2006).

A data cube consists of a set of data dimensions and a set of measures. Each dimension usually has a set of hierarchical levels. For example, a product dimension may have three hierarchal levels: All, Family and Article, where Article could be a set of attributes (e.g., {iTwin, iPower, DV-400, EN-700, aStar, aDream}), Family could be {Desktop, Laptop, MP3} and All is the total aggregation level. The frequency measure in data cube is called COUNT, which is used to evaluate the occurrences of the corresponding data values for data cube cells.

A meta-rule in multidimensional databases usually has the following format:

$$\text{“}P_1 \wedge P_2 \wedge \ldots \wedge P_m \rightarrow Q_1 \wedge Q_2 \wedge \ldots \wedge Q_n\text{”}$$

where P_i and Q_j are some predicates which can be sets of data fields in different dimension levels. The meta-rule defines the portion of the data cube to be mined.

The mining process starts to provide a meta-rule and define a minimum support and a minimum confidence. The traditional way to define the support and confidence is the use of the numbers of occurrences of data values. For example, the support can be computed according to the frequency of units of facts based on the COUNT measure. It was also recommended in the OLAP context (Messaoud et al., 2006) that users were often interested in observing facts based on summarized values of measures rather than the numbers of occurrences. Therefore, SUM measure based definitions for the support and confidence were presented in (Messaoud et al., 2006). The second step is to choose an approach (the top-down approach or bottom up approach) to produce frequent itemsets. The last step is to generate interesting association rules to meet the requirements in the meta-rule.

Mining Decision Rules through Multi-Tier Structures

User constraint-based association mining can also be implemented using granule mining, which finds interesting associations between granules in databases, where a granule is a predicate that describes common features of a set of objects (e.g., records, or transactions) for a selected set of attributes (or items).

Formally, a multidimensional database can be described as an information table (T, V^T), where T is a set of objects (records) in which each record is a sequences of items, and $V^T = \{a_1, a_2, \ldots, a_n\}$ is a set of selected items (or called attributes in decision tables) for all objects in T. Each item can be a tuple (e.g., <*name*, *cost*, *price*> is a product item).

Table I illustrates an information table, where $V^T = \{a_1, a_2, \ldots, a_7\}$, $T = \{t_1, t_2, \ldots, t_6\}$.

Given an information table, a user can classify attributes into two categories: condition attributions and decision attributes. For example, the high profit products can be condition attributes and low profit products can be decision attributes. Formally, a decision table is a tuple (T, V^T, C, D), where T is a set of objects (records) in which each record is a set of items, and $V^T = \{a_1, a_2, \ldots, a_n\}$ is a set of attributes, $C \cup D \subseteq V^T$ and $C \cap D = \varnothing$.

Objects in a decision table can also be compressed into a granule if they have the same representation (Pawlak, 2002). Table II shows a decision table of the

Table 1. An information table

Object	Items
t_1	a_1 a_2
t_2	a_3 a_4 a_6
t_3	a_3 a_4 a_5 a_6
t_4	a_3 a_4 a_5 a_6
t_5	a_1 a_2 a_6 a_7
t_6	a_1 a_2 a_6 a_7

Table 2. A decision table

Granule	**Products**							**coverset**
	High profit					*Low profit*		
	a_1	a_2	a_3	a_4	a_5	a_6	a_7	
g_1	1	1	0	0	0	0	0	$\{t_1\}$
g_2	0	0	1	1	0	1	0	$\{t_2\}$
g_3	0	0	1	1	1	1	0	$\{t_3, t_4\}$
g_4	1	1	0	0	0	1	1	$\{t_5, t_6\}$

information table in Table I, where $C = \{a_1, a_2, \ldots, a_5\}$, $D = \{a_6, a_7\}$, the set of granules is $\{g_1, g_2, g_3, g_4\}$, and *coverset* is the set of objects that are used to produce a granule.

Each granule can be viewed as a decision rule, where the antecedent is the corresponding part of condition attributes in the granule and the consequence is the corresponding part of decision attributes in the granule.

In (Li and Zhong, 2003), larger granules in decision tables were split into smaller granules and deployed into two tiers: *C-granules* (condition granules) which are granules that only use condition attributes and *D-granules* (decision granules) which are granules that only use decision attributes. Table III illustrates a 2-tier structure for the decision table in Table II, where both (A) and (B) include three small granules.

The following are advantages of using granules for knowledge discovery in databases:

1. A granule describes the feature of a set of objects, but a pattern is a part of an object;
2. The number of granules is much smaller than the numbers of patterns;
3. Decision tables can directly describe multiple values of items; and
4. It provides a user-oriented approach to determine the antecedent (also called premise) and consequence (conclusion) of association rules.

There are also several disadvantages when we discuss granules based on decision tables. The first problem is that we do not understand the relation between association rules (or patterns) and decision rules (or granules). Although decision tables can provide an efficient way to represent discovered knowledge with a small number of attributes, in cases of large number of attributes, decision tables lose their advantages because

Table 3. A 2-tier structure

Condition Granule	a_1	a_2	a_3	a_4	a_5	coverset
cg_1	1	1	0	0	0	$\{t_1, t_5, t_6\}$
cg_2	0	0	1	1	0	$\{t_2\}$
$\boldsymbol{cg_3}$	0	0	1	1	1	$\{t_1, t_4\}$

(a) C-granules

Decision Granule	a_6	a_7	coverset
dg_1	0	0	$\{t_1\}$
dg_2	1	0	$\{t_2, t_3, t_4\}$
$\boldsymbol{dg_3}$	1	1	$\{t_5, t_6\}$

(b) D-granules

they can not be used to organize granules with different sizes. They also have not provided a mechanism to define meaningless rules.

In (Li et al., 2006), a multi-tier structure was presented to overcome the above disadvantages of using granules for knowledge discovery in databases. In this structure, condition attributes can be further split into some tiers and the large multidimensional database is compressed into granules at each tier. The antecedent and consequent of an association rule are both granules, and the associations between them are described by association mappings. For example, condition attributions C can be further spit into two sets of attributes: C_i and C_j. Therefore, in the multi-tier structure, the *C-granules* tier is divided into two tiers: C_i*-granules* and C_j*-granules*.

Let cg_k be a *C-granule*, it can be represented as "$cg_{i,x} \wedge cg_{j,y}$" by using C_i*-granules* tier and C_j*-granules* tier. Decision rule "$cg_k \rightarrow dg_z$" can also have the form of

"$cg_{i,x} \wedge cg_{j,y} \rightarrow dg_z$".

Different to decision tables, we can discuss general association rules (rules with shorter premises) of decision rules. We call "$cg_{i,x} \rightarrow dg_z$" (or "$cg_{i,y} \rightarrow dg_z$") its general rule. We call decision rule "$cg_k \rightarrow dg_z$" meaningless if its confidence is less than or equal to the confidence in its general rule.

A granule mining oriented data warehousing model (Wan et al., 2007) was presented recently which facilitates the representations of multidimensional association rules. This model first constructs a decision table based on a set of selected attributes that meet the user constraints. It then builds up a multi-tier structure of granules based on the nature of these selected attributes. It also generates variant association mappings between granules to find association rules in order to satisfy what users want.

FUTURE TRENDS

Currently it is a big challenge to efficiently find interesting association rules in multidimensional databases for meeting what users want because the huge amount of frequent patterns and interesting association rules (Li and Zhong, 2006) (Wu et al., 2006) . Data mining oriented data warehousing techniques can be used to solve this challenging issue. OLAP technology dose not provide a mechanism to interpret the associations between data items, however, association mining can be conducted using OLAP via data cubes. Granule mining

provides an alternative way to represent association rules through multi-tier structures.

The key research issue is to allow users to semi-supervise the mining process and focus on a specified context from which rules can be extracted in multidimensional databases. It is possible to use data cubes and OLAP techniques to find frequent Meta-rules; however, it is an open issue to find only interesting and useful rules. Granule mining is a promising initiative for solving this issue. It must be interesting to combine granule mining and OLAP techniques for the development of efficient data mining oriented data warehousing models.

CONCLUSION

As mentioned above, it is a challenging task to significantly improve the quality of multidimensional association rule mining. The essential issue is how to represent meaningful multidimensional association rules efficiently. This chapter introduces the current achievements for solving this challenge. The basic idea is to represent discovered knowledge through using data warehousing techniques. Data mining oriented data warehousing can be simple classified into two areas: mining patterns and Meta rules through data cubes and mining granules and decision rules through multi-tier structures.

KEY TERMS

Data Mining Oriented Data Warehousing: Refers to constructing such systems, in which both the data mining and data warehouse are a sub-component cooperating with each other. Using these systems, the data warehouse not only cleans and integrates data, but tailors data to fit the requirements of data mining. Thus, data mining becomes more efficient and accurate.

Decision Rule: A decision rule has the following format: "$X \rightarrow Y$", where X and Y are granules and ($X \wedge Y$) is a large granule, where small granule X is called condition granule and Y is called decision granule. Its support is the fraction of transactions that make both X and Y satisfy; and its confidence is the faction of transactions making X satisfy that also make Y satisfy.

Decision Table: A decision table is a tuple (T, V^T, C, D), where T is a set of objects (records) in which each record is a set of items, and $V^T = \{a_1, a_2, \ldots, a_n\}$ is a set of attributes, $C \cup D \subseteq V^T$ and $C \cap D = \varnothing$.

General Rule: Let "$X \rightarrow Y$" be a decision rule and $X = (X_1 \wedge X_2)$. We call "$X_1 \rightarrow Y$" (or "$X_2 \rightarrow Y$") a general rule of "$X \rightarrow Y$".

Granule: A granule is a predicate that describes common features of a set of objects (e.g., records, or transactions) for a selected set of attributes (or items).

Granule Mining: Granule mining is to find interesting associations between granules in databases.

Meaningless Rule: We call decision rule "$X \rightarrow Y$" meaningless if its confidence is less than or equals to the confidence in one of its general rules.

Meta-Rule: Ameta-rule in multidimensional databases usually has the following format: "$P_1 \wedge P_2 \wedge \ldots \wedge P_m \rightarrow Q_1 \wedge Q_2 \wedge \ldots \wedge Q_n$", where P_i and Q_j are some predicates which can be sets of data fields in different dimension levels.

Multi-Tier Structure: A multi-tier structure is a graph in which vertices are granules and edges are associations between granules. It used to organize discovered granules in multiple tires such that the granules in the same tier have the same size and in the different tiers have the different size.

Pattern Mining: That is the discovery of frequent patterns in databases.

Database Queries, Data Mining, and OLAP

Lutz Hamel
University of Rhode Island, USA

INTRODUCTION

Modern, commercially available relational database systems now routinely include a cadre of data retrieval and analysis tools. Here we shed some light on the interrelationships between the most common tools and components included in today's database systems: query language engines, data mining components, and on-line analytical processing (OLAP) tools. We do so by pair-wise juxtaposition which will underscore their differences and highlight their complementary value.

BACKGROUND

Today's commercially available relational database systems now routinely include tools such as SQL database query engines, data mining components, and OLAP (Craig, Vivona, & Bercovitch, 1999; Hamm, 2007; Melomed, Gorbach, Berger, & Bateman, 2006; Scalzo, 2003; Seidman, 2001). These tools allow developers to construct high powered business intelligence (BI) applications which are not only able to retrieve records efficiently but also support sophisticated analyses such as customer classification and market segmentation. However, with powerful tools so tightly integrated with the database technology understanding the differences between these tools and their comparative advantages and disadvantages becomes critical for effective application development. From the practitioner's point of view questions like the following often arise:

- Is running database queries against large tables considered data mining?
- Can data mining and OLAP be considered synonymous?
- Is OLAP simply a way to speed up certain SQL queries?

The issue is being complicated even further by the fact that data analysis tools are often implemented in terms of data retrieval functionality. Consider the data mining models in the Microsoft SQL server which are implemented through extensions to the SQL database query language (e.g. predict join) (Seidman, 2001) or the proposed SQL extensions to enable decision tree classifiers (Sattler & Dunemann, 2001). OLAP cube definition is routinely accomplished via the data definition language (DDL) facilities of SQL by specifying either a star or snowflake schema (Kimball, 1996).

MAIN THRUST OF THE CHAPTER

The following sections contain the pair wise comparisons between the tools and components considered in this chapter.

Database Queries vs. Data Mining

Virtually all modern, commercial database systems are based on the relational model formalized by Codd in the 60s and 70s (Codd, 1970) and the SQL language (Date, 2000) which allows the user to efficiently and effectively manipulate a database. In this model a database table is a representation of a mathematical relation, that is, a set of items that share certain characteristics or attributes. Here, each table column represents an attribute of the relation and each record in the table represents a member of this relation. In relational databases the tables are usually named after the kind of relation they represent. Figure 1 is an example of a table that represents the set or relation of all the customers of a particular store. In this case the store tracks the total amount of money spent by its customers.

Relational databases do not only allow for the creation of tables but also for the manipulation of the tables and the data within them. The most fundamental operation on a database is the query. This operation enables the user to retrieve data from database tables by asserting that the retrieved data needs to fulfill certain criteria. As an example, consider the fact that the store owner might be interested in finding out which customers spent more than $100 at the store. The fol-

Figure 1. A relational database table representing customers of a store

Id	*Name*	*ZIP*	*Sex*	*Age*	*Income*	*Children*	*Car*	*Total Spent*
5	Peter	05566	M	35	$40,000	2	Mini Van	$250.00
...	...	...	...	...	...	...	...	...
22	Maureen	04477	F	26	$55,000	0	Coupe	$50.00

lowing query returns all the customers from the above customer table that spent more than $100:

```
SELECT * FROM CUSTOMER_TABLE WHERE
TOTAL_SPENT > $100;
```

This query returns a list of all instances in the table where the value of the attribute *Total Spent* is larger than $100. As this example highlights, queries act as filters that allow the user to select instances from a table based on certain attribute values. It does not matter how large or small the database table is, a query will simply return all the instances from a table that satisfy the attribute value constraints given in the query. This straightforward approach to retrieving data from a database has also a drawback. Assume for a moment that our example store is a large store with tens of thousands of customers (perhaps an online store). Firing the above query against the customer table in the database will most likely produce a result set containing a very large number of customers and not much can be learned from this query except for the fact that a large number of customers spent more than $100 at the store. Our innate analytical capabilities are quickly overwhelmed by large volumes of data.

This is where differences between querying a database and mining a database surface. In contrast to a query which simply returns the data that fulfills certain constraints, data mining constructs models of the data in question. The models can be viewed as high level summaries of the underlying data and are in most cases more useful than the raw data, since in a business sense they usually represent understandable and actionable items (Berry & Linoff, 2004). Depending on the questions of interest, data mining models can take on very different forms. They include decision trees and decision rules for classification tasks, association rules for market basket analysis, as well as clustering for market segmentation among many other possible models. Good overviews of current data mining techniques and models can be found in (Berry & Linoff, 2004; Han & Kamber, 2001; Hand, Mannila, & Smyth, 2001; Hastie, Tibshirani, & Friedman, 2001).

To continue our store example, in contrast to a query, a data mining algorithm that constructs decision rules might return the following set of rules for customers that spent more than $100 from the store database:

```
IF AGE > 35 AND CAR = MINIVAN THEN
TOTAL SPENT > $100
```

or

```
IF SEX = M AND ZIP = 05566 THEN TOTAL
SPENT > $100
```

These rules are understandable because they summarize hundreds, possibly thousands, of records in the customer database and it would be difficult to glean this information off the query result. The rules are also actionable. Consider that the first rule tells the store owner that adults over the age of 35 that own a mini van are likely to spend more than $100. Having access to this information allows the store owner to adjust the inventory to cater to this segment of the population, assuming that this represents a desirable cross-section of the customer base. Similar with the second rule, male customers that reside in a certain ZIP code are likely to spend more than $100. Looking at census information for this particular ZIP code the store owner could again adjust the store inventory to also cater to this population segment presumably increasing the attractiveness of the store and thereby increasing sales.

As we have shown, the fundamental difference between database queries and data mining is the fact that in contrast to queries data mining does not return raw data that satisfies certain constraints, but returns models of the data in question. These models are attrac-

tive because in general they represent understandable and actionable items. Since no such modeling ever occurs in database queries we do not consider running queries against database tables as data mining, it does not matter how large the tables are.

Database Queries vs. OLAP

In a typical relational database queries are posed against a set of normalized database tables in order to retrieve instances that fulfill certain constraints on their attribute values (Date, 2000). The normalized tables are usually associated with each other via primary/foreign keys. For example, a normalized database of our store with multiple store locations or sales units might look something like the database given in Figure 2. Here, PK and FK indicate primary and foreign keys, respectively.

From a user perspective it might be interesting to ask some of the following questions:

- How much did sales unit A earn in January?
- How much did sales unit B earn in February?
- What was their combined sales amount for the first quarter?

Even though it is possible to extract this information with standard SQL queries from our database, the normalized nature of the database makes the formulation of the appropriate SQL queries very difficult. Furthermore, the query process is likely to be slow due to the fact that it must perform complex joins and multiple scans of entire database tables in order to compute the desired aggregates.

By rearranging the database tables in a slightly different manner and using a process called pre-aggregation or *computing cubes* the above questions can be answered with much less computational power enabling a real time analysis of aggregate attribute values – OLAP (Craig et al., 1999; Kimball, 1996; Scalzo, 2003). In order to enable OLAP, the database tables are usually arranged into a star schema where the inner-most table is called the fact table and the outer tables are called dimension tables. Figure 3 shows a star schema representation of our store organized along the main dimensions of the store business: customers, sales units, products, and time.

The dimension tables give rise to the dimensions in the pre-aggregated data cubes. The fact table relates the dimensions to each other and specifies the measures which are to be aggregated. Here the measures are "dollar_total", "sales_tax", and "shipping_charge". Figure 4 shows a three-dimensional data cube pre-aggregated from the star schema in Figure 3 (in this cube we ignored the customer dimension, since it is difficult to illustrate four-dimensional cubes). In the cube building process the measures are aggregated

Figure 2. Normalized database schema for a store

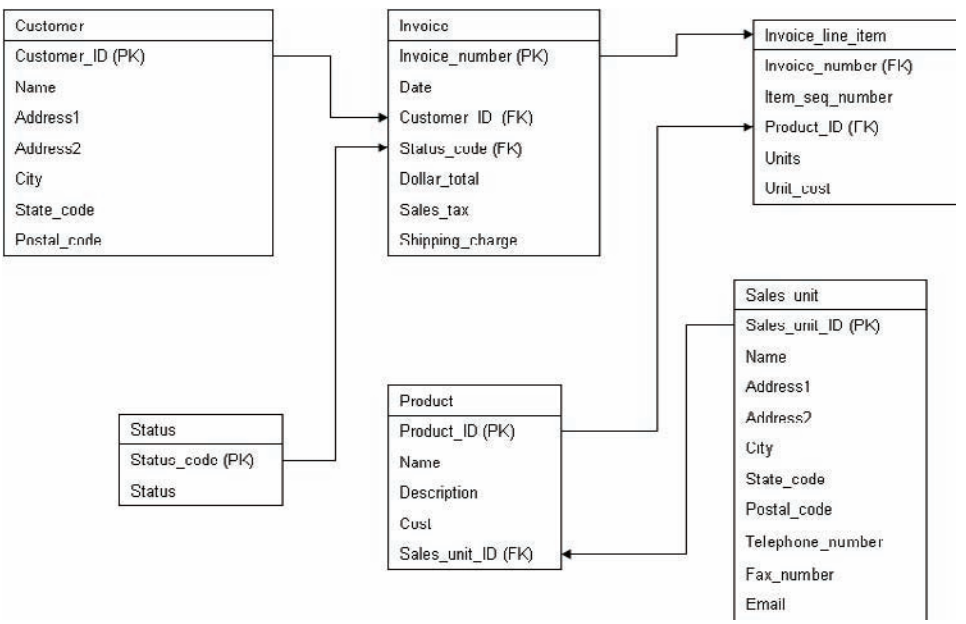

Figure 3. Star schema for a store database

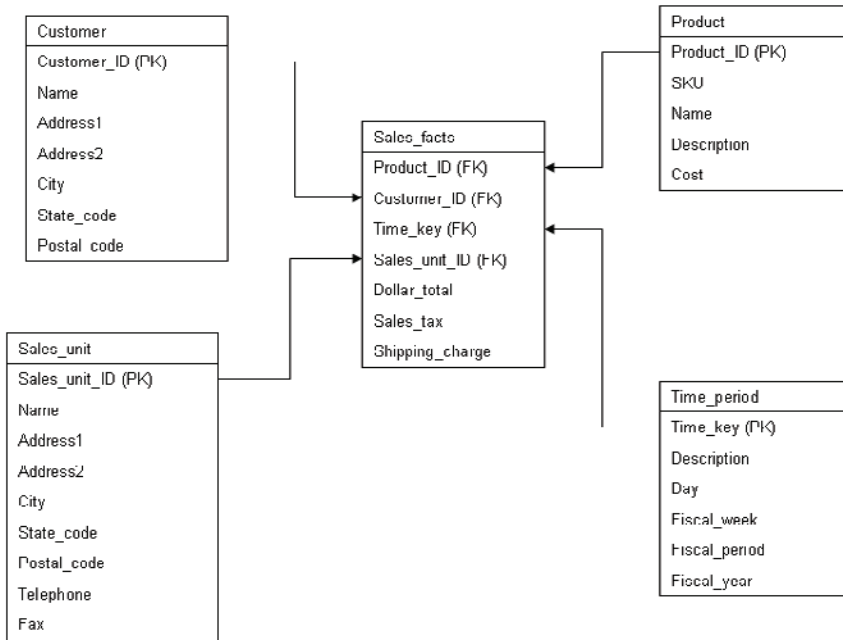

Figure 4. A three-dimensional data cube

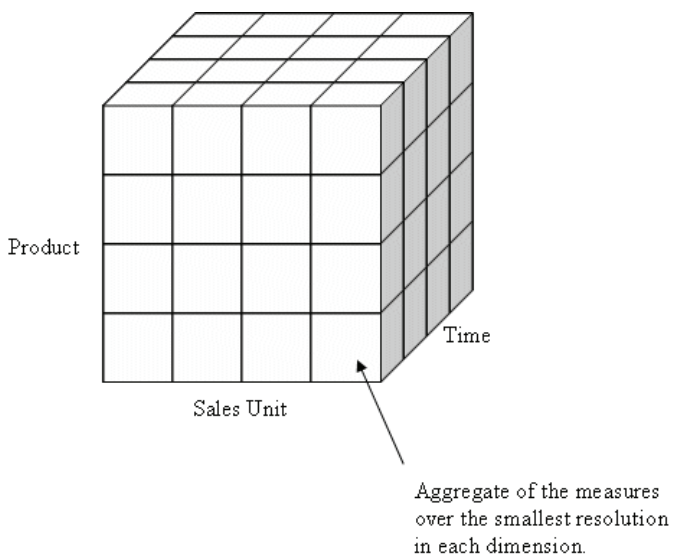

along the smallest unit in each dimension giving rise to small pre-aggregated segments in a cube.

Data cubes can be seen as a compact representation of pre-computed query results[1]. Essentially, each segment in a data cube represents a pre-computed query result to a particular query within a given star schema. The efficiency of cube querying allows the user to interactively move from one segment in the cube to another enabling the inspection of query results in real time. Cube querying also allows the user to group and ungroup segments, as well as project segments onto given dimensions. This corresponds to such OLAP operations as roll-ups, drill-downs, and slice-and-dice, respectively (Gray, Bosworth, Layman, & Pirahesh, 1997). These specialized operations in turn provide answers to the kind of questions mentioned above.

As we have seen, OLAP is enabled by organizing a relational database in a way that allows for the pre-aggregation of certain query results. The resulting data cubes hold the pre-aggregated results giving the user the ability to analyze these aggregated results in real time using specialized OLAP operations. In a larger context we can view OLAP as a methodology for the organization of databases along the dimensions of a business making the database more comprehensible to the end user.

Data Mining vs. OLAP

Is OLAP data mining? As we have seen, OLAP is enabled by a change to the data definition of a relational database in such a way that it allows for the pre-computation of certain query results. OLAP itself is a way to look at these pre-aggregated query results in real time. However, OLAP itself is still simply a way to evaluate queries which is different from building models of the data as in data mining. Therefore, from a technical point of view we cannot consider OLAP to be data mining. Where data mining tools model data and return actionable rules, OLAP allows users to compare and contrast measures along business dimensions in real time.

It is interesting to note, that recently a tight integration of data mining and OLAP has occurred. For example, Microsoft SQL Server 2000 not only allows OLAP tools to access the data cubes but also enables its data mining tools to mine data cubes (Seidman, 2001).

FUTURE TRENDS

Perhaps the most important trend in the area of data mining and relational databases is the liberation of data mining tools from the "single table requirement." This new breed of data mining algorithms is able to take advantage of the full relational structure of a relational database obviating the need of constructing a single table that contains all the information to be used in the data mining task (Dézeroski & Lavraéc, 2001; Getoor, L., & Taskar, B., 2007). This allows for data mining tasks to be represented naturally in terms of the actual database structures, e.g. (Yin, Han, Yang, & Yu, 2004), and also allows for a natural and tight integration of data mining tools with relational databases.

CONCLUSION

Modern, commercially available relational database systems now routinely include a cadre of data retrieval and analysis tools. Here, we briefly described and contrasted the most often bundled tools: SQL database query engines, data mining components, and OLAP tools. Contrary to many assertions in the literature and business press, performing queries on large tables or manipulating query data via OLAP tools is not considered data mining due to the fact that no data modeling occurs in these tools. On the other hand, these three tools complement each other and allow developers to pick the tool that is right for their application: queries allow ad hoc access to virtually any instance in a database; data mining tools can generate high-level, actionable summaries of data residing in database tables; and OLAP allows for real-time access to pre-aggregated measures along important business dimensions. In this light it does not seem surprising that all three tools are now routinely bundled.

NOTE

Figures 2 and 3 are based on Figures 3.2 and 3.3 from (Craig et al., 1999), respectively.

KEY TERMS

D

Business Intelligence: Business intelligence (BI) is a broad category of technologies that allows for gathering, storing, accessing and analyzing data to help business users make better decisions. (Source: http://www.oranz.co.uk/glossary_text.htm)

Data Cubes: Also known as OLAP cubes. Data stored in a format that allows users to perform fast multi-dimensional analysis across different points of view. The data is often sourced from a data warehouse and relates to a particular business function. (Source: http://www.oranz.co.uk/glossary_text.htm)

OLAP: On-Line Analytical Processing - a category of applications and technologies for collecting, managing, processing and presenting multidimensional data for analysis and management purposes. (Source: http://www.olapreport.com/glossary.htm)

Normalized Database: A database design that arranges data in such a way that it is held at its lowest level avoiding redundant attributes, keys, and relationships. (Source: http://www.oranz.co.uk/glossary_text.htm)

Query: This term generally refers to databases. A query is used to retrieve database records that match certain criteria. (Source: http://usa.visa.com/business/merchants/online_trans_glossary.html)

SQL: Structured Query Language - SQL is a standardized programming language for defining, retrieving, and inserting data objects in relational databases.

Star Schema: A database design that is based on a central detail fact table linked to surrounding dimension tables. Star schemas allow access to data using business terms and perspectives. (Source: http://www.ds.uillinois.edu/glossary.asp)

ENDNOTE

[1] Another interpretation of data cubes is as an effective representation of multidimensional data along the main business dimensions (Pendse, 2001).

Database Sampling for Data Mining

Patricia E.N. Lutu
University of Pretoria, South Africa

INTRODUCTION

In data mining, sampling may be used as a technique for reducing the amount of data presented to a data mining algorithm. Other strategies for data reduction include dimension reduction, data compression, and discretisation. For sampling, the aim is to draw, from a database, a random sample, which has the same characteristics as the original database. This chapter looks at the sampling methods that are traditionally available from the area of statistics, how these methods have been adapted to database sampling in general, and database sampling for data mining in particular.

BACKGROUND

Given the rate at which database / data warehouse sizes are growing, attempts at creating faster / more efficient algorithms that can process massive data sets, may eventually become futile exercises. Modern database and data warehouse sizes are in the region of 10's or 100's of terabytes, and sizes continue to grow. A query issued on such a database / data warehouse could easily return several millions of records.

While the costs of data storage continue to decrease, the analysis of data continues to be hard. This is the case for even traditionally simple problems requiring aggregation, for example, the computation of a mean value for some database attribute. In the case of data mining, the computation of very sophisticated functions, on very large number of database records, can take several hours, or even days. For inductive algorithms, the problem of lengthy computations is compounded by the fact that many iterations are needed in order to measure the training accuracy as well as the generalization accuracy.

There is plenty of evidence to suggest that for inductive data mining, the learning curve flattens after only a small percentage of the available data, from a large data set has been processed (Catlett 1991; Kohavi 1996; Provost et al, 1999). The problem of overfitting (Dietterich, 1995), also dictates that the mining of massive data sets should be avoided. The sampling of databases has been studied by researchers for some time. For data mining, sampling should be used as a data reduction technique, allowing a data set to be represented by a much smaller random sample that can be processed much more efficiently.

MAIN THRUST OF THE CHAPTER

There are a number of key issues to be considered before obtaining a suitable random sample for a data mining task. It is essential to understand the strengths and weaknesses of each sampling method. It is also essential to understand which sampling methods are more suitable to the type of data to be processed and the data mining algorithm to be employed. For research purposes, we need to look at a variety of sampling methods used by statisticians, and attempt to adapt them to sampling for data mining.

Some Basics of Statistical Sampling Theory

In statistics, the theory of sampling, also known as statistical estimation, or the representative method, deals with the study of suitable methods of selecting a representative sample of a population, in order to study or estimate values of specific characteristics of the population (Neyman, 1934). Since the characteristics being studied can only be estimated from the sample, confidence intervals are calculated to give the range of values within which the actual value will fall, with a given probability.

There are a number of sampling methods discussed in the literature, for example the book by Rao (Rao, 2000). Some methods appear to be more suited to

database sampling that others. Simple random sampling (SRS) stratified random sampling and cluster sampling are three such methods. Simple random sampling involves selecting at random, elements of the population, P, to be studied. The method of selection may be either with replacement (SRSWR) or without replacement (SRSWOR). For very large populations, however, SRSWR and SRSWOR are equivalent. For simple random sampling, the probabilities of inclusion of the elements may or may not be uniform. If the probabilities are not uniform then a weighted random sample is obtained.

The second method of sampling is stratified random sampling. Here, before the samples are drawn, the population P, is divided into several strata, p_1, p_2,.. p_k, and the sample S is composed of k partial samples s_1, s_2,.., s_k, each drawn randomly, with replacement or not, from one of the strata. Rao (2000) discusses several methods of allocating the number of sampled elements for each stratum. Bryant et al (1960) argue that, if the sample is allocated to the strata in proportion to the number of elements in the strata, it is virtually certain that the stratified sample estimate will have a smaller variance than a simple random sample of the same size. The stratification of a sample may be done according to one criterion. Most commonly though, there are several alternative criteria that may be used for stratification. When this is the case, the different criteria may all be employed to achieve multi-way stratification. Neyman (1934) argues that there are situations when it is very difficult to use an individual unit as the unit of sampling. For such situations, the sampling unit should be a group of elements, and each stratum should be composed of several groups. In comparison with stratified random sampling, where samples are selected from each stratum, in cluster sampling, a sample of clusters is selected and observations/measurements are made on the clusters. Cluster sampling and stratification may be combined (Rao, 2000).

Database Sampling Methods

Database sampling has been practiced for many years for purposes of estimating aggregate query results, database auditing, query optimization, and, obtaining samples for further statistical processing (Olken, 1993). Static sampling (Olken, 1993) and adaptive (dynamic) sampling (Haas & Swami, 1992) are two alternatives for obtaining samples for data mining tasks. In recent years, many studies have been conducted in applying sampling to inductive and non-inductive data mining (John & Langley, 1996; Provost et al, 1999; Toivonen, 1996).

Simple Random Sampling

Simple random sampling is by far, the simplest method of sampling a database. Simple random sampling may be implemented using sequential random sampling or reservoir sampling. For sequential random sampling, the problem is to draw a random sample of size n without replacement, from a file containing N records. The simplest sequential random sampling method is due to Fan et al (1962) and Jones (1962). An independent uniform random variate (from the uniform interval (0,1)) is generated for each record in the file to determine whether the record should be included in the sample. If m records have already been chosen from among the first t records in the file, the $(t+1)^{st}$ record is chosen with probability (RQsize / RMsize), where RQsize = (n-m) is the number of records that still need to be chosen for the sample, and RMsize = (N-t) is the number of records in the file, still to be processed. This sampling method is commonly referred to as method S (Vitter, 1987).

The *reservoir sampling* method (Fan et al, 1962; Jones, 1962; Vitter, 1985 & 1987) is a sequential sampling method over a finite population of database records, with an unknown population size. Olken, 1993) discuss its use in sampling of database query outputs on the fly. This technique produces a sample of size S, by initially placing the first S records of the database/file/query in the reservoir. For each subsequent k^{th} database record, that record is accepted with probability S / k. If accepted, it replaces a randomly selected record in the reservoir.

Acceptance/Rejection sampling (A/R sampling) can be used to obtain *weighted samples* (Olken 1993). For a weighted random sample, the probabilities of inclusion of the elements of the population are not uniform. For database sampling, the inclusion probability of a data record is proportional to some weight calculated from the record's attributes. Suppose that one database record r_j is to be drawn from a file of n records with the probability of inclusion being proportional to the weight w_j. This may be done by generating a uniformly distributed random integer j, $1 \leq j \leq n$ and then accepting the sampled record r_j with probability $\alpha_j = w_j /$

w_{max}, where w_{max} is the maximum possible value for w_j. The acceptance test is performed by generating another uniform random variate u_j, $0 \leq u_j \leq 1$, and accepting r_j iff $u_j < \alpha_j$. If r_j is rejected, the process is repeated until some r_j is accepted.

Stratified Sampling

Density biased sampling (Palmer & Faloutsos, 2000), is a method that combines clustering and stratified sampling. In density biased sampling, the aim is to sample so that within each cluster points are selected uniformly, the sample is density preserving, and sample is biased by cluster size. Density preserving in this context means that the expected sum of weights of the sampled points for each cluster is proportional to the cluster's size. Since it would be infeasible to determine the clusters apriori, groups are used instead, to represent all the regions in n-dimensional space. Sampling is then done to be density preserving for each group. The groups are formed by 'placing' a d-dimensional grid over the data. In the d-dimensional grid, the d dimensions of each cell are labeled either with a bin value for numeric attributes, or by a discrete value for categorical attributes. The d-dimensional grid defines the strata for multi-way stratified sampling. A one-pass algorithm is used to perform the weighted sampling, based on the reservoir algorithm.

Adaptive Sampling

Lipton et al (1990) use adaptive sampling, also known as sequential sampling, for database sampling. In sequential sampling, a decision is made after each sampled element, whether to continue sampling. Olken (1993) has observed that sequential sampling algorithms outperform conventional single-stage algorithms , in terms of the number of sample elements required, since they can adjust the sample size to the population parameters. Haas and Swami (1992) have proved that sequential sampling uses the minimum sample size for the required accuracy.

John and Langley (1996) have proposed a method they call dynamic sampling, which combines database sampling with the estimation of classifier accuracy. The method is most efficiently applied to classification algorithms which are incremental, for example naïve Bayes and artificial neural-network algorithms such as backpropagation. They define the concept of 'probably close enough' (PCE), which they use for determining when a sample size provides an accuracy that is probably good enough. 'Good enough' in this context means that there is a small probability δ that the mining algorithm could do better by using the entire database. The smallest sample size n, is chosen from a database of size N, so that: $Pr(acc(N) - acc(n) > \varepsilon) <= \delta$, where: acc(n) is the accuracy after processing a sample of size n, and ε is a parameter that describes what 'close enough' means. The method works by gradually increasing the sample size n until the PCE condition is satisfied.

Provost, Jensen and Oates (1999) use progressive sampling, another form of adaptive sampling, and analyse its efficiency relative to induction with all available examples. The purpose of progressive sampling is to establish n_{min}, the size of the smallest sufficient sample. They address the issue of convergence, where convergence means that a learning algorithm has reached its plateau of accuracy. In order to detect convergence, they define the notion of a sampling schedule S as $S = \{n_o, n_1, .., n_k\}$ where n_i is an integer that specifies the size of the sample, and S is a sequence of sample sizes to be provided to an inductive algorithm. They show that schedules which n_i increases geometrically as: $\{no, a.n_o, a^2.n_o, .., a^k.n_o\}$, are asymptotically optimal. As one can see, progressive sampling is similar the adaptive sampling method of John and Langley (1996), except that a non-linear increment for the sample size is used.

THE SAMPLING PROCESS

Several decisions need to be made when sampling a database. One needs to decide on a sampling method, a suitable sample size, the a level accuracy that can be tolerated. These issues are discussed below.

Deciding on a Sampling Method

The data to be sampled may be balanced, imbalanced, clustered or unclustered. These characteristics will affect the quality of the sample obtained. While simple random sampling is very easy to implement, it may produce non-representative samples for data that is imbalanced or clustered. On the other hand, stratified sampling, with a good choice of strata cells, can be used to produce representative samples, regardless

of the characteristics of the data. Implementation of one-way stratification should be straight forward, however, for multi-way stratification, there are many considerations to be made. For example, in density-biased sampling, a d-dimensional grid is used. Suppose each dimension has n possible values (or bins). The multi-way stratification will result in n^d strata cells. For large d, this is a very large number of cells. When it is not easy to estimate the sample size in advance, adaptive (or dynamic) sampling may be employed, if the data mining algorithm is incremental.

Determining the Representative Sample Size

For static sampling, the question must be asked: 'What is the size of a representative sample?'. A sample is considered statistically valid if it is sufficiently similar to the database from where it is drawn (John & Langley, 1996). Univariate sampling may be used to test that each field in the sample comes from the same distribution as the parent database. For categorical fields, the chi-squared test can be used to test the hypothesis that the sample and the database come from the same distribution. For continuous-valued fields, a 'large-sample' test can be used to test the hypothesis that the sample and the database have the same mean. It must however be pointed out that, obtaining fixed size representative samples from a database is not a trivial task, and, consultation with a statistician is recommended.

For inductive algorithms, the results from the theory of probably approximately correct (PAC) learning have been suggested in the literature (Valiant, 1984; Haussler, 1990). These have however been largely criticized for overestimating the sample size (eg. Haussler, 1990). For incremental inductive algorithms, dynamic sampling (John & Langley, 1996; Provost et al, 1999) may be employed to determine when a sufficient sample has been processed. For association rule mining, the methods described by Toivonen (1996) may be used to determine the sample size.

Determining the Accuracy and Confidence of Results Obtained from Samples

For the task of inductive data mining, suppose we have estimated the classification error for a classifier constructed from sample S, to be $error_s$ (h), as the proportion of the test examples that are misclassified. Statistical theory, based on the central limit theorem, enables us to conclude that, with approximately N% probability, the true error lies in the interval:

$$Error_s(h) \pm Z_N \sqrt{(Error_s(h)(1-Error_s(h))/n)}$$

As an example, for a 95% probability, the value of Z_N is 1.96. Note that, $Error_S(h)$ is the mean error and $(Error_S(h)(1-Error_S(h))/n)$ is the variance of the error. Mitchell (1997, chapter 5) gives a detailed discussion of the estimation of classifier accuracy and confidence intervals. For non–inductive data mining algorithms, there are known ways of estimating the error and confidence in the results obtained from samples. For association rule mining, for example Toivonen (1996) states that the lower bound for the size of the sample, given an error bound ε and a maximum probability δ is given by:

$$|s| \geq \frac{1}{2\varepsilon^2} \ln \frac{2}{\delta}$$

The value ε is the error in estimating the frequencies of frequent item sets for some give set of attributes.

FUTURE TRENDS

There two main thrusts in research on establishing the sufficient sample size for a data mining task. The theoretical approach, most notably the PAC framework and the Vapnik-Chernonenkis (VC) dimension have produced results which are largely criticized by data mining researchers and practitioners. However, research will continue in this area, and may eventually yield practical guidelines. On the empirical front, researchers will continue to conduct simulations that will lead to generalizations on how to establish sufficient sample sizes.

CONCLUSIONS

Modern databases and data warehouses are massive, and will continue to grow in size. It is essential for researchers to investigate data reduction techniques that can greatly reduce the amount of data presented

to a data mining algorithm. More than fifty years of research has produced a variety of sampling algorithms for database tables and query result sets. The selection of a sampling method should depend on the nature of the data as well as the algorithm to be employed. Estimation of sample sizes for static sampling, is a tricky issue. More research in this area is needed in order to provide practical guidelines. Stratified sampling would appear to be a versatile approach to sampling any type of data. However, more research is needed to address especially the issue of how to define the strata for sampling.

KEY TERMS

Cluster Sampling: In cluster sampling, a sample of clusters is selected and observations / measurements are made on the clusters.

Density-Biased Sampling: A database sampling method that combines clustering and stratified sampling.

Dynamic Sampling (Adaptive Sampling): A method of sampling where sampling and processing of data proceed in tandem. After processing each incremental part f the sample, a decision is made whether to continue sampling or not.

Reservoir Sampling: A database sampling method that implements uniform random sampling on a database table of unknown size, or a query result set of unknown size.

Sequential Random Sampling: A database sampling method that implements uniform random sampling on a database table whose size is known.

Simple Random Sampling: Simple random sampling involves selecting at random, elements of the population to be studied. The sample S, is obtained by selecting at random, single elements of the population P.

Simple Random Sampling With Replacement (SRSWR): A method of simple random sampling where an element stands a chance of being selected more than once.

Simple Random Sampling Without Replacement (SRSWOR): A method of simple random sampling where each element stands a chance of being selected only once.

Static Sampling: A method of sampling where the whole sample is obtained before processing begins. The user must specify the sample size.

Stratified Sampling: For this method, before the samples are drawn, the population P, is divided into several strata, $p_1, p_2,.. p_k$, and the sample S is composed of k partial samples $s_1, s_2,.., s_k$, each drawn randomly, with replacement or not, from one of the strata.

Uniform Random Sampling: A method of simple random sampling where the probabilities of inclusion for each element are equal.

Weighted Random Sampling: A method of simple random sampling where the probabilities of inclusion for each element are not equal.

Database Security and Statistical Database Security

Edgar R. Weippl
Secure Business Austria, Austria

INTRODUCTION

In this article we will present an introduction to issues relevant to database security and statistical database security. We will briefly cover various security models, elaborate on how data analysis in data warehouses (DWH) might compromise an individual's privacy, and explain which safeguards can be used to prevent attacks.

In most companies, databases are an essential part of IT infrastructure since they store critical business data. In the last two decades, databases have been used to process increasing amounts of transactional data, such as, a complete account of a person's purchases from a retailer or connection data from calls made on a cell phone.

As soon as this data became available from transactional databases and online transactional processing (OLTP) became well established, the next logical step was to use the knowledge contained in the vast amounts of data. Today, data warehouses (DWH) store aggregated data in an optimal way to serve queries related to business analysis.

In recent years, most people have begun to focus their attention on security. Early OLTP applications were mainly concerned with integrity of data during transactions; today privacy and secrecy are more important as databases store an increasing amount of information about individuals, and data from different systems can be aggregated. Thuraisingham (2002) summarizes the requirements briefly as "*However, we do not want the information to be used in an incorrect manner."*

All security requirements stem from one of three basic requirements: confidentiality (aka secrecy), integrity, and availability (CIA). Confidentiality refers to the requirement that only authorized subjects, that is, people or processes should be permitted to read data. Integrity means that unauthorized modifications must not be permitted. This includes both modifications by unauthorized people and incorrect modification by authorized users. To correctly perform the services requested, the system needs to remain available; a denial-of-service compromises the requirement of availability.

Other security requirements may include privacy, non-repudiation, and separation of duties. These requirements are, however, composite requirements that can be traced back to one of the three basic requirements. Privacy, for instance, is the non-disclosure (=confidentiality) of personal data; non-repudiation refers to the integrity of transaction logs and integrity of origin. Throughout this article we will focus only on technical attacks and safeguards and not on social engineering. Social engineering is often the easiest and, in many cases, a very successful attack vector. For an in-depth coverage of social engineering we recommend (Böck, 2007).

In Section 2 we cover the most relevant access control models; in Section 3 we provide an overview of security in statistical databases. Finally, in Section 4 we highlight the essentials of securing not only the transactional and the statistical databases but the entire system.

BACKGROUND

Access Control is the most important technique or mechanism for implementing the requirements of confidentiality and integrity. Since databases were among the first large-scale systems in military applications, there is a long history of security models, dating back to the 1960s. The basic principle in all access control models is that a *subject* is or is not permitted to perform a certain *operation* on an *object*. This process is described by the triplet (s, op, o). A security policy specifies who is authorized to do what. A security mechanism allows enforcement of a chosen security policy.

One can distinguish between two fundamentally different access control mechanisms: discretionary access control (DAC) and mandatory access control (MAC). In DAC models the user decides which subject is able

to access which object to perform a certain operation. In contrast, when using MAC, the system decides who is allowed to access which resource and the individual user has no discretion to decide on access rights.

Discretionary Access Control (DAC)

In relational database management systems (DBMS), the objects that need to be protected are tables and views. Modern DBMS allow a fine granularity of access control so that access to individual fields of a record can be controlled.

By default, a subject has no access. Subjects may then be *granted* access, which can be *revoked* anytime. In most systems the creator of a table or a view is automatically granted all privileges related to it. The DBMS keeps track of who subsequently gains and loses privileges, and ensures that only requests from subjects who have the required privileges—at the time the request is executed—are allowed.

Mandatory Access Control (MAC)

Mandatory Access Control is based on system-wide policies that cannot be changed by individual users. Each object in the database is automatically assigned a security class based on the access privileges of the user who created the object.

The most widely known implementation of a MAC system is a multi-level security (MLS) system. MLS systems were first described by Bell LaPadula (Bell, 1975) in the 1960s. Each subject, which could either be a user or user program, is assigned a *clearance* for a security class. Objects are assigned security *levels*. Security levels and clearances can be freely defined as long as all items are comparable pair-wise. Most common are security classes (i.e., levels and clearances), such as, top secret (TS), secret (S), confidential (C), and unclassified (U).

Rules based on security levels and clearances govern who can read or write which objects. Today, there are only a few commercially available systems that support MAC, such as, SELinux or also Oracle DBMS (Version 9 and higher) when the Oracle Label Security (OLS) option is installed.

The main reason to use a MAC system is that it prevents inherent flaws of discretionary access control, which are commonly referred to as the Trojan horse problem. The user Alice creates a program and gives Bob INSERT privileges for the table mySecret. Bob knows nothing about this. Alice modifies the code of an executable that Bob uses so that it additionally writes Bob's secret data to the table mySecret. Now, Alice can see Bob's secret data. While the modification of the application code is beyond the DBMS' control, it can still prevent the use of the database as a channel for secret information.

ACCESS CONTROL FOR RELATIONAL DATABASES

Role-Based Access Control (RBAC)

With RBAC (Sandhu, 2000), system administrators create roles according to the job functions defined in a company; they grant permissions to those roles and subsequently assign users to the roles on the basis of their specific job responsibilities and qualifications. Thus, roles define the authority of users, the competence that users have, and the trust that the company gives to the user. Roles define both, the specific individuals allowed to access objects and the extent to which or the mode in which they are allowed to access the object (see Sandhu & Coyne & Feinstein & Youman, 1996). Access decisions are based on the roles a user has activated (Sandhu & Ferraiolo & Kuhn, 2000).

The basic RBAC model consists of four entities: users, roles, permissions, and sessions. A user is a subject who accesses different, protected objects. A role is a named job function that describes the authority, trust, responsibility, and competence of a role member. A permission is an approval for a particular type of access to one or more objects. Permissions describe which actions can be performed on a protected object and may apply to one or more objects. Both permissions and users are assigned to roles. These assignments, in turn, define the scope of access rights a user has with respect to an object. By definition, the user assignment and permission assignment relations are many-to-many relationships.

Users establish sessions during which they may activate a subset of the roles they belong to. A session maps one user to many possible roles, which results in the fact that multiple roles can be activated simultaneously and every session is assigned with a single user. Moreover, a user might have multiple sessions opened simultaneously. Belonging to several roles, a user can

invoke any subset of roles to accomplish a given task. In other words, sessions enable a dynamic activation of user privileges (see Sandhu & Coyne & Feinstein & Youman, 1996).

We will briefly summarize various properties of the NISTs RBAC model as pointed out by Sandhu et al. (Sandhu & Ferraiolo & Kuhn, 2000). RBAC does not define the degree of scalability implemented in a system with respect to the number of roles, number of permissions, size of role hierarchy, or limits on user-role assignments, etc.

Coexistence with MAC / DAC

Mandatory access control (MAC) is based on distinct levels of security to which subjects and objects are assigned. Discretionary access control (DAC) controls access to an object on the basis of an individual user's permissions and/or prohibitions. RBAC, however, is an independent component of these access controls and can coexist with MAC and DAC. RBAC can be used to enforce MAC and DAC policies, as shown in (Osborn & Sandhu & Munawer, 2000). The authors point out the possibilities and configurations necessary to use RBAC in the sense of MAC or DAC.

Levels Defined in the NIST Model of RBAC

The NIST Model of RBAC is organized into four levels of increasing functional capabilities as mentioned above: (1) flat RBAC, (2) hierarchical RBAC, (3) constrained RBAC, and (4) symmetric RBAC. These levels are cumulative such that each adds exactly one new requirement. The following subsections will offer a brief presentation of the four levels.

The basic principle is that users are assigned to roles (user-role assignment, indicated through the membership association), permissions are assigned to roles (permission-role assignment, indicated through the authorization association) and users gain permissions defined in the role(s) they activate. A user can activate several roles within a session (indicated through the n-ary activation association). As all these assignments are many-to-many relationships; a user can be assigned to many roles and a role can contain many permissions. Flat RBAC requires a user-role review whereby the roles assigned to a specific user can be determined as well as users assigned to a specific role. Similarly, flat RBAC requires a permission-role review. Finally, flat RBAC requires that users can simultaneously use permissions granted to them via multiple roles.

Flat RBAC represents the traditional group-based access control as it can be found in various operating systems (e.g., Novell Netware, Windows NT). The requirements of flat RBAC are obvious and obligatory for any form of RBAC. According to (Sandhu & Ferraiolo & Kuhn, 2000), the main issue in defining flat RBAC is to determine which features to exclude.

Hierarchical RBAC supports role hierarchies built using the sub-role and super-role association. A hierarchy defines a seniority relation between roles, whereby senior roles acquire the permissions of their juniors.

Role hierarchies may serve three different purposes:

- *Inheritance hierarchies* whereby activation of a role implies activation of all junior roles.
- *Activation hierarchies* whereby there is no implication of the activation of all junior roles (each junior role must be explicitly activated to enable its permissions in a session); or a combination of both.

Constrained RBAC supports separation of duties (SOD). SOD is a technique for reducing the possibility of fraud and accidental damage. It spreads responsibility and authority for an action or task over multiple users thereby reducing the risk of fraud.

Symmetric RBAC adds requirements for permission-role review similar to the user-role review introduced in flat RBAC. Thus, the roles to which a particular permission is assigned can be determined as well as permissions assigned to a specific role. However, implementing this requirement in large-scale distributed systems may be a very complex challenge.

Usage Control

According to Bertino et al. (2006), secure data mining is an aspect of secure knowledge management. The authors emphasize the importance of usage control (cf. Park 2004) to implement continuous decisions of whether a resource may or may not be used. Similar to the reference monitor in classical access control, Thuraisingham (2005) proposed to use a privacy controller to "*limit and watch access to the DBMS (that access the data in the database)*." She sees a privacy constraint as a form of integrity constraint, and proposes to use mechanisms

of the DBMS for guaranteeing integrity: "*In these techniques, some integrity constraints, which are called derivation rules, are handled during query processing, some integrity constraints, known as integrity rules, are handled during database updates, and some integrity constraints, known as schema rules, are handled during database design.*" Thuraisingham (2005)

STATISTICAL DATABASE SECURITY

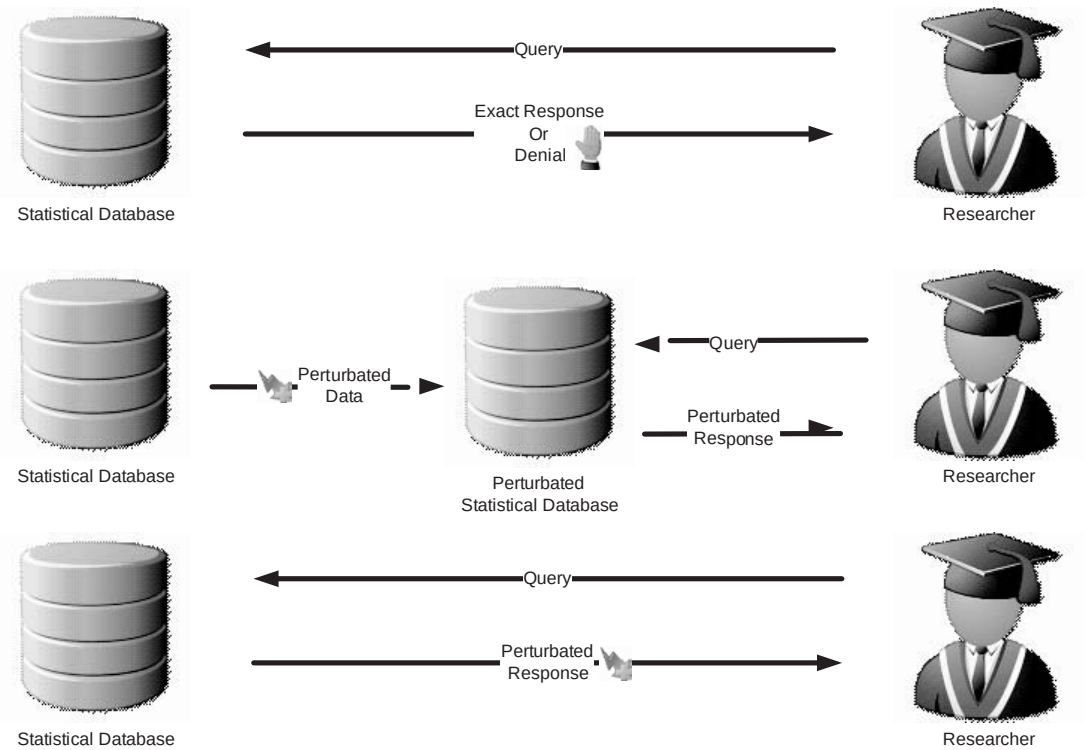
A statistical database contains information about individuals, but allows only aggregate queries (such as asking for the average age instead than Bob Smith's age). Permitting queries that return aggregate results only may seem sufficient to protect an individual's privacy. There is, however, a new problem compared to traditional database security: Inference can be used to infer some secret information.

A very simple example illustrates how inference causes information leakage: If I know Alice is the oldest employee, I can ask "How many employees are older than X years?" Repeating this process for different values of X until the database returns the value 1 allows us to infer Alice's age.

The first approach to prevent this kind of "attack" is to enforce that each query must return data aggregated from at least N rows, with N being certainly larger than 1 and—in the best case—a very large number. Yet, unfortunately, this is no real solution. The first step is to repeatedly ask "How many employees are older than X?" until the system rejects the query because the query would return less than N rows. Now one has identified a set of N+1 employees, including Alice, who are older than X; let X=66 at this point. Next, ask "Tell me the sum of ages of all employees who are older than X?" Let result be R. Next, ask "Tell me the sum of ages of all employees who are not called Alice and are older than X?" Let result be RR. Finally, subtract RR from R to obtain Alice's age.

For an in-depth description we recommend (Castano, 1996).

Figure 1. Security control models (Adam, 1989). Restriction-based protection either gives the correct answer or no answer to a query (top); data may be modified (perturbated) before it is stored in the data warehouse or the statistical database (middle); online perturbation modifies the answers for each query (bottom).



Restriction-Based Techniques

The technique will protect against the aforementioned inference attacks by restricting queries that could reveal confidential data on individuals (Castano, 1996).

Query Set Size Control

Enforcing a minimum set size for returned information does not offer adequate protection for information as we explained in Section 3's introductory example. Denning (Denning, 1982) described trackers that are sequences of queries that are all within the size limits allowed by the database; when combined with AND statements and negations, information on individuals can be inferred. While simple trackers require some background information (for instance, Alice is the only female employee in department D1 who is older than 35), general trackers (Schlörer, 1980), (Denning, 1979) can be used without in-depth background knowledge.

An Audit-Based Expanded Query Set Size Control

The general idea of this control is to store an "assumed information base," that is, to keep a history of all the requests issued by the user. It is also referred to as query set overlap control (Adam, 1989). The system has to calculate all possible inferences (= assumed information base) that could be created based on all queries the user issued; for each new query it has to decide whether the query could be combined with the assumed information base to infer information that should remain confidential.

Perturbation-Based Techniques

Perturbation-based techniques are characterized by modifying the data so that privacy of individuals can still be guaranteed even if more detailed data is returned than in restriction-based techniques. Data can be modified in the original data or in the results returned.

Data Swapping

Data is exchanged between different records so that no original data remains but in a way that the calculated statistics are not impacted.

Random Sample Queries

Set of answers to a specific query are created dynamically so that not all relevant data items are included in the answer. Instead, a random subset is returned. Since the user cannot decide how this random sample is drawn, inference attacks are much harder. If issuing similar queries, the attacker can attempt to remove the sampling errors. These attacks are possible for small data sets; large data sets can be adequately protected by using random sample queries.

Fixed Perturbation (Modify Data)

Unlike the random sample query approach, data modifications and selections are not performed dynamically for each query. Instead, data is modified (though not swapped) as soon as it is stored in the database. The modifications are performed in such a way that they do not significantly influence statistical results.

Query-Based Perturbation

In contrast to fixed perturbation, query-based perturbation modifies data—as the name suggests—for each query dynamically. The advantage is that the amount of perturbation, and thus the accuracy, can be varied individually for different users. More trustworthy users can receive more precise results.

FUTURE TRENDS

According to Mukherjee et al. (2006), the problem with perturbation techniques is that Euclidean-distance-based mining algorithms no longer work well, i.e. distances between data points cannot be reconstructed. The authors propose to use Fourier-related transforms to obscure sensitive data which helps to preserve the original distances at least partly.

Another approach proposed by Domingo-Ferrer et al (2006) is to aggregate data from the original database in small groups. Since this aggregation is done prior to publishing the data the data protector can decide how large such a "micro" group should be.

CONCLUSION

In the previous section we gave a detailed introduction to access control and focused on role-based access control. RBAC is currently the dominant access control model for database systems. While access control is certainly one of the most fundamental mechanisms to ensure that security requirements, such as, confidentiality, integrity, and—at least to some extent—availability are implemented, there are several other aspects that need to be considered, too.

Figure 2 shows how data is extracted from the source databases, transformed and loaded into the data warehouse. It may then be used for analysis and reporting. The transactional database can be secured with the "classical" models of database security such as RBAC or even mandatory access control. Research in this area dates back to the early times of (military) databases in the 1960s. Once data is extracted, transformed and loaded into a DWH, the data will be used in data analysis–this is what a DWH is created for in the first place. DWH security and methods of statistical database security are then used to secure the DWH against attacks such as inference. Nonetheless, overall security can be achieved only by securing all possible attack vectors and not only the operational database (source data) and the DWH itself.

It is essential to secure all of the servers including remote, file, and physical access and to thoroughly understand all communication and transformation processes. Attacks could be launched before or after data is transformed, when it is stored in the data warehouse, or when being retrieved.

KEY TERMS

Availability: A system or service is available to authorized users.

CIA: Confidentiality, integrity, availability; the most basic security requirements.

Confidentiality: Only authorized subjects should have read access to information.

DWH: Data warehouse

ETL: The process of Extracting, Transforming (or Transporting) and Loading source data into a DWH.

Integrity: No unauthorized modifications or modifications by unauthorized subjects are made.

OLAP: Online Analytical Processing

Data-Driven Revision of Decision Models

Martin Žnidaršič

Marko Bohanec
Jožef Stefan Institute, Slovenia

Blaž Zupan
University of Ljubljana, Slovenia, and Baylor College of Medicine, USA

INTRODUCTION

Computer models are representations of problem environment that facilitate analysis with high computing power and representation capabilities. They can be either inferred from the data using data mining techniques or designed manually by experts according to their knowledge and experience. When models represent environments that change over time, they must be properly updated or periodically rebuilt to remain useful. The latter is required when changes in the modelled environment are substantial. When changes are slight, models can be merely adapted by revision.

Model revision is a process that gathers knowledge about changes in the modelled environment and updates the model accordingly. When performed manually, this process is demanding, expensive and time consuming. However, it can be automated to some extent if current data about the modelled phenomena is available. Data-based revision is a procedure of changing the model so as to better comply with new empirical data, but which at the same time keeps as much of the original contents as possible. In the following we describe the model revision principles in general and then focus on a solution for a specific type of models, the qualitative multi-attribute decision models as used in DEX methodology.

BACKGROUND

The task of data-driven revision is to adapt the initial model to accommodate for the new data, while at the same time making use of the background knowledge, which was used in the construction of the initial model. Revision is to be applied only when the changes of the modelled concepts are not substantial, that is, if we deal with concept drift (Tsymbal, 2004). If the changes of the modeled system are substantial, it is usually better to construct the model from scratch.

Depending on the field of research, procedures of this kind are most often referred to as knowledge refinement or theory revision. Most of research in this field is done on propositional rule bases (Ginsberg, 1989; Mahoney & Mooney, 1994; Yang, Parekh, Honavar & Dobbs, 1999; Carbonara & Sleeman, 1999) and Bayesian networks (Buntine, 1990; Ramachandran & Mooney, 1998), but many principles of these methods are shared with those of revision procedures for other knowledge representations, such as case-based reasoning systems (Kelbassa, 2003).

Multi-criteria decision models (MCDM) are models used in decision analysis (Clemen, 1996). Data-driven revision can be a valuable tool for the ones that are used for longer periods of time. In our previous work, we have developed revision methods (Žnidaršič & Bohanec, 2005; Žnidaršič, Bohanec & Zupan, 2006) for two types of MCDM models of DEX methodology (Bohanec & Rajkovič, 1990; Bohanec, 2003). An input to MCDM models is criteria-based description of alternatives, where a model represents a utility function to evaluate the given set of criteria values. MCDM models are used for evaluation and analysis of decision alternatives. In contrast to traditional numerical MCDM (Saaty, 1980; Keeney & Raiffa, 1993; Triantaphyllou, 2000), the models of DEX methodology are qualitative and have utility functions in form of if-then rules. The concepts in these models are structured hierarchically and their values are defined according to the values of their immediate descendants in the hierarchy (see Figure 1). This dependency is specified with qualitative rule-based utility functions, which can be defined

as crisp or probabilistic and are usually represented in tabular form (see Table 1). The concepts at the bottom of hierarchy serve as inputs, represent the criteria-based description of alternatives and must be provided by the user.

Models of DEX methodology are usually constructed manually in collaboration of decision analysts and problem domain experts. As an alternative, a method called HINT (Bohanec & Zupan, 2004) was proposed that can infer DEX-like models from data. HINT often requires a large quantity of data and its discovery process may benefit from an active involvement of an expert. The task of revision is simpler and can be achieved completely autonomously with very limited amount of new evidence.

MAIN FOCUS

Revision Goals

For any kind of knowledge representation or model (M), the goal of revision methods (r) is to adapt the model with respect to new evidence from the changed environment. In the case of data-driven revision, evidence is in the form of a set of data items ($D=\{d_1, d_2, .., d_n\}$). The success of adaptation may be demonstrated through the increase of some selected measure (m) that assesses the performance of the model given a set of test data. While standard measures of this kind are, for instance, classification accuracy and mean squared error (Hand, Mannila & Smyth, 2001), any other measure that fits the modelling methodology and problem may be used.

The quality of the model after the revision should thus increase:

$$m\left(r\left(M,D\right),D\right)\geq m\left(M,D\right),$$

where it aims to maximize: $m\left(r\left(M,D\right),D\right)$.

However, revision is a process that tries to preserve the initial background knowledge, rather than subject it entirely to the new data. The maximization from the latter equation must be therefore limited by the type and degree of changes that the revision method is allowed to make. If there exists background data that was used in the initial model construction (D_b) or we are able to reproduce it, we can also limit the revision by fully considering the prior data:

$$m\left(r\left(M,D\right),D_b\right)\geq m\left(M,D_b\right),$$

or at least by minimizing the difference: $m\left(M,D_b\right)-m\left(r\left(M,D\right),D_b\right)$.

Figure 1. A simple hierarchy of concepts of a decision model for car purchase

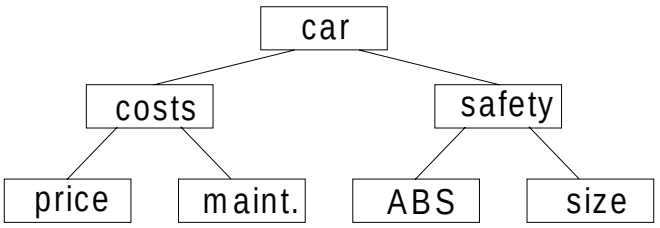

Table 1. Utility function of the concept safety

ABS	size	safety
no	small	<v.good:0.0, good:0.0, accep.:0.1, bad:0.9>
no	medium	<v.good:0.0, good:0.1, accep.:0.7, bad:0.2>
no	big	<v.good:0.1, good:0.8, accep.:0.1, bad:0.0>
yes	small	<v.good:0.0, good:0.0, accep.:0.3, bad:0.7>
yes	medium	<v.good:0.1, good:0.6, accep.:0.3, bad:0.0>
yes	big	<v.good:0.8, good:0.2, accep.:0.0, bad:0.0>

In any case, we must prevent excessive adaptation of a model to the learning data set. This phenomenon is called over-fitting and is a well known problem in data mining. Usually it is controlled by splitting data to separate data sets for learning and testing purposes. There are many approaches to that (Hand, Mannila & Smyth, 2001), but ten fold cross-validation of data is the most common one. With regard to revision, in addition to limiting the type and degree of changes, it is also important to assess the model performance measure on a partition of data that was not used in the learning (revision) process.

Data Processing

New data items get processed by revision methods in two most common ways:

1. *Incremental (singleton iterations)*: As it is beneficial for revision methods to be able to operate even with a single piece of evidence, they are usually implemented as iterations of a basic step: revision based on a single piece of evidence. This way, the revision method considers one data item at a time and performs revision accordingly. However, iterative revision is problematic as the result depends on the order of the data items. To circumvent this problem, the data items are usually ordered in one of the following ways:
   a. *Temporal ordering*: This approach is appropriate when data items are obtained from a data stream or have time stamps, so that they are processed in first-in-first-out manner. Such a setting also makes easy to observe and follow the concept drift.
   b. *Relevance ordering*: Sometimes we can order data items by relevance that is either defined manually in the data acquisition phase or defined through some quantitative measure of relevance. For example, we could order data by observing the quality of model prediction on each data instance, that is, ranking the instances by $m(M, d_i)$, and first revise the model with the data that have the highest or the lowest corresponding value.
   c. *Random ordering*: Random ordering is not informative ordering, but it is often used when the data cannot be ordered in any informative way. This ordering is used also for purposes of method evaluation with unordered data sets. In such situations, the batch approach (see below) is more appropriate. If random ordering is used in singleton iterations of revision, we must take care for the reproducibility of results by saving the learning data set in order of processing or setting and saving the random seed.
2. *Batch processing*: Some revision methods use a whole data set in one step, in a batch (Hand, Mannila & Smyth, 2001). This can be done by utilizing the statistical features of a batch, such as frequencies, medians or averages of attribute values. Batch processing can be also simulated with algorithms for iterative revision if we save the proposed revision changes for each data item and apply them averaged after processing the last data item from the learning data set. Batch methods tend to be less prone to unwanted deviations of models, as the influence of single data items is restrained. Another benefit is easy reproducibility of experimental results, since data properties that are used in batch processing do not change with data item perturbations.

Challenges

The developer of revision methods usually meets the following set of problems:

1. *Unwanted model deviation*: In order to increase the performance of the model on new data, revision makes changes to the model. These changes can cause the model to deviate in an unwanted way, which usually happens when the impact of new data is overemphasized and/or the changes are not properly controlled to stay in line with the original model. This is especially problematic in the revision of decision models, where elements of the model consist of predefined set of relations with their intrinsic interpretation. For the models in form of neural networks, for example, a deviation cannot be regarded as unwanted, as long as it increases the performance measure. Unwanted model deviation can be limited by controlling the changes to be allowed to happen only near the original resolution path of a data item. Another approach would be to check every proposed change for compatibility with the behavior of

the original model on data set that was used to build it, the new data set, or both. This implies continuous computing of model performance with or without a change on at least one dataset and often causes the next potential problem of revision methods.

2. *Computational complexity*: As the task of model revision is simpler than that of model construction from the scratch, we expect its algorithms to be also less computationally demanding. However, the advantage of this simplicity is more often compensated with very low data demand than with the decrease of computational load. Unlike the model construction, revision is a process that is repeated, potentially in real time. It is thus essential to adapt the revision method (for instance the unwanted deviation limitation techniques) to the model and data size. The adaptation is also needed to exploit the features of the problem and the modelling methodology in order to limit the search space of solutions.
3. *Heterogeneous models*: The knowledge contained in the models can be heterogeneous in the sense that some of it was initially supported by more evidence, e.g., the user that defined it was more confident than in the other parts of the model. Not all parts of the model should therefore be revised to the same extent, and the part that relies on the more solid background knowledge should change less in the revision. To take this heterogeneity into account, we must make it explicit in the models. This information is often provided in form of parameters that describe the higher-order uncertainty (Lehner, Laskey, & Dubois, 1996; Wang 2001), i.e. the confidence about the knowledge provided in the model (values, probabilities, etc.). There are data-based revision methods that can utilize such information (Wang, 1993; Wang, 2001; Žnidaršič, Bohanec & Zupan, 2006). An example of one such method is presented in the next section.

Solutions for MCDM

Data-based revision of MCDM is both interesting and challenging. We have developed and experimentally tested two distinct revision methods for two variants of qualitative MCDM of DEX methodology. Both methods operate on probabilistic utility functions (see Table 1) and both rely on user defined parameters of the degree of changes. The first method (*rev_trust*) uses a parameter named *trust* that is provided for the whole learning data set and represents the users' trust in new empirical data. The second method (*rev_conf*) is intended to revise models containing heterogeneous knowledge. *Rev_conf* can exploit the parameters named *confidence*, which are provided for each rule in every utility function of the model to represent the users' confidence about the values in these rules.

The two methods have a common incremental operation strategy: they process data iteratively by considering one data item at a time. The data item consists of values of the input attributes (concepts at the bottom of hierarchy) and a value of the topmost concept. We represent a generic data item with a set of values $d_1, \ldots, d_n$ of input concepts and with the value of the topmost target concept g that also represents the utility of the item:

$[d_1, \ldots, d_n, g]$.

For the model from Figure 1, the data item could be for instance: [price=low, maint.=medium, ABS=yes, size=small, car=bad]. Both methods proceed through the hierarchy with each data item in a recursive top-down fashion. The revision first changes the utility function of the topmost concept (G), for which a true value (g) is given. The change is applied to the probability distribution in the rule with the highest weight according to the input values. The change is made so as to emphasize the true value g of its goal attribute G for the given values of input concepts. In the second step, the algorithm investigates whether the probability of g can be increased for current alternative without changing the utility function of G, but rather by changing the utility functions of the G's descendants. A combination of descendants values, which results in such a change, is then used as the true goal value in the next revision step, when this process is repeated on each descendant.

Apart from the described similar principles of operation, the methods *rev_trust* and *rev_conf* differ in some important aspects of the above mentioned procedures. The differences are briefly presented here and summarized in Table 2. For more elaborate descriptions of algorithms see the literature (Žnidaršič & Bohanec, 2005; Žnidaršič, Bohanec & Zupan, 2006).

Table 2: Summary of differences between the methods rev_trust and rev_conf

procedure	*rev_trust*	*rev_conf*
revision change	$p(g)$ + *trust*, normalization	according to the *confidence* of goal distribution
selection of descendant's value	values yielding distribution closest to target distribution biased towards g	values yielding max. value of g
divergence control	measure check	near resolution path

The first difference is in the computation of revision change. *Rev_trust* increases the probability of g in the selected goal distribution by a user defined parameter *trust* and then normalizes the distribution, whereas *rev_conf* uses the parameter *confidence* of the selected distribution and increases the g's probability accordingly (higher *confidence* - smaller revision).

The next difference is in the selection of candidate values for revision in descendants. *Rev_trust* selects a specified number of value combinations, which result closest to a special precomputed goal distribution biased towards g. *Rev_conf* is simpler in this aspect: it selects a value combination that results in a distribution with maximum probability of g. If there are more such combinations, all get selected.

The last difference is associated with the previous one, namely, as both methods potentially select more than one candidate combination of descendants values for the next recursive step, only the best one must be chosen. This is important for avoiding unwanted model deviations. *Rev_trust* selects the best combination according to a performance measure, whereas *rev_conf* selects the combination, which is the closest to the original resolution path of the input values.

Experimental results indicate (Žnidaršič & Bohanec, 2005; Žnidaršič, Bohanec & Zupan, 2006) that *rev_trust* is more successful in controlling the unwanted divergence and in increasing the performance measure. However, the second approach is much faster and offers heterogeneous revision of models. *Rev_conf* is also more autonomous, as it automatically adapts the rate of revision once the *confidence* parameters in the model are set. Therefore it is not easy to recommend one approach over the other. There is also room for mixed approaches with a subset of features from the first method and a subset of features from the other. Investigating the most interesting mixture of approaches from the both presented methods is the topic of further research. The most promising seems to be the narrowing of the space of revision options near the resolution path, but with a bigger set of candidates, among which the best ones are pinpointed using a performance measure check. Such a check proved to be beneficial for avoiding unwanted diversion, while at the same time its computational demands should not be problematic on a narrowed amount of candidate changes.

FUTURE TRENDS

With growing availability of data and limited amount of time for development and maintenance of computer models, automatic revision is a valuable approach for extending their lifetime. In the future, the revision methods could be adapted also to representations of higher complexity, like mechanistic models, which are commonly used in natural sciences. With advances in sensor and monitoring technology, the environmental management is one among many domains that could largely benefit from revision methods for complex phenomena representations.

CONCLUSION

Autonomous data-driven revision is a useful maintenance tool, which aims at saving valuable expert time for the adaptation of computer models to slight changes in the modelled environment. Revision methods generally share some common goals and features, but there is a wide choice of approaches even inside a particular modelling methodology. Their choice depends on the methodology, data and/or model size and the specific features of the modelling problem. Knowing the specific problem and general features of revision approaches, we must decide whether we should build the model from the scratch or should we revise it and how should we proceed to revise it. For

multi-criteria decision models of DEX methodology, we have introduced two alternative revision methods, *rev_trust* and *rev_conf*. The former is useful for small and homogeneous models, whereas the latter is more appropriate for large and heterogenous models.

KEY TERM

Background Knowledge: Knowledge used in a process, such as a construction of computer models, which is not made explicit. It influences the knowledge representations indirectly, for example by defining a structure of concepts or a set of values that a concept might have.

Batch Processing: Processing data in a batch at a time. Usually by considering statistical properties of a data set, like averages and frequencies of values.

Concept Drift: A change of concepts in the modelled environment. It causes the models, which are based on old empirical data, to become inconsistent with the new situation in the environment and new empirical data.

Data-Driven Revision: A process of revising knowledge and knowledge representations with empirical data, which describes the current situation in the modelled environment. Revision takes the initial state of knowledge as a starting point and preserves it as much as possible.

Incremental Processing: Processing data one data item at a time. An approach followed when processing must be possible to perform even on a single data item and when a suitable ordering of data items exists.

Mechanistic Model: A computer model, which is built so as to represent particular natural phenomena in the highest possible detail. Mechanistic models are based on domain expert knowledge and general physical laws, hence the name mechanistic or physical. They are complex and computationally demanding, but very useful for detailed simulations of processes which would be hard to empirically experiment with (such as big-scale nuclear tests).

Model Deviation: A change of parameters in the model, which causes concept representations to become inconsistent with their original meaning. Usually this is a consequence of uncontrolled adaptation of the model to empirical data.

Multi Criteria Decision Models (MCDM): Decision models for decision problems, which aim at satisfying several (usually conflicting) criteria. In these models, the main decision goal is decomposed into several hierarchical layers of criteria. This way, the problem is decomposed into smaller and smaller subproblems in order to become feasible to accurately describe and analyze.

Decision Tree Induction

INTRODUCTION

Decision Tree Induction (DTI) is a tool to induce a classification or regression model from (usually large) datasets characterized by n objects (records), each one containing a set **x** of numerical or nominal attributes, and a special feature *y* designed as its outcome. Statisticians use the terms "predictors" to identify attributes and "response variable" for the outcome. DTI builds a model that summarizes the underlying relationships between **x** and *y*. Actually, two kinds of model can be estimated using decision trees: *classification trees* if *y* is nominal, and *regression trees* if *y* is numerical. Hereinafter we refer to classification trees to show the main features of DTI. For a detailed insight into the characteristics of regression trees see Hastie et al. (2001).

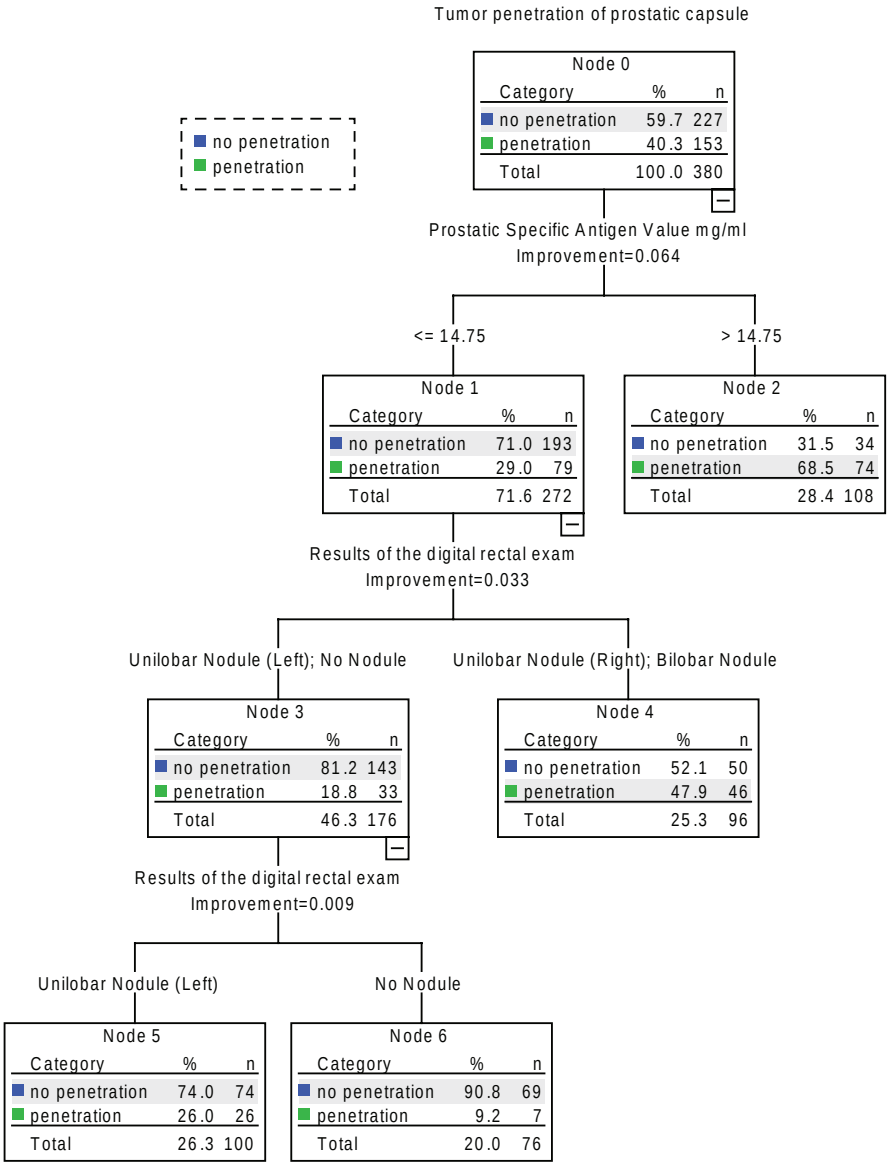
As an example of classification tree, let us consider a sample of patients with prostate cancer on which data such as those summarized in Figure 1 have been collected. Suppose a new patient is observed and we want to determine if the tumor has penetrated the prostatic capsule on the basis of the other available information. Posing a series of questions about the characteristic of the patient can help to predict the tumor's penetration. DTI proceeds in such a way, inducing a series of follow-up (usually binary) questions about the attributes of an unknown instance until a conclusion about what is its most likely class label is reached. Questions and their alternative answers can be represented hierarchically in the form of a decision tree, such as the one depicted in Figure 2.

The decision tree contains a root node and some internal and terminal nodes. The root node and the internal ones are used to partition instances of the dataset into smaller subsets of relatively homogeneous classes. To classify a previously unlabelled instance, say $i^* \left(i^* = 1, \ldots, n\right)$, we start from the test condition in

Figure 1. The prostate cancer dataset

Age in years	Result of the digital rectal exam	Result of he detection of capsular involvment in rectal exam	Prostatic specific antigen value mg/ml	Tumor penetration of prostatic capsule
65	Unilobar Nodule (Left)	No	1.400	*no penetration*
70	No Nodule	Yes	4.900	*no penetration*
71	Unilobar Nodule (Right)	Yes	3.300	*penetration*
68	Bilobar Nodule	Yes	31.900	*no penetration*
69	No Nodule	No	3.900	*no penetration*
68	No Nodule	Yes	13.000	*no penetration*
68	Bilobar Nodule	Yes	4.000	*penetration*
72	Unilobar Nodule (Left)	Yes	21.200	*penetration*
72	Bilobar Nodule	Yes	22.700	*penetration*
…	……..	…..	…….	……..…

Figure 2. An illustrative example of a decision tree for the prostate cancer classification



the root node and follow the appropriate pattern based on the outcome of the test. When an internal node is reached a new test condition is applied, and so on down to a terminal node. Encountering a terminal node, the modal class of the instances of that node is the class label of i^*. Going back to the prostate cancer classification problem, a new subject presenting a prostatic specific antigen value lower than 4.75, and an unilobar nodule on the left side will be classified as "no penetration". It is evident that decision trees can easily be converted into IF-THEN rules and used for decision making purposes.

BACKGROUND

DTI is useful for data mining applications because of the possibility to represent functions of numerical and

nominal attributes as well as of its feasibility, predictive ability and interpretability. It can effectively handle missing values and noisy data and can be used either as an explanatory tool for distinguishing objects of different classes or as a prediction tool to class labels of previously unseen objects.

Some of the well-known DTI algorithms include ID3 (Quinlan, 1983), CART (Breiman et al., 1984), C4.5 (Quinlan, 1993), FAST (Mola and Siciliano, 1997), SLIQ (Metha et al., 1997) and GUIDE (Loh, 2002). All these algorithms use a greedy, top-down recursive partitioning approach. They primarily differ in terms of the splitting criteria, the type of splits (2-way or multiway) and the handling of the overfitting problem.

MAIN THRUST

DTI uses a greedy, top-down recursive partitioning approach to induce a decision tree from data. In general, DTI involves the following tasks: decision tree growing and decision tree pruning.

Growing a Decision Tree

Decision trees use a greedy heuristic to make a series of locally optimum decisions about which attribute value to use for data partitioning. A test condition depending on a splitting method is applied to partition the data into more homogeneous subgroups at each step of the greedy algorithm.

Splitting methods differ with respect to the type of attribute: for nominal attributes the test condition is expressed as a question about one or more of its values $(\text{e.g.: } x_i = a?)$ whose outcomes are "Yes"/"No". Grouping of attribute values is required for algorithms using 2-way splits. For ordinal or continuous attributes the test condition is expressed on the basis of a threshold value υ such as $(x_i \le \upsilon?)$ or $(x_i > \upsilon?)$. Considering all possible split points υ, the best one υ^* partitioning the instances into homogeneous subgroups is selected. A splitting function accounts for the class distribution of instances both in the parent node and in the children nodes computing the decrease in the degree of impurity $\Delta(\upsilon, t)$ for each possible υ. It depends on the impurity measure of the parent node t (prior to splitting) against the weighted-averaged impurity measure of the children nodes (after splitting), denoted with t_r and t_l.

As for the single node t, if $p(i \mid t)$ is the proportion of instances belonging to class i and C classes are observed, the impurity $\omega(t)$ can be computed alternatively as follows:

Entropy: $\omega(t) = -\sum_{i=1}^{C} p(i \mid t) \log p(i \mid t)$

Gini: $\omega(t) = 1 - \sum_{i=1}^{C} \left[p(i \mid t) \right]^2$

Classification Error: $\omega(t) = 1 - \max_i \left[p(i \mid t) \right]$

To select the best split point, the value υ^* such that $\Delta(v,t) = \omega(t) - \left[\omega(t_l) p(t_l) + \omega(t_r) p(t_r) \right] = \max!$ with $p(t_l)$ and $p(t_r)$ are the proportions of instances falling into the two sub-nodes, where has to be found.

When entropy is used as the impurity measure $\omega(t)$, the degree of impurity $\Delta(\upsilon, t)$ is known as Information Gain.

Data partitioning proceeds recursively until a stopping rule is satisfied: this usually happens when the number of instances in a node is lower than a previously-specified minimum number necessary for splitting, as well as when the same instances belong to the same class or have the same attribute values.

Pruning a Decision Tree

DTI algorithms require a pruning step following the tree growing one in order to control for the size of the induced model and to avoid in this way data overfitting. Usually, data is partitioned into a training set (containing two-third of the data) and a test set (with the remaining one-third). Training set contains labeled instances and is used for tree growing. It is assumed that the test set contains unlabelled instances and is used for selecting the final decision tree: to check whether a decision tree, say D, is generalizable, it is necessary to evaluate its performance on the test set in terms of misclassification error by comparing the true class labels of the test data against those predicted by D. Reduced-size trees perform poorly on both training and test sets causing underfitting. Instead, increasing the size of D improves both training and test errors up to a "critical size" from which test errors increase even though corresponding training errors decrease. This means that D overfits the data and cannot be generalized to class prediction of unseen objects. In the machine learning framework, the training error is named resbstitution error and the test error is known as *generalization error*.

It is possible to prevent overfitting by haltering tree growing before it becomes too complex (*pre-pruning*). In this framework, one can assume the training data is a good representation of the overall data and use the resubstitution error as an optimistic estimate of the error of the final DTI model (*optimistic approach*). Alternatively, Quinlan (1987) proposed a pessimistic approach that penalizes complicated models by assigning a cost penalty to each terminal node of the decision tree: for C4.5, the generalization error is $\pi(t)/n_t + \varepsilon$, where, for a node t, n_t is the number of instances and $\pi(t)$ is the missclassification error. It is assumed $\pi(t)$ follows a Binomial distribution and that ε is the upper bound for $\pi(t)$ computed from such a distribution (Quinlan, 1993).

An alternative pruning strategy is based on the growing of the entire tree and the subsequent retrospective trimming of some of its internal nodes (*post-pruning*): the subtree departing from each internal node is replaced with a new terminal node whose class label derives from the majority class of instances belonging to the subtree. The subtree is definitively replaced by the terminal node if such a replacement induces an improvement of the generalization error. Pruning stops when no further improvements can be achieved. The generalization error can be estimated through either the optimistic or pessimistic approaches.

Other post-pruning algorithms, such as CART, use a complexity measure that accounts for both tree size and generalization error. Once the entire tree is grown using training instances, a penalty parameter expressing the gain/cost tradeoff for trimming each subtree is used to generate a sequence of pruned trees, and the tree in the sequence presenting the lowest generalization error (0-SE rule) or the one with a generalization error within one standard error of its minimum (1-SE rule) is selected. Cappelli et al. (2002) improved this approach introducing a statistical testing pruning to achieve the most reliable decision rule from a sequence of pruned trees.

Pruning algorithms can be combined with *k-fold cross-validation* when few instances are available. Training data is divided into k disjoint blocks and a tree is grown k times on k-1 blocks estimating the error by testing the model on the remaining block. In this case, the generalization error is the average error made for the k runs.

Averaging Decision Trees

A different approach is based on the generation of a set of candidate trees and their aggregation in order to improve their generalization ability. Tree averaging requires the definition of a suitable set of trees and their associated weights and classifies a new object by averaging over the set of weighted trees (Oliver and Hand, 1995). Either a compromise rule or a consensus rule can be used for averaging. An alternative method consists in summarizing the information of each tree in a table cross-classifying terminal nodes outcomes with the response classes in order to assess the generalization ability through a statistical index and select the tree providing the maximum value of such index (Siciliano, 1998).

Ensemble Methods

Ensemble methods are based on a weighted or non weighted aggregation of single trees (the so called *weak learners*) in order to improve the overall generalization error induced by each single tree. These methods are more accurate than a single tree if they have a generalization error that is lower than random guessing and if the generalization errors of the different trees are uncorrelated (Dietterich, 2000).

Bagging (Bootstrap Aggregating) (Breiman, 1996) works by randomly replicating training instances in order to induce single trees whose aggregation by majority voting provides the final classification. Breiman (1998) argues that bagging is able to improve the performance of unstable classifiers (i.e. trees with high variance). Thus, bagging is said to be a reduction variance method.

AdaBoost (Adaptive Boosting) (Freud and Schapire, 1996; Schapire et al., 1998) uses iteratively bootstrap replication of the training instances. At each iteration, previously-misclassified instances receive higher probability of being sampled. The final classification is obtained by majority voting. Boosting forces the decision tree to learn by its error, and is able to improve the performance of trees with both high bias (such as single-split trees) and variance.

Finally, Random Forest (Breiman, 2001) is an ensemble of unpruned trees obtained by randomly resampling training instances and attributes. The overall performance of the method derives from averaging the generalization errors obtained in each run. Simultane-

ously, suitable measures of attributes importance are obtained to enrich the interpretation of the model.

FUTURE TRENDS

Combining Trees with Other Statistical Tools

A consolidated literature about the incorporation of parametric and nonparametric models into trees appeared in recent years. Several algorithms have been introduced as hybrid or functional trees (Gama, 2004), among the machine learning community. As an example, DTI is used for regression smoothing purposes in Conversano (2002): a novel class of semiparametric models named Generalized Additive Multi-Mixture Models (GAM-MM) is introduced to perform statistical learning for both classification and regression tasks. These models works using an iterative estimation algorithm evaluating the predictive power of a set of suitable mixtures of smoothers/classifiers associated to each attribute. Trees are part of such a set that defines the estimation functions associated to each predictor on the basis of bagged scoring measures taking into account the trade-off between estimation accuracy and model complexity. Other hybrid approaches are presented in Chan and Loh (2004), Su et al. (2004), Choi et al. (2005) and Hothorn et al. (2006).

Another important streamline highlights the use of decision trees for exploratory and decision purposes. Some examples are the multi-budget trees and two-stage discriminant trees (Siciliano et al., 2004), the stepwise model tree induction method (Malerba et al. (2004), the multivariate response trees (Siciliano and Mola, 2000) and the three-way data trees (Tutore et al., 2007). In the same line, Conversano et al. (2001) highlights the idea of using DTI to preliminarily induce homogenous subsamples in data mining applications.

Trees for Data Imputation and Data Validation

DTI has also been used to solve data quality problems because of its extreme flexibility and its ability to easily handle missing data during the tree growing process. But DTI does not permit to perform missing data imputation in a straightforward manner when dealing with multivariate data. Conversano and Siciliano (2004) defined a decision tree-based incremental approach for missing data imputation using the principle of "statistical learning by information retrieval". Data can be used to impute missing values in an incremental manner, starting from the subset of instances presenting the lowest proportion of missingness up to the subset presenting the maximum number of missingness. In each step of the algorithm a decision tree is learned for the attribute presenting missing values using complete instances. Imputation is made for the class attribute inducing the final classification rule through either cross-validation or boosting.

CONCLUSION

In the last two decades, computational enhancements highly contributed to the increase in popularity of DTI algorithms. This cause the successful use of Decision Tree Induction (DTI) using recursive partitioning algorithms in many diverse areas such as radar signal classification, character recognition, remote sensing, medical diagnosis, expert systems, and speech recognition, to name only a few. But recursive partitioning and DTI are two faces of the same medal. While the computational time has been rapidly reducing, the statistician is making more use of computationally intensive methods to find out unbiased and accurate classification rules for unlabelled objects. Nevertheless, DTI cannot result in finding out simply a number (the misclassification error), but also an accurate and interpretable model.

Software enhancements based on interactive user interface and customized routines should empower the effectiveness of trees with respect to interpretability, identification and robustness.

KEY TERMS

AdaBoost (Adaptive Boosting): An iterative bootstrap replication of the training instances such that, at any iteration, misclassified instances receive higher probability to be included in the current bootstrap sample and the final decision rule is obtained by majority voting.

Bagging (Bootstrap Aggregating): A bootstrap replication of the training instances, each having the same probability to be included in the bootstrap sample. The single decision trees (weak learners) are aggregated to provide a final decision rule consisting in either the average (for regression trees) or the majority voting (for classification trees) of the weak learners' outcome.

Classification Tree: An oriented tree structure obtained by recursively partitioning a sample of objects on the basis of a sequential partitioning of the attribute space such to obtain internally homogenous groups and externally heterogeneous groups of objects with respect to a categorical attribute.

Decision Rule: The result of an induction procedure providing the final assignment of a response class/value to a new object for that only the attribute measurements are known. Such rule can be drawn in the form of a decision tree.

Ensemble: A combination, typically by weighted or unweighted aggregation, of single decision trees able to improve the overall accuracy of any single induction method.

Exploratory Tree: An oriented tree graph formed by internal nodes, that allow to describe the conditional interaction paths between the response attribute and the other attributes, and terminal nodes, that allow to describe the conditional interaction paths between the response attribute and the other attributes.

Fast Algorithm for Splitting Trees (FAST): A splitting procedure to grow a binary tree using a suitable mathematical property of the impurity proportional reduction measure to find out the optimal split at each node without trying out necessarily all the candidate splits.

Production Rule: A tree path characterized by a sequence of interactions between attributes yielding to a specific class/value of the response.

Pruning: A top-down or bottom-up selective algorithm to reduce the dimensionality of a tree structure in terms of the number of its terminal nodes.

Random Forest: An ensemble of unpruned trees obtained by randomly resampling training instances and attributes. The overall performance of the method derives from averaging the generalization errors obtained in each run.

Recursive Partitioning Algorithm: A recursive algorithm to form disjoint and exhaustive subgroups of objects from a given group in order to build up a decision tree.

Regression Tree: An oriented tree structure obtained by recursively partitioning a sample of objects on the basis of a sequential partitioning of the attributes space such to obtain internally homogenous groups and externally heterogeneous groups of objects with respect to a numerical attribute.

Deep Web Mining through Web Services

Monica Maceli
Drexel University, USA

Min Song
New Jersey Institute of Technology & Temple University, USA

INTRODUCTION

With the increase in Web-based databases and dynamically-generated Web pages, the concept of the "deep Web" has arisen. The deep Web refers to Web content that, while it may be freely and publicly accessible, is stored, queried, and retrieved through a database and one or more search interfaces, rendering the Web content largely hidden from conventional search and spidering techniques. These methods are adapted to a more static model of the "surface Web", or series of static, linked Web pages. The amount of deep Web data is truly staggering; a July 2000 study claimed 550 billion documents (Bergman, 2000), while a September 2004 study estimated 450,000 deep Web databases (Chang, He, Li, Patel, & Zhang, 2004).

In pursuit of a truly searchable Web, it comes as no surprise that the deep Web is an important and increasingly studied area of research in the field of Web mining. The challenges include issues such as new crawling and Web mining techniques, query translation across multiple target databases, and the integration and discovery of often quite disparate interfaces and database structures (He, Chang, & Han, 2004; He, Zhang, & Chang, 2004; Liddle, Yau, & Embley, 2002; Zhang, He, & Chang, 2004).

Similarly, as the Web platform continues to evolve to support applications more complex than the simple transfer of HTML documents over HTTP, there is a strong need for the interoperability of applications and data across a variety of platforms. From the client perspective, there is the need to encapsulate these interactions out of view of the end user (Balke & Wagner, 2004). Web services provide a robust, scalable and increasingly commonplace solution to these needs.

As identified in earlier research efforts, due to the inherent nature of the deep Web, dynamic and ad hoc information retrieval becomes a requirement for mining such sources (Chang, He, & Zhang, 2004; Chang, He, Li, Patel, & Zhang, 2004). The platform and program-agnostic nature of Web services, combined with the power and simplicity of HTTP transport, makes Web services an ideal technique for application to the field of deep Web mining. We have identified, and will explore, specific areas in which Web services can offer solutions in the realm of deep Web mining, particularly when serving the need for dynamic, ad-hoc information gathering.

BACKGROUND

Web Services

In the distributed computing environment of the internet, Web services provide for application-to-application interaction through a set of standards and protocols that are agnostic to vendor, platform and language (W3C, 2004). First developed in the late 1990s (with the first version of SOAP being submitted to the W3C in 2000), Web services are an XML-based framework for passing messages between software applications (Haas, 2003). Web services operate on a request/response paradigm, with messages being transmitted back and forth between applications using the common standards and protocols of HTTP, eXtensible Markup Language (XML), Simple Object Access Protocol (SOAP), and Web Services Description Language (WSDL) (W3C, 2004). Web services are currently used in many contexts, with a common function being to facilitate inter-application communication between the large number of vendors, customers, and partners that interact with today's complex organizations (Nandigam, Gudivada, & Kalavala, 2005). A simple Web service is illustrated by the below diagram; a Web service provider (consisting of a Web server connecting to a database server) exposes an XML-based API (Application Programming Interface)

to a catalog application. The application manipulates the data (in this example, results of a query on a collection of books) to serve both the needs of an end user, and those of other applications.

Semantic Web Vision

Web services are considered an integral part of the semantic Web vision, which consists of Web content described through markup in order to become fully machine-interpretable and processable. The existing Web is endowed with only minimal semantics; the semantic Web movement endeavors to enhance and increase this semantic data. Additionally, the semantic Web will provide great strides in overcoming the issues of language complexity and ambiguity that currently inhibit effective machine processing. The projected result will be a more useful Web where information can be intelligently shared, combined, and identified.

Semantic Web services are Web services combined with ontologies (high-level metadata) that describe Web service content, capabilities and properties, effectively merging the technical strengths of Web services with the descriptive capacity of ontologies (Narayanan & McIlraith, 2002; Terziyan & Kononenko, 2003). Ontologies are vital to the concept of the semantic Web, describing and defining the relationships and concepts which allow for interoperability. Not surprisingly, there has been a great deal of recent research exploring topics such as how to construct, model, use, personalize, maintain, classify, and transform the semantic Web ontologies (Acuña & Marcos, 2006; Alani, 2006; Jiang & Tan, 2006; Lei, 2005; Pathak & Koul, 2005). Ultimately, by describing both what the Web service provides and how to interact with it in a machine-readable fashion, semantic Web services will allow automation in such areas as Web service discovery, integration and interoperation.

Deep Web Challenges

As identified in earlier works (Chang, He, & Zhang, 2004; Chang, He, Li, Patel, & Zhang, 2004), dynamic and ad-hoc integration will be a requirement for large-scale efforts to mine the deep Web. Current deep Web mining research is exploring Web query interface integration, which allows for the querying of multiple hidden Web databases through a unified interface (Bergholz & Chidlovskii, 2004; He, Chang, & Han, 2004; Liu & Chen-Chuan-Chang, 2004). The below figure illustrates the current challenges of the distributed Web environment. The Web consists of both static Web pages and database-specific interfaces; while static pages are easily mined, the Web databases are hidden behind one or more dynamic querying interfaces, presenting an obstacle to mining efforts.

These studies exploit such techniques as interface extraction, schema matching, and interface unification to integrate the variations in database schema and display into a meaningful and useful service for the user (He, Zhang, & Chang, 2004). Interface extraction seeks to automatically extract the relevant attributes from the HTML of the query interface Web page, schema matching identifies semantic similarity between these attributes, and interface unification refers to the construction of a single unified interface based upon the identified matches (He, Zhang, & Chang, 2004). Such unified interfaces then serve as a mediator between the user and the multiple deep Web databases that are being queried; the request and aggregation of this data

Figure 1. High-level Web service example

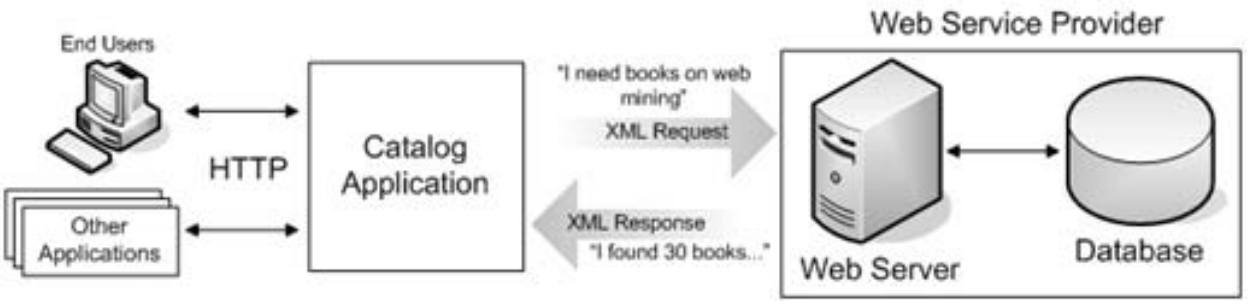

Figure 2. Web databases and associated interfaces of the deep Web, as well as static Web pages of the surface Web

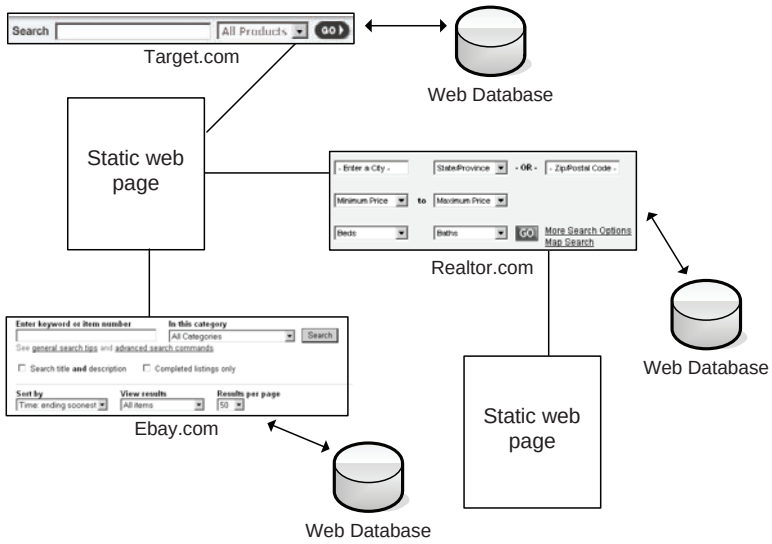


is thusly hidden from the user, providing a seamless and usable interface. On a large scale, however, such solutions provide many challenges in the huge and data-heavy environment of the Web. In particular, schema matching across disparate databases can be challenging and require techniques such as statistical analysis of patterns and exploration of context information to be successful.

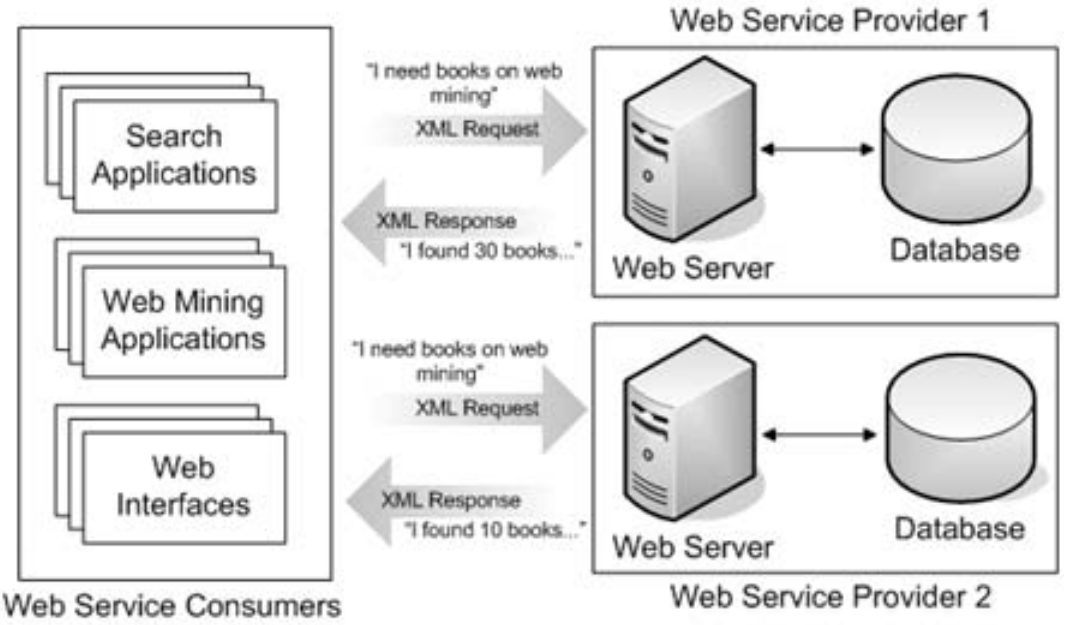
MAIN FOCUS

Current deep Web mining research has found two primary requirements for success - the ability to retrieve data in a dynamic fashion (as Web sources are continually evolving) and in an ad-hoc manner (as queries are tailored to users' varying needs) (Chang, He, & Zhang, 2004). By providing standardized APIs (Application Programming Interfaces) against which to dynamically request data, Web services can make significant contributions to the field of deep Web mining. Web services can encapsulate database-specific algorithms and structure, providing only a standardized search API to a Web mining tool or search interface. Semantic Web services are an effective means of exposing the structured database information of the deep Web to both search engines and dynamic search applications (and, as is the nature of Web services, to any other desired application).

The current research in deep Web mining endeavors to discover semantics and matches between the varying query interfaces of the deep Web, in order to both identify appropriate sources and to translate the user's query across schemas effectively and logically (Bergholz & Chidlovskii, 2004; He, Chang, & Han, 2004; He, Zhang, & Chang, 2004). Web services can be considered an effective data delivery system in such an environment. The below diagram illustrates a high-level view of a system in which semantically-endowed Web services provide dynamic results to a host of applications, including deep Web mining applications.

As discussed earlier, Web services offer a myriad of benefits and their success lies in their ability to provide dynamic and extremely flexible interaction between distributed and heterogeneous Web systems. Interoperability issues can be largely negated when software components are exposed as Web services (Nandigam, Gudivada, & Kalavala, 2005). Web services have the ability to take advantage of pre-existing systems by providing a standardized wrapper of communication on top of existing applications. In this manner they do not require the replacement or rewriting of systems, and subsequently take a relatively small amount of time to implement. The platform-independent nature of Web services allows for a true separation of display and data;

Figure 3. Web service APIs providing data to multiple applications



the result is that the same Web service can be called from multiple applications, platforms, and device types, and combined and used in a truly unlimited number of ways. In addition to deep Web mining, Web services have application in the field of meta-searching and federated search, which are analogous library solutions for integration of disparate databases.

Additionally, there is similar research in the area of Web personalization and intelligent search, where the appropriate Web services will be chosen at run-time based on user preferences (Balke &Wagner, 2004). These techniques allow multiple databases and data stores to be queried through one, seamless interface that is tailored to a particular search term or area of interest. In addition to being a more efficient method of searching the Web, such interfaces more closely match users' current mental model and expectations of how a search tool "should" behave (Nielsen, 2005).

Web Service Challenges

As we will explore in the future trends section of the study, there are significant efforts underway in the standardization and proliferation of Web services, and these factors remain the chief obstacles to such a system. Although Web services are quite popular in achieving the interoperability of organizations' internal applications, such services are not as consistently provided publicly. There are an increasing number of available Web services, but they are not provided by every system or database-driven application of the deep Web (Nandigam, Gudivada, & Kalavala, 2005). Alternative techniques such as mediators and screen-scrapers exist to submit deep Web queries, but are much more inefficient and labor-intensive.

When dealing with the many databases of the deep Web, the query often must be translated to be meaningful to every target system, which can require significant processing (Chang, He, & Zhang, 2004). Not surprisingly, this translation can also have an effect on the quality and relevance of the results provided. Similarly, the results returned are only as good as those of the target system and the de-duplication of data is a cost-heavy requirement as well.

FUTURE TRENDS

Previous studies have shown that the data-rich, structured environment of the deep Web continues to grow

at a rate faster than that of the surface Web, indicating a wealth of opportunities for exploring deep Web mining (Bergman, 2000; Chang, He, Li, Patel, & Zhang, 2004). Significant progress remains to be made in the realm of Web services development and standardization as well. Both industry and academic research initiatives have explored methods of standardizing Web service discovery, invocation, composition, and monitoring, with the World Wide Web Consortium (W3C) leading such efforts (W3C, 2004). The end goal of these endeavors are Web-based applications that can automatically discover an appropriate Web service, obtain the proper steps to invoke the service, create composite interoperability of multiple services when necessary, and monitor the service properties during the lifespan of the interaction (Alesso, 2004; Hull & Su, 2005).

Along with standardization initiatives and frontier research, there is a general increase in the popularity of Web services, both in industry and academia, with a variety of public services currently available (Fan & Kambhampati, 2005). Businesses and organizations continue to open entry to their capabilities through Web services; a well-used example is Amazon.com's Web service which provides access to its product database, and claimed 65,000 developers as of November 2004 (Nandigam, Gudivada, & Kalavala, 2005). Research on the current state of Web services has focused on the discovery of such existing services, with UDDI (Universal Description, Discovery, and Integration) providing a registry for businesses to list their services, aiding in discovery and interaction of systems (Nandigam, Gudivada, & Kalavala, 2005).

All of these developments will provide a strong framework for dynamic mining of the deep Web through Web services, and can be summarized as follows:

1. Increase in the number of publicly available Web services, as well as those used for organizations' internal applications
2. Higher percentage of quality Web services registered and discoverable through UDDI
3. Further standardization of semantic Web services' ontologies, ultimately allowing for machines to select, aggregate, and manipulate Web service data in a dynamic fashion, including deep Web information.
4. Further improvements to intelligent search, where users' queries can be tailored and distributed to multiple, relevant sources at run-time.
5. Continuing research in exposing and manipulating deep Web data as well as applying semantics to the variety of information types and sources currently available on the Web

CONCLUSION

In the distributed and deep data environment of the internet, there is a strong need for the merging and collation of multiple data sources into a single search interface or request. These data stores and databases are often part of the "deep Web" and are out of the range of classic search engines and crawlers. In the absence of authoritative deep Web mining tools, Web services and other techniques can be leveraged to provide dynamic, integrated solutions and the interoperability of multiple systems. Semantic Web services can expose the structured, high-quality data of the deep Web to Web mining efforts. These systems can provide simultaneous searching of multiple databases and data stores. However, such solutions are not without their own challenges and limitations, which must be carefully managed and addressed, and significant standardization efforts are still required.

KEY TERMS

Deep Web: Deep Web is content that resides in searchable databases, the results from which can only be discovered by a direct query.

Ontologies: Ontologies are meta-data which provide a machine-processable and controlled vocabulary of terms and semantics; they are critical to the semantic Web vision as ontologies support both human and computer understanding of data.

Semantic Web: Semantic Web is a self describing machine processable Web of extensible dynamic information; a huge logic based database of semantically marked up information, ready for output and processing.

Surface Web: The surface Web refers to the static Web pages of the Internet which are linked together by hyperlinks and are easily crawled by conventional Web crawlers.

UDDI (Universal Description, Discovery, and Integration): UDDI, or Universal Description, Discovery, and Integration, is an XML-based registry for Web services, providing a means for finding and using public Web services.

Web Mining: Web mining is the automated discovery of useful information from the Web documents using data mining and natural language processing techniques.

Web Services: Web services can be defined as a standardized way of integrating Web-based applications using the XML, SOAP, WSDL and UDDI open standards over an Internet protocol backbone.

DFM as a Conceptual Model for Data Warehouse

Matteo Golfarelli
University of Bologna, Italy

INTRODUCTION

Conceptual modeling is widely recognized to be the necessary foundation for building a database that is well-documented and fully satisfies the user requirements. In particular, from the designer point of view the availability of a conceptual model provides a higher level of abstraction in describing the warehousing process and its architecture in all its aspects.

Typically conceptual models rely on a graphical notation that facilitates writing, understanding, and managing conceptual schemata by both designers and users. The *Entity/Relationship* (E/R) model (Chen, 1976) is widespread in the enterprises as a conceptual formalism to provide standard documentation for relational information systems; nevertheless, as E/R is oriented to support queries that navigate associations between data rather than synthesize them, it is not well-suited for data warehousing (Kimball, 1998). Actually, the E/R model has enough expressivity to represent most concepts necessary for modeling a *Data Warehouse* (DW); on the other hand, in its basic form, it is not able to properly emphasize the key aspects of the multidimensional model, so that its usage for DWs is expensive from the point of view of the graphical notation and not intuitive (Rizzi, 2006).

Some designers claim that star schemata are expressive enough for conceptual modeling. Actually, a star schema is just a (denormalized) relational schema, so it merely defines a set of relations and integrity constraints. Using star schema for conceptual modeling is like starting to build a complex software by writing the code, without the support of any static, functional, or dynamic model, which typically leads to very poor results from the points of view of adherence to user requirements, maintenance, and reuse. For all these reasons, in the last few years the research literature has proposed several original approaches for modeling a DW, some based on extensions of known conceptual formalisms (e.g. E/R, *Unified Modeling Language* (UML)), some based on ad hoc ones. Remarkably, a comparison of the different models made by Abello (2006) pointed out that, abstracting from their graphical form, the core expressivity is similar, thus proving that the academic community reached an informal agreement on the required expressivity.

This paper discusses the expressivity of an ad hoc conceptual model, the Dimensional Fact Model (DFM), in order to let the user verify the usefulness of a conceptual modeling step in DW design. After a brief listing of the main conceptual model proposals, the basic and advanced features in DW conceptual modeling are introduced and described by examples. Finally, the current trends in DW conceptual modeling are reported and the conclusions are drawn.

BACKGROUND

In the last few years multidimensional modeling attracted the attention of several researchers that defined different solutions each focusing on the set of information they considered strictly relevant. Some of these solutions have no (Agrawal, 1997; Pedersen, 1999) or limited (Cabibbo, 1998) graphical support, and are aimed at establishing a formal foundation for representing cubes and hierarchies and an algebra for querying them. On the other hand, we believe that a distinguishing feature of conceptual models is that of providing a graphical support to be easily understood by both designers and users when discussing and validating requirements. So we will classify "strict" conceptual models for DWs according to the graphical formalism they rely on that could be either E/R, object-oriented or ad hoc. Some claim that E/R extensions should be adopted since (1) E/R has been tested for years; (2) designers are familiar with E/R; (3) E/R has proved to be flexible and powerful enough to adapt to a variety of application domains; and (4) several important research results were obtained for the E/R model (Franconi, 2004; Sapia, 1999; Tryfona, 1999). On the other hand, advocates of object-oriented models argue that (1) they are more

Table 1. Comparison between conceptual models (√: supported feature; −: not supported or not explained how to support; p partially supported; QL query language; A: algebra; C: calculus)

	Agrawal 1997	Cabibbo 1998	Pedersen 1999	Franconi 2004	Sapia 1999	Tryfona 1999	Luján 2006	Abello 2006	Tsois 2001	Hüsemann 2000	Rizzi 2006
Reference conceptual model	–	Maths	Maths	E/R	E/R	E/R	UML	UML	–	–	–

Describes hierarchies besides aggregation issues	–	√	–	–	√	√	–	√	√	√	√
Allows multiple measure to be represented	P	–	√	√	√	√	√	√	7	√	√
Models summarizzability semantics	–	–	–	–	–	P	√	√	–	√	√
Treats symmetrically measures and dimensions	√	–	√	–	–	P	–	P	–	–	–
Multiple subjects (fact) can be represented	–	√	–	–	√	–	√	√	–	√	√
Models many-to-many rel. within hierarchies	P	–	√	√	–	√	√	√	√	–	√

expressive and better represent static and dynamic properties of information systems; (2) they provide powerful mechanisms for expressing requirements and constraints; (3) object-orientation is currently the dominant trend in data modeling; and (4) UML, in particular, is a standard and is naturally extensible (Luján-Mora, 2006; Abello, 2006). Finally, we believe that ad hoc models compensate for designers' lack of familiarity since (1) they achieve better notational economy; (2) they give proper emphasis to the peculiarities of the multidimensional model, and thus (3) they are more intuitive and readable by non-expert users (Rizzi, 2006; Hüsemann, 2000; Tsois, 2001).

Table 1 reports a comparison of the conceptual models discussed according to a subset of the criteria[1] proposed by Abello (2006). The subset has been defined considering the most common features (i.e. those supported by most of the models) that define the core expressivity for multidimensional conceptual modeling.

MAIN FOCUS

The Basics of the Dimensional Fact Model

The Dimensional Fact Model is a graphical conceptual model, specifically devised for multidimensional design, aimed at:

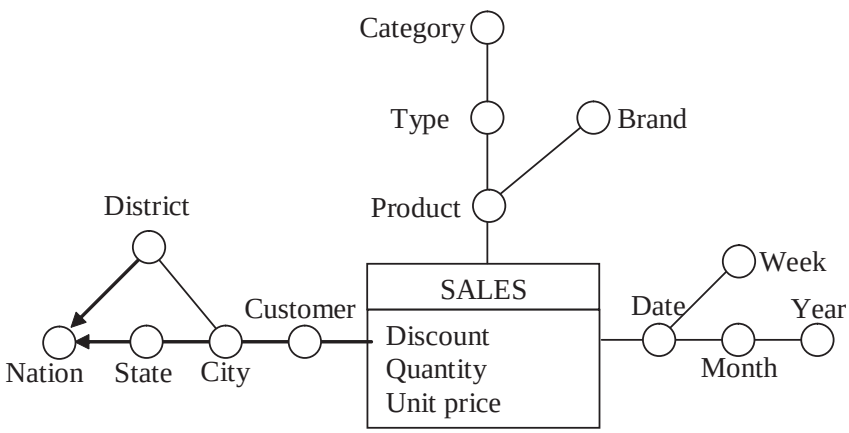
- effectively supporting conceptual design;
- providing an environment in which user queries can be intuitively expressed;
- supporting the dialogue between the designer and the end-users to refine the specification of requirements;
- creating a stable platform to ground logical design;
- providing an expressive and non-ambiguous design documentation.

DFM was first proposed in 1998 by Golfarelli and Rizzi and continuously enriched and refined during the following years in order to optimally suit the variety of modeling situations that may be encountered in real projects of small to large complexity.

The representation of reality built using the DFM consists of a set of fact schemata. The basic concepts modeled are facts, measures, dimensions, and hierarchies. In the following we intuitively define these concepts, referring the reader to Figure 1 that depicts a simple fact schema for modeling invoices at line granularity; a formal definition of the same concepts can be found in (Rizzi, 2006).

Definition 1. A *fact* is a focus of interest for the decision-making process; typically, it models a set of events occurring in the enterprise world. A fact is graphically represented by a box with two sections, one for the fact name and one for the measures.

Figure 1. A basic fact schema for the SALES fact



Examples of facts in the trade domain are sales, shipments, purchases; in the financial domain: stock exchange transactions, contracts for insurance policies. It is essential for a fact to have some dynamic aspects, i.e., to evolve somehow across time.

The concepts represented in the data source by frequently-updated archives are good candidates for facts; those represented by almost-static archives are not. As a matter of fact, very few things are completely static; even the relationship between cities and regions might change, if some borders were revised. Thus, the choice of facts should be based either on the average periodicity of changes, or on the specific interests of analysis.

Definition 2. A *measure* is a numerical property of a fact, and describes one of its quantitative aspects of interests for analysis. Measures are included in the bottom section of the fact.

For instance, each invoice line is measured by the number of units sold, the price per unit, the net amount, etc. The reason why measures should be numerical is that they are used for computations. A fact may also have no measures, if the only interesting thing to be recorded is the occurrence of events; in this case the fact scheme is said to be empty and is typically queried to count the events that occurred.

Definition 3. A *dimension* is a fact property with a finite domain, and describes one of its analysis coordinates. The set of dimensions of a fact determine its finest representation granularity. Graphically, dimensions are represented as circles attached to the fact by straight lines.

Typical dimensions for the invoice fact are product, customer, agent. Usually one of the dimensions of the fact represents the time (at any granularity) that is necessary to extract time series from the DW data.

The relationship between measures and dimensions is expressed, at the instance level, by the concept of event.

Definition 4. A *primary event* is an occurrence of a fact, and is identified by a tuple of values, one for each dimension. Each primary event is described by one value for each measure.

Primary events are the elemental information which can be represented (in the cube metaphor, they correspond to the cube cells). In the invoice example they model the invoicing of one product to one customer made by one agent on one day.

Aggregation is the basic OLAP operation, since it allows significant information to be summarized from large amounts of data. From a conceptual point of view, aggregation is carried out on primary events thanks to the definition of dimension attributes and hierarchies.

Definition 5. A *dimension attribute* is a property, with a finite domain, of a dimension. Like dimensions, it is represented by a circle.

For instance, a product is described by its type, category, and brand; a customer, by its city and its nation. The relationships between dimension attributes are expressed by hierarchies.

Definition 6. A *hierarchy* is a directed graph, rooted in a dimension, whose nodes are all the dimension attributes that describe that dimension, and whose arcs model many-to-one associations between pairs of dimension attributes. Arcs are graphically represented by straight lines.

Hierarchies should reproduce the pattern of inter-attribute functional dependencies expressed by the data source. Hierarchies determine how primary events can be aggregated into secondary events and selected significantly for the decision-making process.

Definition 7. Given a set of dimension attributes, each tuple of their values identifies a *secondary event* that aggregates all the corresponding primary events. Each secondary event is described by a value for each measure, that summarizes the values taken by the same measure in the corresponding primary events.

The dimension in which a hierarchy is rooted defines its finest aggregation granularity, while the other dimension attributes progressively define coarser ones. For instance, thanks to the existence of a many-to-one association between products and their categories, the invoicing events may be grouped according to the

category of the products. When two nodes a_1, a_2 of a hierarchy share the same descendent a_3 (i.e. when two dimension attributes within a hierarchy are connected by two or more alternative paths of many-to-one associations) this is the case of a convergence, meaning that for each instance of the hierarchy we can have different values for a_1, a_2, but we will have only one value for a_3. For example, in the geographic hierarchy on dimension customer (Figure 1): customers live in cities, which are grouped into states belonging to nations. Suppose that customers are also grouped into sales districts, and that no inclusion relationships exist between districts and cities/states; on the other hand, sales districts never cross the nation boundaries. In this case, each customer belongs to exactly one nation whichever of the two paths is followed (customer→city→state→nation or customer→sale district→nation).

It should be noted that the existence of apparently equal attributes does not always determine a convergence. If in the invoice fact we had a brand city attribute on the product hierarchy, representing the city where a brand is manufactured, there would be no convergence with attribute (customer) city, since a product manufactured in a city can obviously be sold to customers of other cities as well.

Advanced Features of the Dimensional Fact Model

In this section we introduce, with the support of Figure 2, some additional constructs of DFM that enable us to best capture those peculiarities of the application domain and that turn out to be necessary for the designer during logical design.

In several cases it is useful to represent additional information about a dimension attribute, though it is not interesting to use such information for aggregation. For instance, the user may ask to know the address of each store, but will hardly be interested in aggregating sales according to the address of the store.

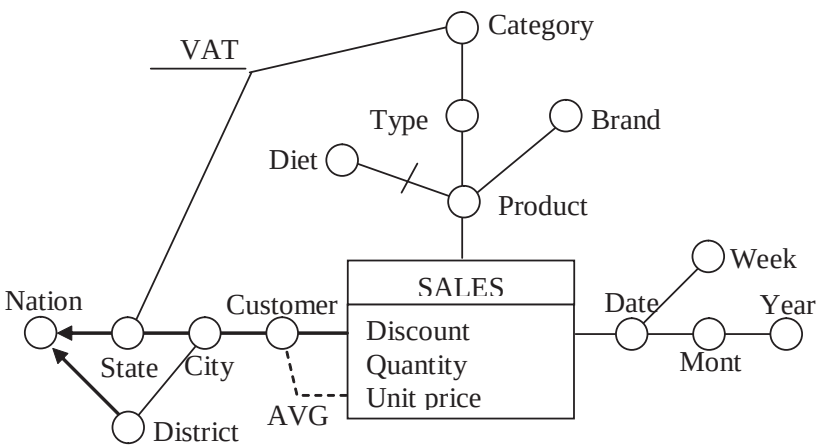
Definition 8. A *descriptive attribute* specifies a property of a dimension attribute, to which it is related by an one-to-one association. Descriptive attributes are not used for aggregation; they are always leaves of their hierarchy and are graphically represented by horizontal lines.

Usually a descriptive attribute either has a continuously-valued domain (for instance, the weight of a product), or is related to a dimension attribute by a one-to-one association (for instance, the address of a customer).

Definition 9. A *cross-dimension attribute* is an (either dimensional or descriptive) attribute whose value is determined by the combination of two or more dimension attributes, possibly belonging to different hierarchies. It is denoted by connecting the arcs that determine it by a curved line.

For instance, if the VAT on a product depends on both the product category and the state where the prod-

Figure 2. The complete fact schema for the SALES fact



uct is sold, it can be represented by a cross-dimension attribute.

Definition 10. An *optional arc* models the fact that an association represented within the fact scheme is undefined for a subset of the events. An optional arc is graphically denoted by marking it with a dash.

For instance, attribute diet takes a value only for food products; for other products, it is undefined.

In most cases, as already said, hierarchies include attributes related by many-to-one associations. On the other hand, in some situations it is necessary to include also those attributes that, for a single value taken by their father attribute, take several values.

Definition 11. A *multiple arc* is an arc, within a hierarchy, modeling a many-to-many association between the two dimension attributes it connects. Graphically, it is denoted by doubling the line that represents the arc.

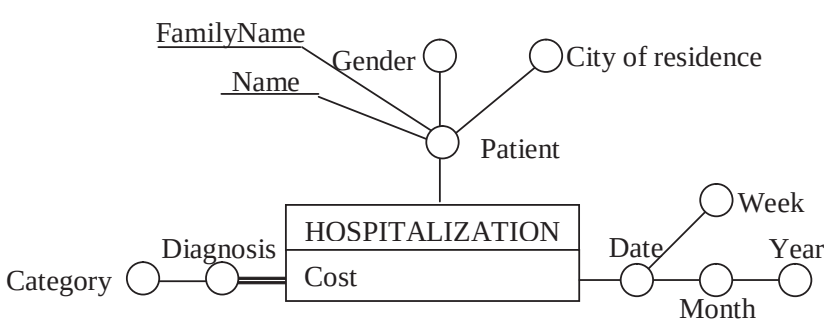
Consider the fact schema modeling the hospitalization of patient in a hospital, represented in Figure 3, whose dimensions are date, patient and diagnosis. Users will probably be interested in analyzing the cost of staying in hospital for different diagnoses, but, since for each hospitalization the doctor in charge of the patient could specify up to 7 diagnoses, the relationship between the fact and the diagnoses must be modeled as a multiple arc.

Summarizability is the property of correcting summarizing measures along hierarchies (Lenz, 1997). Aggregation requires defining a proper operator to compose the measure values characterizing primary events into measure values characterizing each secondary event. Usually, most measures in a fact scheme are *additive*, meaning that they can be aggregated on different dimensions using the SUM operator. An example of additive measure in the sale scheme is *quantity*: the quantity sold in a given month is the sum of the quantities sold on all the days of that month. A measure may be *non-additive* on one or more dimensions. Examples of this are all the measures expressing a level, such as an inventory level, a temperature, etc. An inventory level is non-additive on time, but it is additive on the other dimensions. A temperature measure is non-additive on all the dimensions, since adding up two temperatures hardly makes sense. However, this kind of non-additive measures can still be aggregated by using operators such as average, maximum, minimum. The set of operators applicable to a given measure can be directly represented on the fact scheme by labeling a dashed line connecting a measure and a dimension with the name of the operators (see Figure 2). In order to increase readability the information is omitted for the SUM operator that is chosen as default. If the schema readability is affected in any way we recommend substituting the graphical representation with a tabular one showing measures on the rows and dimensions on the columns: each cell will contain the set of allowed operators for a given dimension and a given measure.

FUTURE TRENDS

Future trends in DWing were recently discussed by the academic community in the Perspective Seminar "Data Warehousing at the Crossroads" that took place

Figure 3. The fact schema for the HOSPITALIZATION fact



at Dagstuhl, Germany, in August 2004. Here we report the requirements related to conceptual modeling expressed by the group:

- Standardization. Though several conceptual models have been proposed, none of them has been accepted as a standard. On the other hand, the ''Common Warehouse Metamodel'' (OMG, 2001) standard is too general, and not conceived as a conceptual model (Abello, 2006). An effort is needed to promote the adoption of a design methodology centered on conceptual modeling.
- Implementation of CASE tools. No commercial case tools currently support conceptual models; on the other hand, a tool capable of drawing conceptual schemata and deploying relational tables directly from them has already been prototyped and would be a valuable support for both the research and industrial communities.
- Conceptual models for the DW process. Conceptual modeling can support all the steps in the DW process. For example design and implementation of ETL procedures could be simplified adopting a proper conceptual modeling phase. Though some approaches are already available (Trujillo, 2003; Simitsis, 2007), the topic requires further investigation. Similarly, the definition of security polices, that are particularly relevant in DW systems, can be modeled at the conceptual level (Fernandez, 2007). Finally, ad-hoc conceptual models may be applied in the area of analytic applications built on top of DW. For example, the design of What-if analysis applications is centered on the definition of the simulation model (Golfarelli, 2006), whose definition requires an ad-hoc expressivity that is not available in any known conceptual models.

CONCLUSION

In this paper we have proposed the DFM as a model that covers the core expressivity required for supporting the conceptual design of DW applications and that presents further constructs for effectively describing the designer solutions.

Since 1998, the DFM has been successfully adopted in several different DW projects in the fields of large-scale retail trade, telecommunications, health, justice, and education, where it has proved expressive enough to capture a wide variety of modeling situations. Remarkably, in most projects the DFM was also used to directly support dialogue with end-users aimed at validating requirements, and to express the expected workload for the DW to be used for logical and physical design. Overall, our on-the-field experience confirmed that adopting conceptual modeling within a DW project brings great advantages since:

- Conceptual schemata are the best support for discussing, verifying, and refining user specifications since they achieve the optimal trade-off between expressivity and clarity. Star schemata could hardly be used to this purpose.
- Conceptual schemata are an irreplaceable component of the project documentation.
- They provide a solid and platform-independent foundation for logical and physical design.
- They make turn-over of designers and administrators on a DW project quicker and simpler.

KEY TERMS

Aggregation: The process by which data values are collected with the intent to manage the collection as a single unit.

Conceptual Model: A formalism, with a given expressivity, suited for describing part of the reality, based on some basic constructs and a set of logical and quantitative relationships between them.

DFM: Dimensional Fact Model is a graphical conceptual model specifically devised for describing a multidimensional system.

ETL: The processes of Extracting, Transforming, and Loading data from source data systems into a data warehouse.

Fact: A focus of interest for the decision-making process; typically, it models a set of events occurring in the enterprise world.

Summarizability: The property of correcting summarizing measures along hierarchies by defining a proper operator to compose the measure values characterizing basic events into measure values characterizing aggregated events.

What-If Analysis: What-if analysis is as a data-intensive simulation whose goal is to inspect the behavior of a complex system under some given hypotheses called scenarios.

ENDNOTE

Direction-Aware Proximity on Graphs

Hanghang Tong

Carnegie Mellon University, USA

INTRODUCTION

In many graph mining settings, measuring node proximity is a fundamental problem. While most of existing measurements are (implicitly or explicitly) designed for undirected graphs; edge directions in the graph provide a new perspective to proximity measurement: measuring the proximity from A to B; rather than between A and B. (See Figure 1 as an example).

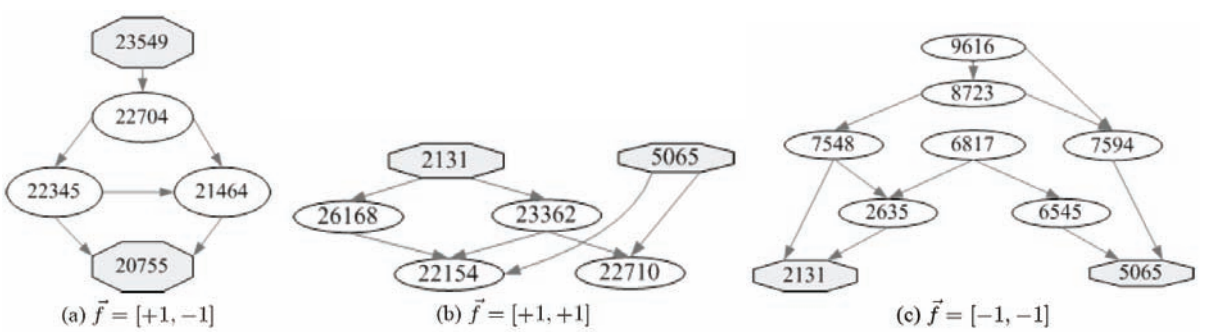
In this chapter, we study the role of edge direction in measuring proximity on graphs. To be specific, we will address the following fundamental research questions in the context of direction-aware proximity:

1. **Problem definitions:** How to define a direction-aware proximity?
2. **Computational issues:** How to compute the proximity score efficiently?
3. **Applications:** How can direction-aware proximity benefit graph mining?

BACKGROUND

In the literature, there are several measures of node proximity. Most standard measures are based on basic graph theoretical concepts -the shortest path length and the maximum flow. However the dependency of these measures on a single element of the graph, the shortest path or the minimum cut, makes them more suitable to managed networks, but inappropriate for measuring the random nature of relationships within social networks or other self organizing networks. Consequently, some works suggested more involved measures such as the sink-augmented delivered current (Faloutsos, Mccurley & Tomkins, 2004), cycle free effective conductance

Figure 1. An example of Dir-CePS. Each node represents a paper and edge denotes 'cited-by' relationship. By employing directional information, Dir-CePS can explore several relationships among the same query nodes (the two octagonal nodes): (a) A query-node to query-node relations; (b) common descendants of the query nodes (paper number 22154 apparently merged the two areas of papers 2131 and 5036); (c) common ancestors of the query nodes: paper 9616 seems to be the paper that initiated the research areas of the query papers/nodes. See 'Main Focus' section for the description of Dir-CePS algorithm.



(Koren, North & Volinsky, 2006), survivable network (Grötschel, Monma & Stoer, 1993), random walks with restart (He, Li, zhang, Tong & Zhang, 2004; Pan, Yang, Faloutsos & Duygulu, 2004). Notice that none of the existing methods meets all the three desirable properties that our approach meets: (a) dealing with directionality, (b) quality of the proximity score and (c) scalability.

Graph proximity is an important building block in many graph mining settings. Representative work includes connection subgraph (Faloutsos, McCurley & Tomkins, 2004; Koren, North & Volinsky, 2006; Tong & Faloutsos 2006), personalized PageRank (Haveliwala, 2002), neighborhood formulation in bipartite graphs (Sun, Qu, Chakrabarti & Faloutsos, 2005), content-based image retrieval (He, Li, zhang, Tong & Zhang, 2004), cross modal correlation discovery (Pan, Yang, Faloutsos & Duygulu, 2004), the BANKS system (Aditya, Bhalotia, Chakrabarti, Hulgeri, Nakhe & Parag 2002), link prediction (Liben-Nowell & Kleinberg, 2003), detecting anomalous nodes and links in the graph (Sun, Qu, Chakrabarti & Faloutsos, 2005), ObjectRank (Balmin, Hristidis & Papakonstantinou, 2004) and RelationalRank (Geerts, Mannila & Terzi, 2004).

MAIN FOCUS

In this Section, we begin by proposing a novel direction-aware proximity definition, based on the notion of escape probability of random walks. It is carefully designed to deal with practical problems such as the inherent noise and uncertainties associated with real life networks. Then, we address computational efficiency, by concentrating on two scenarios: (1) the computation of a single proximity on a large, disk resident graph (with possibly millions of nodes). (2) The computation of multiple pairwise proximities on a medium sized graph (with up to a few tens of thousand nodes). For the former scenario, we develop an iterative solution to avoid matrix inversion, with convergence guarantee. For the latter scenario, we develop an efficient solution, which requires only a single matrix inversion, making careful use of the so-called block-matrix inversion lemma. Finally, we apply our direction-aware proximity to some real life problems. We demonstrate some encouraging results of the proposed direction-aware proximity for predicting the existence of links together with their direction. Another application is so-called "directed center-piece subgraphs."

Direction-Aware Proximity: Definitions

Here we give the main definitions behind our proposed node-to-node proximity measure, namely, the escape probability; then we give the justification for our modifications to it.

Escape Probability

Following some recent works (Faloutsos, McCurley & Tomkins, 2004; Koren, North & Volinsky, 2006; Tong & Faloutsos 2006), our definition is based on properties of random walks associated with the graph. Random walks mesh naturally with the random nature of the self-organizing networks that we deal with here. Importantly, they allow us to characterize relationships based on multiple paths. Random walk notions are known to parallel properties of corresponding electric networks (Doyle & Snell, 1984). For example, this was the basis for the work of Faloutsos et al. (Faloutsos, McCurley & Tomkins, 2004) that measured nodes proximity by employing the notion of effective conductance. Since electric networks are inherently undirected, they cannot be used for our desired directed proximity measure. Nonetheless, the effective conductance can be adequately generalized to handle directional information by using the concept of escape probability (Doyle & Snell, 1984):

DEFINITION 1. The escape probability from node i to node j, $ep_{i,j}$, is the probability that the random particle that starts from node i will visit node j before it returns to node i.

Thus we adopt the escape probability as the starting point for our direction-aware node-to-node proximity score. That is, for the moment, we define the proximity Prox(i, j) from node i to node j as exactly $ep_{i,j}$.

An important quantity for the computation of $ep_{i,j}$ is the *generalized voltage* at each of the nodes, denoted by $v_k(i, j)$: this is defined as the probability that a random particle that starts from node k will visit node j before node i. This way, our proximity measure can be stated as:

$$\text{Prox}(i, j) = ep_{i,j} = \sum_{k=1}^{n} p_{i,k} v_k(i, j) \quad (1)$$

where $p_{i,k}$ is the probability of a direct transition from node i to node k.

For example, in Figure 1(b), we have Prox(A,B)=1 and Prox(B,A)=0.5, which is consistent with our intuition that connections based on longer paths should be weaker. Table 1 lists the main symbols we used in this chapter. Following standard notations, we use capitals for matrices (e.g., W,P), and arrows for column vectors (e.g., $\vec{1}$).

Practical Modifications

Given a weighted directed graph W, there is a natural random walk associated with it whose transition matrix is the normalized version of W, defined as $P = D^{-1}W$. Recall that D is the diagonal matrix of the node out-degrees (specifically, sum of outgoing weights). However, for real problems, this matrix leads to escape probability scores that might not agree with human intuition. In this subsection, we discuss three necessary modifications, to improve the quality of the resulting escape probability scores.

The first modification is to deal with the degree-1 node or dead end. When measuring the escape probability from i to j, we assume that the random particle must eventually reach either i or j. This means that no matter how long it wanders around, it will make unlimited tries, till reaching i or j. This ignores any noise or friction that practically exists in the system and causes the particle to disappear or decay over time. In particular, this problem is manifested in dead-end paths, or degree-1 nodes, which are very common in practical networks whose degree distribution follows a power law. To address this issue, we model the friction in the system by augmenting it with a new node with a zero out degree known as the universal sink (mimicking an absorbing boundary): Now, each node has some small transition probability, 1-c, to reach the sink; and whenever the random particle has reached the sink, it will stay there forever.

The second modification is to deal with the weakly connected pairs. A weakly connected pair is two nodes that are not connected by any directed path, but become connected when considering undirected paths. For such weakly connected pairs, the direction-aware proximity will be zero. However, in some situations, especially when there are missing links in the graph, this might not be desirable. In fact, while we strive to account for

Table 1. Symbols

Symbol	Definition
$W=[w_{i,j}]$	the weighted graph, $1 \le i, j \le n$, $w_{i,j}$ is the weight
A^T	the transpose of matrix A
D	$n \times n$ diagonal matrix of out-degree: $D_{i,i} = \sum_{j=1}^{n} w_{i,j}$ and $D_{i,j} = 0$ for $i \neq j$
$P=[p_{i,j}]$	the transition matrix associated with the graph
$G=[g_{i,j}]$	the G-matrix associated with P: $G = (I - cP)^{-1}$
$\mathbf{V}$	The whole set of the nodes $\mathbf{V} = \{1,2,...,n\}$
$P(i,:)$, $P(:, j)$	i^{th} row of matrix P, and j^{th} column of matrix P, respectively.
Prox(i, j)	node proximity from node i to node j
$\vec{1}$	A column vector whose all elements are 1's
$\vec{e}_i$	A column vector whose i^{th} element is 1 and the rest elements are 0's
c	$(1 - c)$ is the probability to the sink
n	The total number of nodes in the graph

directionality, we also want to consider some portion of the directed link as an undirected one. For example, in phone-call networks, the fact that person A called person B, implies some symmetric relation between the two persons and thereby a greater probability that B will call A (or has already called A, but this link is missing). A random walk modeling of the problem gives us the flexibility to address this issue by introducing lower probability backward edges: whenever we observe an edge $w_{i,j}$ in the original graph, we put another edge in the opposite direction: $w_{j,i} \propto w_{i,j}$. In other words, we replace the original W with $(1-\beta)W + \beta W^{T}$ $(0 < \beta < 1)$.

The third modification is to deal with the size bias. Many of the graphs we deal with are huge, so when computing the proximity, a frequently used technique is to limit its computation to a much smaller candidate graph, which will significantly speed-up the computation. Existing techniques (Faloutsos, McCurley & Tomkins, 2004; Koren, North & Volinsky, 2006), are looking for a moderately sized graph that contains the relevant portions of the network (relatively to a given proximity query), while still enabling quick computation. These techniques can be directly employed when computing our proximity measure. As pointed out in (Koren, North & Volinsky, 2006), for a robust proximity measure, the score given by the candidate graph should not be greater than the score which is based on the full graph. The desired situation is that the proximity between two nodes will monotonically converge to a stable value as the candidate graph becomes larger. However, this is often not the case if we compute the escape probability directly on the candidate graph. To address this issue, we should work with degree preserving candidate graphs. That is, for every node in the candidate graph, its out degree is the same as in the original graph.

Fast Solutions: FastOneDAP and FastAllDAP

Here we deal with the computational aspects of the directed proximity measures defined by equations (2). First, we will show that straight-forward ways to compute these proximities correspond to solving a specific linear system, which involves a matrix inversion. Then, we will propose fast solutions for computing a single proximity on a large graph or all pairwise proximities on a medium sized graph. Notice that these fast solutions will be also beneficial for measuring undirected proximity. For space limitation, we skip the proofs and experimental evaluations of these fast solutions (See (Tong, Koren & Faloutsos, 2007) for details).

Straightforward Solver

Node proximity is based on the linear system (Doyle & Snell, 1984):

$$v_k(i,j) = \sum_{t=1}^{n} c \cdot p_{k,t} \cdot v_t(i,j) \; (k \neq i, j)$$
$$v_i(i,j) = 0; v_j(i,j) = 1 \qquad (2)$$

By solving the above linear system, we have (Doyle & Snell, 1984):

$$\mathrm{Prox}(i,j) = c^2 P(i,\mathbf{I}) G'' P(\mathbf{I},j) + c p_{i,j} \qquad (3)$$

where $\mathbf{I} = \mathbf{V} - \{i, j\}$; $P(i,\mathbf{I})$ is the i^{th} row of matrix P without its i^{th} and j^{th} elements; $P(\mathbf{I}, j)$ is the j^{th} column of matrix P without its i^{th} and j^{th} elements; and $G'' = (I - cP(\mathbf{I},\mathbf{I}))^{-1}$.

In equation (3), the major computational cost is the inversion of an $O(n) \times O(n)$ matrix (G''), which brings up two computational efficiency challenges: (1) For a large graph, say with hundreds of thousands of nodes, matrix inversion would be very slow if not impossible. In this case we would like to completely avoid matrix inversion when computing a single proximity. (2) The above computation requires a different matrix inversion for each proximity value. Thus, it requires performing k separate matrix inversions to compute k proximities. We will show how to eliminate all matrix inversions, but one, regardless of the number of needed proximities.

Computing a Single Proximity

We propose ***FastOneDAP*** (see Box 1), a fast iterative solution for computing one node proximity. ***FastOneDAP*** is $O(mE)$. In other words, ***FastOneDAP*** is linear in the number of edges in the graph. Often, real graphs are very sparse, which means that E is much less than n^2. Thus, ***FastOneDAP*** is significantly more efficient than the straightforward solver, whose running time is $O(n^3)$ due to matrix inversion.

Box 1.

Algorithm 1: FastOneDAP
Input: the transition matrix P, c, the starting node i and the ending node j
Output: the proximity from i to j: Prox(i, j)

1. Initialize:
   a. If $i > j$, $i_0 = i$; else, $i_0 = i - 1$
   b. $\vec{v}^T = \vec{y}^T = \vec{e}_{i_0}^T$
2. Iterate until convergence:
   a. $\vec{y}^T \leftarrow c\vec{y}^T P(\mathbf{V} - \{j\}, \mathbf{V} - \{j\})$
   b. $\vec{v}^T \leftarrow \vec{v}^T + \vec{y}^T$
3. Normalize: $\vec{v}^T = \dfrac{\vec{v}^T}{\vec{v}^T(i_0)}$
4. Return: $\text{Prox}(i, j) = c\vec{v}^T P(\mathbf{V} - \{j\}, j)$

Box 2.

Algorithm 2: FastAllDAP
Input: The transition matrix P, c
Output: All proximities $\text{Pr} = [\text{Prox}(i, j)]_{1 \le i \ne j \le n}$

1. Compute $G = (I - cP)^{-1} = [g_{i,j}]_{1 \le i,j \le n}$
2. For i = 1:n; j = 1:n
   Compute: $\text{Prox}(i, j) = \dfrac{g_{i,j}}{g_{i,i}g_{j,j} - g_{i,j} \cdot g_{j,i}}$

Computing Multiple Proximities

Suppose that we want to compute all $n(n-1)$ pairwise node proximities. There are various situations where one might want to compute all (or many) proximities. First, collecting all proximities and studying their distribution can reveal interesting features of the network and tell us about its global structure. In addition, some algorithms – such as distance based clustering – require the knowledge of all (or at least many) pairwise proximities. Computation of many pairwise proximities in the same network involves solving many linear systems (in fact, one matrix inversion for each proximity). However, there is a lot of redundancy among different linear systems. In fact, we propose a much more efficient method, that need only solve one linear system (or, invert a single matrix) and leverage its result to quickly solve all the others. Consequently, we suggest the ***FastAllDAP*** algorithm (see Box 2). The major benefit of ***FastAllDAP*** is the dramatic reduction of matrix inversion operations from $n(n-1)$ to a single one. In other words, if we treat the matrix inversion as the basic operation, the complexity of ***FastAllDAP*** is O(1).

Applications: Case Studies

We present two applications of our direction-aware proximity as case studies. Here, we only give the basic ideas of these two applications. For the experimental evaluations and some illustrative examples, please refer to (Tong, Koren & Faloutsos, 2007).

Link Prediction

As a proximity measurement, our direction-aware proximity can be directly used for link prediction. More specifically, it can be used for the following two tasks:

T1: (*Existence*) Given two nodes, predict the existence of a link between them

T2: (*Direction*) Given two adjacent (linked) nodes, predict the direction of their link

For T1, we use the simple rule:

A1: Predict a link between i and j iff Prox(i,j) + Prox(j, i) > th (th is a given threshold)

As for directionality prediction, T2, we use the rule:

A2: Predict a link from i to j if Prox(i, j) + Prox(j, i), otherwise predict the opposite direction

Directed Center-Piece Subgraph

The concept connection subgraphs, or center-piece subgraphs, was proposed in (Faloutsos, McCurley & Tomkins, 2004; Tong & Faloutsos, 2006): Given Q query nodes, it creates a subgraph H that shows the relationships between the query nodes. The resulting subgraph should contain the nodes that have strong connection to all or most of the query nodes. Moreover, since this subgraph H is used for visually demonstrating node relations, its visual complexity is capped by setting an upper limit, or a budget on its size. These so-called connection subgraphs (or center-piece subgraphs) were proved useful in various applications, but currently only handle undirected relationships.

With our direction-aware proximity, the algorithm for constructing center-piece subgraphs (CePS) can be naturally generalized to handle directed graphs. A central operation in the original CePS algorithm was to compute an importance score, $r(i, j)$ for a single node j w.r.t. a single query node q_i. Subsequently, these per-query importance scores are combined to importance scores w.r.t. the whole query set, thereby measuring how important each node is relatively to the given group of query nodes. This combination is done through a so-called K_softAND integration that produces $r(\mathbf{Q}, j)$ – the importance score for a single node j w.r.t. the whole query set $\mathbf{Q}$. For more details please refer to (Tong & Faloutsos, 2006).

The main modification that we introduce to the original CePS algorithm is the use of directed proximity for calculating importance scores. The resulting algorithm is named **Dir-CePS** and is given in Algorithm 3 (see Box 3). Directional information must also involve the input to **Dir-CePS** , through the token vector $f = [f_1, ..., f_Q]$ ($f = \pm 1$), which splits the query set into "sources" and "targets", such that each proximity or path are computed from some source to some target. The remaining parts of **Dir-CePS** are exactly the same as in (Tong & Faloutsos, 2006); details are skipped here due to space limitations.

FUTURE TRENDS

We have demonstrated how to encode the edge direction in measuring proximity. Future work in this line includes

Box 3.

Algorithm 3: Dir-CePS
Input: digraph W, query set $\mathbf{Q}$, budget b, token vector $f = [f_1, ..., f_Q]$ ($f = \pm 1$)
Output: the resulting subgraph H

1. For each query node $q_i \in \mathbf{Q}$, each node j in the graph
   If $f_{q_i} = +1$, $r(i, j) = \text{Prox}(q_i, j)$; else $r(i, j) = \text{Prox}(j, q_i)$
2. Combine $r(i, j)$ to get $r(\mathbf{Q}, j)$ by k_SoftAND
3. While H is not big enough
   a. Pick up the node $pd = \arg\max_{j \notin H} r(Q, j)$
   b. For each active source q_i wrt pd
      i. If $f_{q_i} = +1$, find a key path from q_i to pd; else, find a key path from pd to q_i
      ii. Add the key path to H

(1) to generalize the node proximity to measure the relationship between two groups of nodes (see (Tong, Koren & Faloutsos, 2007)); (2) to use parallelism to enable even faster computation of node proximity; and (3) to explore the direction-aware proximity in other data mining tasks.

CONCLUSION

In this work, we study the role of directionality in measuring proximity on graphs. We define a direction-aware proximity measure based on the notion of escape probability. This measure naturally weights and quantifies the multiple relationships which are reflected through the many paths connecting node pairs. Moreover, the proposed proximity measure is carefully designed to deal with practical situations such as accounting for noise and facing partial information.

Given the growing size of networked data, a good proximity measure should be accompanied with a fast algorithm. Consequently we offer fast solutions, addressing two settings. First, we present an iterative algorithm, with convergence guarantee, to compute a single node-to-node proximity value on a large graph. Second, we propose an accurate algorithm that computes all (or many) pairwise proximities on a medium sized graph. These proposed algorithms achieve orders of magnitude speedup compared to straightforward approaches, without quality loss.

Finally, we have studied the applications of the proposed proximity measure to real datasets. Encouraging results demonstrate that the measure is effective for link prediction. Importantly, being direction-aware, it enables predicting not only the existence of the link but also its direction. We also demonstrate how to encode the direction information into the so-called "directed center-piece subgraphs."

KEY TERMS

Degree Preserving: An operation on the candidate graph, ensuring that the out-degree for each node in the candidate graph is the same as that in the original graph.

Direction Aware Node Proximity: A measure of the closeness from one node to another on the directed graph.

Escape Probability (from node *i* to node *j*): The probability that a random particle that starts from node *i* will visit node *j* before it returns to node *i*.

Generalized Voltage (wrt node *i* to node *j* at node *k*): The probability that a random particle that starts from node *k* will visit node *j* before node *i*

Monotonicity of Proxmity: The property of proximity, measuring that the proximity measured on the smaller candidate graph is always not bigger than that measured on a larger candidate graph.

Transition Matrix: A square matrix, each of whose rows consists of nonnegative real numbers, with each row summing to 1, representing the probability of direct transition between two nodes.

Universal Sink: A node in the graph that has in-link from every other node but no out-link.

Discovering an Effective Measure in Data Mining

Takao Ito
Ube National College of Technology, Japan

INTRODUCTION

One of the most important issues in data mining is to discover an implicit relationship between words in a large corpus and labels in a large database. The relationship between words and labels often is expressed as a function of distance measures. An effective measure would be useful not only for getting the high precision of data mining, but also for time saving of the operation in data mining. In previous research, many measures for calculating the one-to-many relationship have been proposed, such as the complementary similarity measure, the mutual information, and the phi coefficient. Some research showed that the complementary similarity measure is the most effective. The author reviewed previous research related to the measures in one-to-many relationships and proposed a new idea to get an effective one, based on the heuristic approach in this article.

BACKGROUND

Generally, the knowledge discover in databases (KDD) process consists of six stages: data selection, cleaning, enrichment, coding, data mining, and reporting (Adriaans & Zantinge, 1996). Needless to say, data mining is the most important part in the KDD. There are various techniques, such as statistical techniques, association rules, and query tools in a database, for different purposes in data mining. (Agrawal, Mannila, Srikant, Toivonen & Verkamo, 1996; Berland & Charniak, 1999; Caraballo, 1999; Fayyad, Piatetsky-Shapiro, Smyth & Uthurusamy, 1996; Han & Kamber, 2001).

When two words or labels in a large database have some implicit relationship with each other, one of the different purposes is to find out the two relative words or labels effectively. In order to find out relationships between words or labels in a large database, the author found the existence of at least six distance measures after reviewing previously conducted research.

The first one is the mutual information proposed by Church and Hanks (1990). The second one is the confidence proposed by Agrawal and Srikant (1995). The third one is the complementary similarity measure (CSM) presented by Hagita and Sawaki (1995). The fourth one is the dice coefficient. The fifth one is the Phi coefficient. The last two are both mentioned by Manning and Schutze (1999). The sixth one is the proposal measure (PM) suggested by Ishiduka, Yamamoto, and Umemura (2003). It is one of the several new measures developed by them in their paper.

In order to evaluate these distance measures, formulas are required. Yamamoto and Umemura (2002) analyzed these measures and expressed them in four parameters of a, b, c, and d (Table 1).

Suppose that there are two words or labels, x and y, and they are associated together in a large database. The meanings of these parameters in these formulas are as follows:

a. The number of documents/records that have x and y both.
b. The number of documents/records that have x but not y.
c. The number of documents/records that do not have x but do have y.
d. The number of documents/records that do not have either x or y.
n. The total number of parameters a, b, c, and d.

Umemura (2002) pointed out the following in his paper: "Occurrence patterns of words in documents can be expressed as binary. When two vectors are similar, the two words corresponding to the vectors may have some implicit relationship with each other." Yamamoto and Umemura (2002) completed their experiment to test the validity of these indexes under Umemura's con-

Table 1. Kind of distance measures and their formulas

No	Kind of Distance Measures	Formula
1	the mutual information	$I(x_1; y_1) = \log \frac{an}{(a+b)(a+c)}$
2	the confidence	$conf(Y \mid X) = \frac{a}{a+c}$
3	the complementary similarity measure	$S_c(\vec{F}, \vec{T}) = \frac{ad - bc}{\sqrt{(a+c)(b+d)}}$
4	the dice coefficient	$S_d(F, T) = \frac{2a}{(a+b)+(a+c)}$
5	the Phi coefficient	$\varphi_{DE} = \frac{ad - bc}{\sqrt{(a+b)(a+c)(b+d)(c+d)}}$
6	the proposal measure	$S(\vec{F}, \vec{T}) = \frac{a^2 b}{1+c}$

cept. The result of the experiment of distance measures without noisy pattern from their experiment can be seen in Figure 1 (Yamamoto & Umemura, 2002).

The experiment by Yamamoto and Umemura (2002) showed that the most effective measure is the CSM. They indicated in their paper as follows: "All graphs showed that the most effective measure is the complementary similarity measure, and the next is the confidence and the third is asymmetrical average mutual information. And the least is the average mutual information" (Yamamoto and Umemura, 2002). They also completed their experiments with noisy pattern and found the same result (Yamamoto & Umemura, 2002).

MAIN THRUST

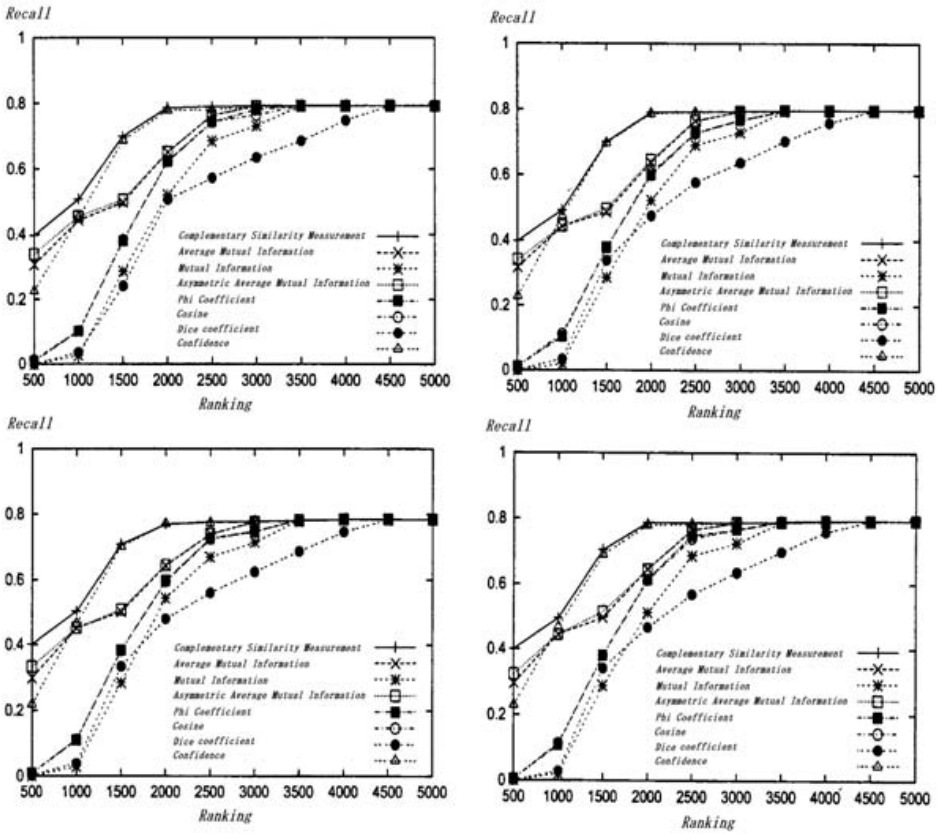
How to select a distance measure is a very important issue, because it has a great influence on the result of data mining (Fayyad, Piatetsky-Shapiro & Smyth, 1996; Glymour, Madigan, Pregibon & Smyth, 1997) The author completed the following three kinds of experiments, based upon the heuristic approach, in order to discover an effective measure in this article (Aho, Kernighan & Weinberger, 1995).

RESULT OF THE THREE KINDS OF EXPERIMENTS

All of these three kinds of experiments are executed under the following conditions. In order to discover an effective measure, the author selected actual data of a place's name, such as the name of prefecture and the name of a city in Japan from the articles of a nationally circulated newspaper, the *Yomiuri*. The reasons for choosing a place's name are as follows: first, there are one-to-many relationships between the name of a prefecture and the name of a city; second, the one-to-many relationship can be checked easily from the maps and telephone directory. Generally speaking, the first name, such as the name of a prefecture, consists of another name, such as the name of a city. For instance, Fukuoka City is geographically located in Fukuoka Prefecture, and Kitakyushu City also is included in Fukuoka Prefecture, so there are one-to-many relationships between the name of the prefecture and the name of the city.

The distance measure would be calculated with a large database in the experiments. The experiments were executed as follows:

Figure 1. Result of the experiment of distance measures without noisy pattern



Step 1. Establish the database of the newspaper.
Step 2. Choose the prefecture name and city name from the database mentioned in step 1.
Step 3. Count the number of parameters a, b, c, and d from the newspaper articles.
Step 4. Then, calculate the distance measure adopted.
Step 5. Sort the result calculated in step 4 in descent order upon the distance measure.
Step 6. List the top 2,000 from the result of step 5.
Step 7. Judge the one-to-many relationship whether it is correct or not.
Step 8. List the top 1,000 as output data and count its number of correct relationships.
Step 9. Finally, an effective measure will be found from the result of the correct number.

To uncover an effective one, two methods should be considered. The first one is to test various combinations of each variable in distance measure and to find the best combination, depending upon the result. The second one is to assume that the function is a stable one and that only part of the function can be varied.

The first one is the experiment with the PM.

The total number of combinations of five variables is 3,125. The author calculated all combinations, except for the case when the denominator of the PM becomes zero. The result of the top 20 in the PM experiment, using a year's amount of articles from the *Yomiuri* in 1991, is calculated as follows.

In Table 2, the No. 1 function of a11c1 has a highest correct number, which means

$$S(\vec{F},\vec{T}) = \frac{a \times 1 \times 1}{c+1} = \frac{a}{1+c}.$$

The No. 11 function of 1a1c0 means

$$S(\vec{F},\vec{T}) = \frac{1 \times a \times 1}{c+0} = \frac{a}{c}.$$

The rest function in Table 2 can be read as mentioned previously.

This result appears to be satisfactory. But to prove whether it is satisfactory or not, another experiment should be done. The author adopted the Phi coefficient and calculated its correct number. To compare with the result of the PM experiment, the author completed the experiment of iterating the exponential index of denominator in the Phi coefficient from 0 to 2, with 0.01 step based upon the idea of fractal dimension in the complex theory instead of fixed exponential index at 0.5. The result of the top 20 in this experiment, using a year's amount of articles from the *Yomiuri* in 1991, just like the first experiment, can be seen in Table 3.

Compared with the result of the PM experiment mentioned previously, it is obvious that the number of correct relationships is less than that of the PM experiment; therefore, it is necessary to uncover a new, more effective measure. From the previous research done by Yamamoto and Umemura (2002), the author found that an effective measure is the CSM.

The author completed the third experiment using the CMS. The experiment began by iterating the exponential index of the denominator in the CSM from 0 to 1, with 0.01 steps just like the second experiment. Table 4 shows the result of the top 20 in this experiment, using a year's amount of articles from the *Yomiuri* from 1991-1997.

Table 2. Result of the top 20 in the PM experiment

No	Function	Correct Number	No	Function	Correct Number
1	a11c1	789	11	1a1c0	778
2	a111c	789	12	1a10c	778
3	1a1c1	789	13	11acc	778
4	1a11c	789	14	11ac0	778
5	11ac1	789	15	11a0c	778
6	11a1c	789	16	aa1cc	715
7	a11cc	778	17	aa1c0	715
8	a11c0	778	18	aa10c	715
9	a110c	778	19	a1acc	715
10	1a1cc	778	20	a1ac0	715

Table 3. Result of the top 20 in the Phi coefficient experiment

No	Exponential Index	Correct Number	No	Exponential index	Correct Number
1	0.26	499	11	0.20	465
2	0.25	497	12	0.31	464
3	0.27	495	13	0.19	457
4	0.24	493	14	0.32	445
5	0.28	491	15	0.18	442
6	0.23	488	16	0.17	431
7	0.29	480	17	0.16	422
8	0.22	478	18	0.15	414
9	0.21	472	19	0.14	410
10	0.30	470	20	0.13	403

It is obvious by these results that the CSM is more effective than the PM and the Phi coefficient. The relationship of the complete result of the exponential index of the denominator in the CSM and the correct number can be seen as in Figure 2.

The most effective exponential index of the denominator in the CSM is from 0.73 to 0.85, but not as 0.5, as many researchers believe. It would be hard to get the best result with the usual method using the CSM.

Determine the Most Effective Exponential Index of the Denominator in the CSM

To discover the most effective exponential index of the denominator in the CSM, a calculation about the relationship between the exponential index and the total number of documents of n was carried out, but none was found. In fact, it is hard to consider that the exponential index would vary with the difference of the number of documents.

The details of the four parameters of a, b, c, and d in Table 4 are listed in Table 5.

The author adopted the average of the cumulative exponential index to find the most effective exponential index of the denominator in the CSM. Based upon the results in Table 4, calculations for the average of the cumulative exponential index of the top 20 and those results are presented in Figure 3.

From the results in Figure 3, it is easy to understand that the exponential index converges at a constant value of about 0.78. Therefore, the exponential index could be fixed at a certain value, and it will not vary with the size of documents.

In this article, the author puts the exponential index at 0.78 to forecast the correct number. The gap between the calculation result forecast by the revised method and the maximum result of the third experiment is illustrated in Figure 4.

FUTURE TRENDS

Many indexes have been developed for the discovery of an effective measure to determine an implicit relationship between words in a large corpus or labels in a large database. Ishiduka, Yamamoto, and Umemura (2003) referred to part of them in their research paper. Almost all of these approaches were developed by a variety of mathematical and statistical techniques, a conception of neural network, and the association rules.

For many things in the world, part of the economic phenomena obtain a normal distribution referred to in statistics, but others do not, so the author developed the CSM measure from the idea of fractal dimension in this article. Conventional approaches may be inherently inaccurate, because usually they are based upon

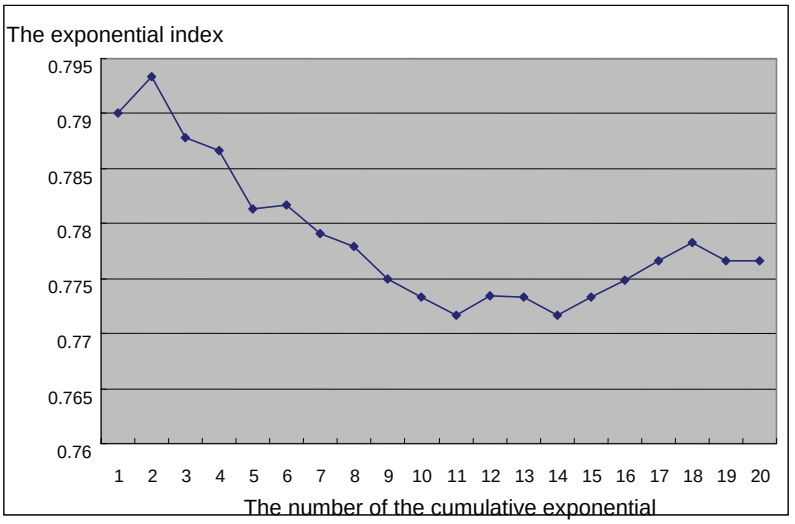

Figure 4. Gaps between the maximum correct number and the correct number forecasted by the revised meth-

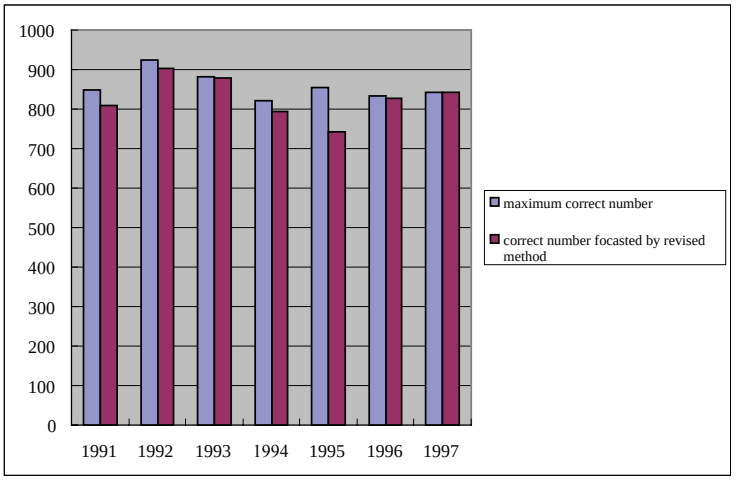

linear mathematics. The events of a concurrence pattern of correlated pair words may be explained better by nonlinear mathematics. Typical tools of nonlinear mathematics are complex theories, such as chaos theory, cellular automaton, percolation model, and fractal theory. It is not hard to predict that many more new measures will be developed in the near future, based upon the complex theory.

CONCLUSION

Based upon previous research of the distance measures, the author discovered an effective measure of distance measure in one-to-many relationships with the heuristic approach. Three kinds of experiments were conducted, and it was confirmed that an effective measure is the CSM. In addition, it was discovered that the most effective exponential of the denominator in the CSM is 0.78, not 0.50, as many researchers believe.

A great deal of work still needs to be carried out, and one of them is the meaning of the 0.78. The meaning of the most effective exponential of denominator 0.78 in the CSM should be explained and proved mathematically, although its validity has been evaluated in this article.

ACKNOWLEDGMENTS

The author would like to express his gratitude to the following: Kyoji Umemura, Professor, Toyohashi University of Technology; Taisuke Horiuchi, Associate Professor, Nagano National College of Technology; Eiko Yamamoto, Researcher, Communication Research Laboratories; Yuji Minami, Associate Professor, Ube National College of Technology; Michael Hall, Lecturer, Nakamura-Gakuen University; who suggested a large number of improvements, both in content and computer program.

KEY TERMS

Complementary Similarity Measurement: An index developed experientially to recognize a poorly printed character by measuring the resemblance of the correct pattern of the character expressed in a vector. The author calls this a diversion index to identify the one-to-many relationship in the concurrence patterns of words in a large corpus or labels in a large database in this article.

Confidence: An asymmetric index that shows the percentage of records for which A occurred within the group of records and for which the other two, X and

Y, actually occurred under the association rule of X, Y => A.

Correct Number: For example, if the city name is included in the prefecture name geographically, the author calls it correct. So, in this index, the correct number indicates the total number of correct one-to-many relationship calculated on the basis of the distance measures.

Distance Measure: One of the calculation techniques to discover the relationship between two implicit words in a large corpus or labels in a large database from the viewpoint of similarity.

Mutual Information: Shows the amount of information that one random variable x contains about another y. In other words, it compares the probability of observing x and y, together with the probabilities of observing x and y independently.

Phi Coefficient: One metric for corpus similarity measured upon the chi square test. It is an index to calculate the frequencies of the four parameters of a, b, c, and d in documents based upon the chi square test with the frequencies expected for independence.

Proposal Measure: An index to measure the concurrence frequency of the correlated pair words in documents, based upon the frequency of two implicit words that appear. It will have high value, when the two implicit words in a large corpus or labels in a large database occur with each other frequently.

Discovering Knowledge from XML Documents

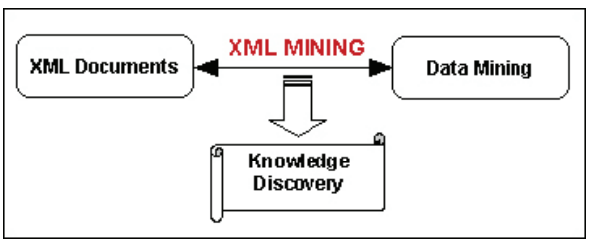
Richi Nayak
Queensland University of Technology, Australia

INTRODUCTION

XML is the new standard for information exchange and retrieval. An XML document has a schema that defines the data definition and structure of the XML document (Abiteboul et al., 2000). Due to the wide acceptance of XML, a number of techniques are required to retrieve and analyze the vast number of XML documents. Automatic deduction of the structure of XML documents for storing semi-structured data has been an active subject among researchers (Abiteboul et al., 2000; Green et al., 2002). A number of query languages for retrieving data from various XML data sources also has been developed (Abiteboul et al., 2000; W3c, 2004). The use of these query languages is limited (e.g., limited types of inputs and outputs, and users of these languages should know exactly what kinds of information are to be accessed). Data mining, on the other hand, allows the user to search out unknown facts, the information hidden behind the data. It also enables users to pose more complex queries (Dunham, 2003).

Figure 1 illustrates the idea of integrating data mining algorithms with XML documents to achieve knowledge discovery. For example, after identifying similarities among various XML documents, a mining technique can analyze links between tags occurring together within the documents. This may prove useful in the analysis of e-commerce Web documents recommending personalization of Web pages.

Figure 1. XML mining scheme



BACKGROUND: WHAT IS XML MINING?

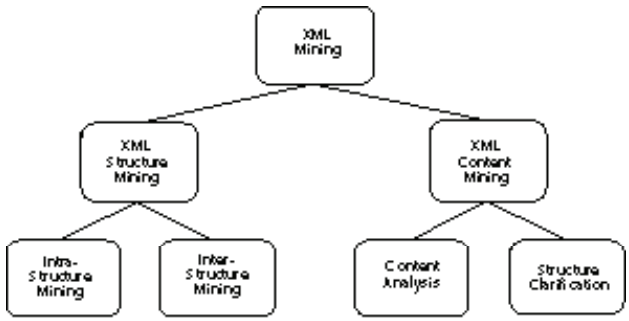
XML mining includes mining of structures as well as contents from XML documents, depicted in Figure 2 (Nayak et al., 2002). Element tags and their nesting therein dictate the structure of an XML document (Abiteboul et al., 2000). For example, the textual structure enclosed by <author>… </author> is used to describe the author tuple and its corresponding text in the document. Since XML provides a mechanism for tagging names with data, knowledge discovery on the semantics of the documents becomes easier for improving document retrieval on the Web. Mining of XML structure is essentially mining of schema including intrastructure mining, and interstructure mining.

Intrastructure Mining

Concerned with the structure within an XML document. Knowledge is discovered about the internal structure of XML documents in this type of mining. The following mining tasks can be applied.

The classification task of data mining maps a new XML document to a predefined class of documents. A schema is interpreted as a description of a class of XML documents. The classification procedure takes a collection of schemas as a training set and classifies new XML documents according to this training set.

Figure 2. A taxonomy of XML mining



The clustering task of data mining identifies similarities among various XML documents. A clustering algorithm takes a collection of schemas to group them together on the basis of self-similarity. These similarities are then used to generate new schema. As a generalization, the new schema is a superclass to the training set of schemas. This generated set of clustered schemas can now be used in classifying new schemas. The superclass schema also can be used in integration of heterogeneous XML documents for each application domain. This allows users to find, collect, filter, and manage information sources more effectively on the Internet.

The association data mining describes relationships between tags that tend to occur together in XML documents that can be useful in the future. By transforming the tree structure of XML into a pseudo-transaction, it becomes possible to generate rules of the form "if an XML document contains a <craft> tag, then 80% of the time it also will contain a <licence> tag." Such a rule then may be applied in determining the appropriate interpretation for homographic tags.

Interstructure Mining

Concerned with the structure between XML documents. Knowledge is discovered about the relationship between subjects, organizations, and nodes on the Web in this type of mining. The following mining tasks can be applied.

Clustering schemas involves identifying similar schemas. The clusters are used in defining hierarchies of schemas. The schema hierarchy overlaps instances on the Web, thus discovering authorities and hubs (Garofalakis et al. 1999). Creators of schema are identified as authorities, and creators of instances are hubs. Additional mining techniques are required to identify all instances of schema present on the Web. The following application of classification can identify the most likely places to mine for instances. Classification is applied with namespaces and URIs (Uniform Resource Identifiers). Having previously associated a set of schemas with a particular namespace or URI, this information is used to classify new XML documents originating from these places.

Content is the text between each start and end tag in XML documents. Mining for XML content is essentially mining for values (an instance of a relation), including content analysis and structural clarification.

Content Analysis

Concerned with analysing texts within XML documents. The following mining tasks can be applied to contents.

Classification is performed on XML content, labeling new XML content as belonging to a predefined class. To reduce the number of comparisons, pre-existing schemas classify the new document's schema. Then, only the instance classifications of the matching schemas need to be considered in classifying a new document.

Clustering on XML content identifies the potential for new classifications. Again, consideration of schemas leads to quicker clustering; similar schemas are likely to have a number of value sets. For example, all schemas concerning vehicles have a set of values representing cars, another set representing boats, and so forth. However, schemas that appear dissimilar may have similar content. Mining XML content inherits some problems faced in text mining and analysis. Synonymy and polysemy can cause difficulties, but the tags surrounding the content usually can help resolve ambiguities.

Structural Clarification

Concerned with distinguishing the similar structured documents based on contents. The following mining tasks can be performed.

Content provides support for alternate clustering of similar schemas. Two distinctly structured schemas may have document instances with identical content. Mining these avails new knowledge. Vice versa, schemas provide support for alternate clustering of content. Two XML documents with distinct content may be clustered together, given that their schemas are similar.

Content also may prove important in clustering schemas that appear different but have instances with similar content. Due to heterogeneity, the incidence of synonyms is increased. Are separate schemas actually describing the same thing, only with different terms? While thesauruses are vital, it is impossible for them to be exhaustive for the English language, let alone handle all languages. Conversely, schemas appearing similar actually are completely different, given homographs. The similarity of the content does not distinguish the semantic intention of the tags. Mining, in this case, pro-

vides probabilities of a tag having a particular meaning or a relationship between meaning and a URI.

METHODS OF XML STRUCTURE MINING

Mining of structures from a well-formed or valid document is straightforward, since a valid document has a schema mechanism that defines the syntax and structure of the document. However, since the presence of schema is not mandatory for a well-formed XML document, the document may not always have an accompanying schema. To describe the semantic structure of the documents, schema extraction tools are needed to generate schema for the given well-formed XML documents.

DTD Generator (Kay, 2000) generates the DTD for a given XML document. However, the DTD generator yields a distinct DTD for every XML document; hence, a set of DTDs is defined for a collection of XML documents rather than an overall DTD. Thus, the application of data mining operations will be difficult in this matter. Tools such as XTRACT (Garofalakis, 2000) and DTD-Miner (Moh et al., 2000) infer an accurate and semantically meaningful DTD schema for a given collection of XML documents. However, these tools depend critically on being given a relatively homogeneous collection of XML documents. In such heterogeneous and flexible environment as the Web, it is not reasonable to assume that XML documents related to the same topic have the same document structure.

Due to a number of limitations using DTDs as an internal structure, such as limited set of data types, loose structure constraints, and limitation of content to textual, many researchers propose the extraction of XML schema as an extension to XML DTDs (Feng et al., 2002; Vianu, 2001). In Chidlovskii (2002), a novel XML schema extraction algorithm is proposed, based on the Extended Context-Free Grammars (ECFG) with a range of regular expressions. Feng et al. (2002) also presented a semantic network-based design to convey the semantics carried by the XML hierarchical data structures of XML documents and to transform the model into an XML schema. However, both of these proposed algorithms are very complex.

Mining of structures from ill-formed XML documents (that lack any fixed and rigid structure) are performed by applying the structure extraction approaches developed for semi-structured documents. But not all of these techniques can effectively support the structure extraction from XML documents that is required for further application of data mining algorithms. For instance, the NoDoSe tool (Adelberg & Denny, 1999) determines the structure of a semi-structured document and then extracts the data. This system is based primarily on plain text and HTML files, and it does not support XML. Moreover, in Green, et al. (2002), the proposed extraction algorithm considers both structure and contents in semi-structured documents, but the purpose is to query and build an index. They are difficult to use without some alteration and adaptation for the application of data mining algorithms.

An alternative method is to approach the document as the Object Exchange Model (OEM) (Nestorov et al. 1999; Wang et al. 2000) data by using the corresponding data graph to produce the most specific data guide (Nayak et al., 2002). The data graph represents the interactions between the objects in a given data domain. When extracting a schema from a data graph, the goal is to produce the most specific schema graph from the original graph. This way of extracting schema is more general than using the schema for a guide, because most of the XML documents do not have a schema, and sometimes, if they have a schema, they do not conform to it.

METHODS OF XML CONTENT MINING

Before knowledge discovery in XML documents occurs, it is necessary to query XML tags and content to prepare the XML material for mining. An SQL-based query can extract data from XML documents. There are a number of query languages, some specifically designed for XML and some for semi-structured data, in general. Semi-structured data can be described by the grammar of SSD (semi-structured data) expressions. The translation of XML to SSD expression is easily automated (Abiteboul et al., 2000). Query languages for semi-structured data exploit path expressions. In this way, data can be queried to an arbitrary depth. Path expressions are elementary queries with the results returned as a set of nodes. However, the ability to return results as semi-structured data is required, which path expressions alone cannot do. Combining path expressions with SQL-style syntax provides greater flexibility in testing for equality, performing

joins, and specifying the form of query results. Two such languages are Lorel (Abiteboul et al., 2000) and Unstructured Query Language (UnQL) (Farnandez et al., 2000). UnQL requires more precision and is more reliant on path expressions.

XML-QL, XML-GL, XSL, and Xquery are designed specifically for querying XML (W3c, 2004). XML-QL (Garofalsaki et al., 1999) and Xquery bring together regular path expressions, SQL-style query techniques, and XML syntax. The great benefit is the construction of the result in XML and, thus, transforming XML data from one schema to another. Extensible Stylesheet Language (XSL) is not implemented as a query language but is intended as a tool for transforming XML to HTML. However, XSL'_S select pattern is a mechanism for information retrieval and, as such, is akin to a query (W3c, 2004). XML-GL (Ceri et al., 1999) is a graphical language for querying and restructuring XML documents.

FUTURE TRENDS

There has been extensive effort to devise new technologies to process and integrate XML documents, but a lot of open possibilities still exist. For example, integration of data mining, XML data models and database languages will increase the functionality of relational database products, data warehouses, and XML products. Also, to satisfy the range of data mining users (from naive to expert users), future work should include mining user graphs that are structural information of Web usages, as well as visualization of mined data. As data mining is applied to large semantic documents or XML documents, extraction of information should consider rights management of shared data. XML mining should have the authorization level to empower security to restrict only appropriate users to discover classified information.

CONCLUSION

XML has proved effective in the process of transmitting and sharing data over the Internet. Companies want to bring this advantage into analytical data, as well. As XML material becomes more abundant, the ability to gain knowledge from XML sources decreases due to their heterogeneity and structural irregularity; the idea behind the XML data mining looks like a solution to put to work. Using XML data in the mining process has become possible through new Web-based technologies that have been developed. Simple Object Access Protocol (SOAP) is a new technology that has enabled XML to be used in data mining. For example, vTag Web Mining Server aims at monitoring and mining of the Web with the use of information agents accessed by SOAP (vtag, 2003). Similarly, XML for Analysis defines a communication structure for an application programming interface, which aims at keeping client programming independent from the mechanics of data transport but, at the same time, providing adequate information concerning the data and ensuring that it is properly handled (XMLanalysis, 2003). Another development, YALE, is an environment for machine learning experiments that uses XML files to describe data mining experiments setup (Yale, 2004). The Data Miner's ARCADE also uses XML as the target language' for all data mining tools within its environment (Arcade, 2004).

KEY TERMS

Ill-Formed XML Documents: Lack any fixed and rigid structure.

Valid XML Document: To be valid, an XML document additionally must conform (at least) to an explicitly associated document schema definition.

Well-Formed XML Documents: To be well-formed, a page's XML must have properly nested tags, unique attributes (per element), one or more elements, exactly one root element, and a number of schema-related constraints. Well-formed documents may have a schema, but they do not conform to it.

XML Content Analysis Mining: Concerned with analysing texts within XML documents.

XML Interstructure Mining: Concerned with the structure between XML documents. Knowledge is discovered about the relationship among subjects, organizations, and nodes on the Web.

XML Intrastructure Mining: Concerned with the structure within an XML document(s). Knowledge is discovered about the internal structure of XML documents.

XML Mining: Knowledge discovery from XML documents (heterogeneous and structural irregular). For example, clustering data mining techniques can group a collection of XML documents together according to the similarity of their structures. Classification data mining techniques can classify a number of heterogeneous XML documents into a set of predefined classification of schemas to improve XML document handling and achieve efficient searches.

XML Structural Clarification Mining: Concerned with distinguishing the similar structured documents based on contents.

Discovering Unknown Patterns in Free Text

Jan H Kroeze
University of Pretoria, South Africa

Machdel C Matthee
University of Pretoria, South Africa

INTRODUCTION

A very large percentage of business and academic data is stored in textual format. With the exception of metadata, such as author, date, title and publisher, this data is not overtly structured like the standard, mainly numerical, data in relational databases. Parallel to data mining, which finds new patterns and trends in numerical data, text mining is the process aimed at discovering unknown patterns in free text. Owing to the importance of competitive and scientific knowledge that can be exploited from these texts, "text mining has become an increasingly popular and essential theme in data mining" (Han & Kamber, 2001, p. 428).

Text mining is an evolving field and its relatively short history goes hand in hand with the recent explosion in availability of electronic textual information. Chen (2001, p. vi) remarks that "text mining is an emerging technical area that is relatively unknown to IT professions". This explains the fact that despite the value of text mining, most research and development efforts still focus on data mining using structured data (Fan et al., 2006).

In the next section, the background and need for text mining will be discussed after which the various uses and techniques of text mining are described. The importance of visualisation and some critical issues will then be discussed followed by some suggestions for future research topics.

BACKGROUND

Definitions of text mining vary a great deal, from views that it is an advanced form of information retrieval (IR) to those that regard it as a sibling of data mining:

- Text mining is the discovery of texts.
- Text mining is the exploration of available texts.
- Text mining is the extraction of information from text.
- Text mining is the discovery of new knowledge in text.
- Text mining is the discovery of new patterns, trends and relations in and among texts.

Han & Kamber (2001, pp. 428-435), for example, devote much of their rather short discussion of text mining to information retrieval. However, one should differentiate between text mining and information retrieval. Text mining does not consist of searching through metadata and full-text databases to find existing information. The point of view expressed by Nasukawa & Nagano (2001, p. 969), to wit that text mining "is a text version of generalized data mining", is correct. Text mining should "focus on finding valuable patterns and rules in text that indicate trends and significant features about specific topics" (ibid., p. 967).

Like data mining, text mining is a proactive process that automatically searches data for new relationships and anomalies to serve as a basis for making business decisions aimed at gaining competitive advantage (cf. Rob & Coronel, 2004, p. 597). Although data mining can require some interaction between the investigator and the data-mining tool, it can be considered as an automatic process because "*data-mining tools automatically search the data for anomalies and possible relationships, thereby identifying problems that have not yet been identified by the end user*", while mere data analysis "*relies on the end users to define the problem, select the data, and initiate the appropriate data analyses to generate the information that helps model and solve problems those end-users uncover*" (ibid.). The same distinction is valid for text mining. Therefore, text-mining tools should also "*initiate* analyses to create knowledge" (ibid., p. 598).

In practice, however, the borders between data analysis, information retrieval and text mining are not always quite so clear. Montes-y-Gómez et al. (2004)

proposed an integrated approach, called *contextual exploration*, which combines robust access (IR), non-sequential navigation (hypertext) and content analysis (text mining).

THE NEED FOR TEXT MINING

Text mining can be used as an effective business intelligence tool for gaining competitive advantage through the discovery of critical, yet hidden, business information. As a matter of fact, all industries traditionally rich in documents and contracts can benefit from text mining (McKnight, 2005). For example, in medical science, text mining is used to build and structure medical knowledge bases, to find undiscovered relations between diseases and medications or to discover gene interactions, functions and relations (De Bruijn & Martin, 2002, p. 8). A recent application of this is where Gajendran, Lin and Fyhrie (2007) use text mining to predict potentially novel target genes for osteoporosis research that has not been reported on in previous research. Also, government intelligence and security agencies find text mining useful in predicting and preventing terrorist attacks and other security threats (Fan et al., 2006).

USES OF TEXT MINING

The different types of text mining have the following in common: it differs from data mining in that it extracts patterns from free (natural language) text rather than from structured databases. However, it does this by using data mining techniques: "it numericizes the unstructured text document and then, using data mining tools and techniques, extracts patterns from them" (Delen and Crossland, 2007:4). In this section various uses of text mining will be discussed, as well as the techniques employed to facilitate these goals. Some examples of the implementation of these text mining approaches will be referred to. The approaches that will be discussed include categorisation, clustering, concept-linking, topic tracking, anomaly detection and web mining.

Categorisation

Categorisation focuses on identifying the main themes of a document after which the document is grouped according to these. Two techniques of categorisation are discussed below:

Keyword-Based Association Analysis

Association analysis looks for correlations between texts based on the occurrence of related keywords or phrases. Texts with similar terms are grouped together. The pre-processing of the texts is very important and includes parsing and stemming, and the removal of words with minimal semantic content. Another issue is the problem of compounds and non-compounds - should the analysis be based on singular words or should word groups be accounted for? (cf. Han & Kamber, 2001, p. 433). Kostoff et al. (2002), for example, have measured the frequencies and proximities of phrases regarding electrochemical power to discover central themes and relationships among them. This knowledge discovery, combined with the interpretation of human experts, can be regarded as an example of knowledge creation through intelligent text mining.

Automatic Document Classification

Electronic documents are classified according to a predefined scheme or training set. The user compiles and refines the classification parameters, which are then used by a computer program to categorise the texts in the given collection automatically (cf. Sullivan, 2001, p. 198). Classification can also be based on the analysis of collocation ("the juxtaposition or association of a particular word with another particular word or words" (The Oxford Dictionary, 9th Edition, 1995)). Words that often appear together probably belong to the same class (Lopes et al., 2004). According to Perrin & Petry (2003) "useful text structure and content can be systematically extracted by collocational lexical analysis" with statistical methods. Text classification can be applied by businesses, for example, to personalise B2C e-commerce applications. Zhang and Jiao (2007) did this by using a model that anticipates customers' heterogeneous requirements as a pre-defined scheme for the classification of e-commerce sites for this purpose (Zhang & Jiao, 2007).

Clustering

Texts are grouped according to their own content into categories that were not previously known. The documents are analysed by a clustering computer program, often a neural network, but the clusters still have to be interpreted by a human expert (Hearst, 1999). Document pre-processing (tagging of parts of speech, lemmatisation, filtering and structuring) precedes the actual clustering phase (Iiritano et al., 2004). The clustering program finds similarities between documents, e.g. common author, same themes, or information from common sources. The program does not need a training set or taxonomy, but generates it dynamically (cf. Sullivan, 2001, p. 201). One example of the use of text clustering in the academic field is found in the work of Delen and Crossland (2007) whose text-mining tool processes articles from three major journals in the management information systems field to identify major themes and trends of research in this area.

Concept Linking

In text databases, concept linking is the finding of meaningful, high levels of correlations between text entities. Concept linking is implemented by the technique called link analysis, "the process of building up networks of interconnected objects through relationships in order to expose patterns and trends" (Westphal, 1998, p. 202). The user can, for example, suggest a broad hypothesis and then analyse the data in order to prove or disprove this hunch. It can also be an automatic or semi-automatic process, in which a surprisingly high number of links between two or more nodes may indicate relations that have hitherto been unknown. Link analysis can also refer to the use of algorithms to build and exploit networks of hyperlinks in order to find relevant and related documents on the Web (Davison, 2003). Concept linking is used, for example, to identify experts by finding and evaluating links between persons and areas of expertise (Ibrahim, 2004). Yoon & Park (2004) use concept linking and information visualisation to construct a visual network of patents, which facilitates the identification of a patent's relative importance: "The coverage of the application is wide, ranging from new idea generation to ex post facto auditing" (ibid, p. 49).

Topic Tracking

Topic tracking is the discovery of a developing trend in politics or business, which may be used to predict recurring events. It thus involves the discovery of patterns that are related to time frames, for example, the origin and development of a news thread (cf. Montes-y-Gómez et al., 2001). The technique that is used to do this is called sequence analysis. A sequential pattern is the arrangement of a number of elements, in which the one leads to the other over time (Wong et al., 2000). An example of topic tracking is a system that remembers user profiles and, based on that, predict other documents of interest to the user (Delen & Crossland, 2007).

Anomaly Detection

Anomaly detection is the finding of information that violates the usual patterns, e.g. a book that refers to a unique source, or a document lacking typical information. Link analysis and keyword-based analysis, referred to above, are techniques that may also be used for this purpose. An example of anomaly detection is the detection of irregularities in news reports or different topic profiles in newspapers (Montes-y-Gómez et al., 2001).

Web Mining

"Text mining is about looking for patterns in natural language text…. Web mining is the slightly more general case of looking for patterns in hypertext and often applies graph theoretical approaches to detect and utilise the structure of web sites." (New Zealand Digital Library, 2002)

In addition to the obvious hypertext analysis, various other techniques are used for web mining. Marked-up language, especially XML tags, facilitates text mining because the tags can often be used to simulate database attributes and to convert data-centric documents into databases, which can then be exploited (Tseng & Hwung, 2002). Mark-up tags also make it possible to create "artificial structures [that] help us understand the relationship between documents and document components" (Sullivan, 2001, p. 51). Such tags could, for example, be used to store linguistic analyses regarding the various language modules of a text, enabling

the application of data warehousing and data mining concepts in the humanities (cf. Kroeze, 2007).

Web-applications nowadays integrate a variety of types of data, and web mining will focus increasingly on the effective exploitation of such multi-faceted data. Web mining will thus often include an integration of various text mining techniques. One such an application of web mining where multiple text mining techniques are used is natural language queries or "question answering" (Q&A). Q&A deals with finding the best answer to a given question on the web (Fan et al., 2006). Another prominent application area of web mining is recommendation systems (e.g. personalisation), the design of which should be robust since security is becoming an increasing concern (Nasraoui et al., 2005).

INFORMATION VISUALISATION

Information visualisation "puts large textual sources in a visual hierarchy or map and provides browsing capabilities, in addition to simple searching" (Fan et al., 2006:80). Although this definition categorises information visualisation as an information retrieval technique and aid, it is often referred to as visual text mining (Fan et al., 2006; Lopes et al., 2007). A broader understanding of information visualisation therefore includes the use of visual techniques for not only information retrieval but also to interpret the findings of text mining efforts. According to Lopes et al. (2007), information visualisation reduces the complexity of text mining by helping the user to build more adequate cognitive models of trends and the general structure of a complex set of documents.

CRITICAL ISSUES

Many sources on text mining refer to text as "unstructured data". However, it is a fallacy that text data are unstructured. Text is actually highly structured in terms of morphology, syntax, semantics and pragmatics. On the other hand, it must be admitted that these structures are not directly visible: "… text represents factual information … in a complex, rich, and opaque manner" (Nasukawa & Nagano, 2001, p. 967).

Authors also differ on the issue of natural language processing within text mining. Some prefer a more statistical approach (cf. Hearst, 1999), while others feel that linguistic parsing is an essential part of text mining. Sullivan (2001, p. 37) regards the representation of meaning by means of syntactic-semantic representations as essential for text mining: "Text processing techniques, based on morphology, syntax, and semantics, are powerful mechanisms for extracting business intelligence information from documents…. We can scan text for meaningful phrase patterns and extract key features and relationships". According to De Bruijn & Martin (2002, p. 16), "[l]arge-scale statistical methods will continue to challenge the position of the more syntax-semantics oriented approaches, although both will hold their own place."

In the light of the various definitions of text mining, it should come as no surprise that authors also differ on what qualifies as text mining and what does not. Building on Hearst (1999), Kroeze, Matthee & Bothma (2003) use the parameters of novelty and data type to distinguish between information retrieval, standard text mining and intelligent text mining (see Figure 1).

Halliman (2001, p. 7) also hints at a scale of newness of information: "Some text mining discussions stress the importance of 'discovering new knowledge.' And the new knowledge is expected to be new to everybody. From a practical point of view, we believe that business text should be 'mined' for information that is 'new enough' to give a company a competitive edge once the information is analyzed."

Another issue is the question of when text mining can be regarded as "intelligent". Intelligent behavior is "the ability to learn from experience and apply knowledge acquired from experience, handle complex situations, solve problems when important information is missing, determine what is important, react quickly and correctly to a new situation, understand visual images, process and manipulate symbols, be creative and imaginative, and use heuristics" (Stair & Reynolds, 2001, p. 421). Intelligent text mining should therefore refer to the interpretation and evaluation of discovered patterns.

FUTURE RESEARCH

Mack and Hehenberger (2002, p. S97) regards the automation of "human-like capabilities for comprehending complicated knowledge structures" as one of the frontiers of "text-based knowledge discovery". Incorporating more artificial intelligence abilities into text-mining tools will facilitate the transition from

Figure 1. A differentiation between information retrieval, standard and intelligent metadata mining, and standard and intelligent text mining (abbreviated from Kroeze, Matthee & Bothma, 2003)

Novelty level: / Data type:	Non-novel investigation: Information retrieval	Semi-novel investigation: Knowledge discovery	Novel investigation: Knowledge creation
Metadata (overtly structured)	Information retrieval of metadata	Standard metadata mining	Intelligent metadata mining
Free text (covertly structured)	Information retrieval of full texts	Standard text mining	Intelligent text mining

mainly statistical procedures to more intelligent forms of text mining. Fan et al. (2006) consider duo-mining as an important future consideration. This involves the integration of data mining and text mining into a single system and will enable users to consolidate information by analyzing both structured data from databases as well as free text from electronic documents and other sources.

CONCLUSION

Text mining can be regarded as the next frontier in the science of knowledge discovery and creation, enabling businesses to acquire sought-after competitive intelligence, and helping scientists of all academic disciplines to formulate and test new hypotheses. The greatest challenges will be to select and integrate the most appropriate technology for specific problems and to popularise these new technologies so that they become instruments that are generally known, accepted and widely used.

KEY TERMS

Business Intelligence: "Any information that reveals threats and opportunities that can motivate a company to take some action" (Halliman, 2001, p. 3).

Competitive Advantage: The head start a business has owing to its access to new or unique information and knowledge about the market in which it is operating.

Hypertext: A collection of texts containing links to each other to form an interconnected network (Sullivan, 2001, p. 46).

Information Retrieval: The searching of a text collection based on a user's request to find a list of documents organised according to its relevance, as judged by the retrieval engine (Montes-y-Gómez et al., 2004). Information retrieval should be distinguished from text mining.

Knowledge Creation: The evaluation and interpretation of patterns, trends or anomalies that have been discovered in a collection of texts (or data in general), as well as the formulation of its implications and consequences, including suggestions concerning reactive business decisions.

Knowledge Discovery: The discovery of patterns, trends or anomalies that already exist in a collection of texts (or data in general), but have not yet been identified or described.

Mark-Up Language: Tags that are inserted in free text to mark structure, formatting and content. XML tags can be used to mark attributes in free text and to transform free text into an exploitable database (cf. Tseng & Hwung, 2002).

Metadata: Information regarding texts, e.g. author, title, publisher, date and place of publication, journal or series, volume, page numbers, key words, etc.

Natural Language Processing (NLP): The automatic analysis and/or processing of human language by computer software, "focussed on understanding the contents of human communications". It can be used to identify relevant data in large collections of free text for a data mining process (Westphal & Blaxton, 1998, p. 116).

Parsing: A (NLP) process that analyses linguistic structures and breaks them down into parts, on the morphological, syntactic or semantic level.

Stemming: Finding the root form of related words, for example singular and plural nouns, or present and past tense verbs, to be used as key terms for calculating occurrences in texts.

Text Mining: The automatic analysis of a large text collection in order to identify previously unknown patterns, trends or anomalies, which can be used to derive business intelligence for competitive advantage or to formulate and test scientific hypotheses.

Discovery Informatics from Data to Knowledge

William W. Agresti
Johns Hopkins University, USA

INTRODUCTION

It is routine to hear and read about the information explosion, how we are all overwhelmed with data and information. Is it progress when our search tools report that our query resulted in 300,000 hits? Or, are we still left to wonder where is the information that we really wanted? How far down the list must we go to find it?

Discovery informatics is a distinctly 21st century emerging methodology that brings together several threads of research and practice aimed at making sense out of massive data sources. It is defined as "the study and practice of employing the full spectrum of computing and analytical science and technology to the singular pursuit of discovering new information by identifying and validating patterns in data" (Agresti, 2003).

BACKGROUND

The rapid rise in the amount of information generated each year may be quite understandable. After all, the world's population is growing, and countries like China and India, with very large populations, are becoming increasingly influential worldwide. However, the real reason why people are confronted with so much more information in their lives and work is that the information has real benefits for them. However, these benefits are not always or often realized, and therein lay the motivation for discovery informatics.

Companies today are data mining with more highly granular data to better understand their customers' buying habits. As a result, there is pressure on all businesses to attain the same level of understanding or be left behind – and being left behind in the 21st century can mean going out of business. Not-for-profits are becoming equally adept at mining data to discover which likely donors are most cost-effective to cultivate. Increasing granularity enables more targeted marketing, but with more data requiring more analysis. A co-conspirator in this infoglut is the declining cost to store the data. Organizations don't need to make choices on what data to keep. They can keep it all.

The task of making sense out of this burgeoning mass of data is growing more difficult every day. Effectively transforming this data into usable knowledge is the challenge of discovery informatics. In this broad-based conceptualization, discovery informatics may be seen as taking shape by drawing on more established disciplines:

- **Data analysis and visualization:** analytic frameworks, interactive data manipulation tools, visualization environments
- **Database management:** data models, data analysis, data structures, data management, federation of databases, data warehouses, database management systems
- **Pattern recognition:** statistical processes, classifier design, image data analysis, similarity measures, feature extraction, fuzzy sets, clustering algorithms
- **Information storage and retrieval:** indexing, content analysis, abstracting, summarization, electronic content management, search algorithms, query formulation, information filtering, relevance and recall, storage networks, storage technology
- **Knowledge management:** knowledge sharing, knowledge bases, tacit and explicit knowledge, relationship management, content structuring, knowledge portals, collaboration support systems
- **Artificial intelligence:** learning, concept formation, neural nets, knowledge acquisition, intelligent systems, inference systems, Bayesian methods, decision support systems, problem solving, intelligent agents, text analysis, natural language processing

What distinguishes discovery informatics is that it brings coherence across dimensions of technologies and domains to focus on discovery. It recognizes and builds upon excellent programs of research and practice in individual disciplines and application areas. It looks selectively across these boundaries to find anything (e.g., ideas, tools, strategies, and heuristics) that will help with the critical task of discovering new information.

To help characterize discovery informatics, it may be useful to see if there are any roughly analogous developments elsewhere. Two examples, knowledge management and core competence, may be instructive as reference points.

Knowledge management, which began its evolution in the early 1990s, is "the practice of transforming the intellectual assets of an organization into business value" (Agresti, 2000). Of course, before 1990 organizations, to varying degrees, knew that the successful delivery of products and services depended on the collective knowledge of employees. However, KM challenged organizations to focus on knowledge and recognize its key role in their success. They found value in addressing questions such as:

- What is the critical knowledge that should be managed?
- Where is the critical knowledge?
- How does knowledge get into products and services?

When C. K. Prahalad and Gary Hamel published their highly influential paper, "The Core Competence of the Corporation," (Prahalad and Hamel, 1990) companies had some capacity to identify what they were good at. However, as with KM, most organizations did not appreciate how identifying and cultivating core competencies (CC) may make the difference between competitive or not. A core competence is not the same as "what you are good at" or "being more vertically integrated." It takes dedication, skill, and leadership to effectively identify, cultivate, and deploy core competences for organizational success.

Both KM and CC illustrate the potential value of taking on a specific perspective. By doing so, an organization will embark on a worthwhile re-examination of familiar topics: its customers, markets, knowledge sources, competitive environment, operations, and success criteria. The claim of this chapter is that discovery informatics represents a distinct perspective; one that is potentially highly beneficial because, like KM and CC, it strikes at what is often an essential element for success and progress, discovery.

Embracing the concept of strategic intelligence for an organization, Liebowitz (2006) has explored the relationships and synergies among knowledge management, business intelligence, and competitive intelligence.

MAIN THRUST OF THE CHAPTER

This section will discuss the common elements of discovery informatics and how it encompasses both the technology and application dimensions.

Common Elements of Discovery Informatics

The only constant in discovery informatics is data and an interacting entity with an interest in discovering new information from it. What varies, and has an enormous effect on the ease of discovering new information, is everything else, notably:

- Data:
  - Volume: How much?
  - Accessibility: Ease of access and analysis?
  - Quality: How clean and complete is it? Can it be trusted as accurate?
  - Uniformity: How homogeneous is the data? Is it in multiple forms, structures, formats, and locations?
  - Medium: Text, numbers, audio, video, image, electronic or magnetic signals or emanations?
  - Structure of the data: Formatted rigidly, partially, or not at all? If text, does it adhere to known language?
- Interacting Entity:
  - Nature: Is it a person or intelligent agent?
  - Need, question, or motivation of the user: What is prompting a person to examine this data? How sharply defined is the question or need? What expectations exist about what might be found? If the motivation is to find

something interesting, what does that mean in context?

A wide variety of activities may be seen as variations on the scheme above. An individual using a search engine to search the Internet for a home mortgage serves as an instance of query-driven discovery. A retail company looking for interesting patterns in its transaction data is engaged in data-driven discovery. An intelligent agent examining newly posted content to the Internet based on a person's profile is also engaged in a process of discovery, only the interacting entity is not a person.

Discovery across Technologies

The technology dimension is considered broadly to include automated hardware and software systems, theories, algorithms, architectures, techniques, methods, and practices. Included here are familiar elements associated with data mining and knowledge discovery, such as clustering, link analysis, rule induction, machine learning, neural networks, evolutionary computation, genetic algorithms, and instance based learning (Wang, 2003).

However, the discovery informatics viewpoint goes further, to activities and advances that are associated with other areas but should be seen as having a role in discovery. Some of these activities, like searching or knowledge sharing, are well known from everyday experience.

Conducting searches on the Internet is a common practice that needs to be recognized as part of a thread of information retrieval. Because it is practiced essentially by all Internet users and it involves keyword search, there is a tendency to minimize its importance. Search technology is extremely sophisticated (Henzinger, 2007).

Searching the Internet has become a routine exercise in information acquisition. The popularity of searching is a testament to the reality of the myriad of complex relationships among concepts, putting an end to any hope that some simple (e.g., tree-like) structure of the Internet will ever be adequate (see, e.g., Weinberger, 2007).

While finding the "right" information by searching is a challenging task, the view from the content-producing side of the Internet reveals its own vexing questions. Businesses want desperately to know how to get their sites to show up in the results of Internet searches. The importance of search results to business is evidenced by the frequent search engine marketing conferences conducted regularly around the world. People use the web to find products and services; "customers vote with their mice" (Moran, 2008). If your company's offerings can emerge from the search process on page one, without having to pay for the privilege, the competitive advantage is yours.

People always have some starting point for their searches. Often it is not a keyword, but instead is a concept. So people are forced to perform the transformation from a notional concept of what is desired to a list of one or more keywords. The net effect can be the familiar many-thousand "hits" from the search engine. Even though the responses are ranked for relevance (itself a rich and research-worthy subject), people may still find that the returned items do not match their intended concepts.

Offering hope for improved search are advances in concept-based search (Houston and Chen, 2004), more intuitive with a person's sense of "Find me content like this," where this can be a concept embodied in an entire document or series of documents. For example, a person may be interested in learning which parts of a new process guideline are being used in practice in the pharmaceutical industry. Trying to obtain that information through keyword searches would typically involve trial and error on various combinations of keywords. What the person would like to do is to point a search tool to an entire folder of multimedia electronic content and ask the tool to effectively integrate over the folder contents and then discover new items that are similar. Current technology can support this ability to associate a "fingerprint" with a document (Heintze, 2004), to characterize its meaning, thereby enabling concept-based searching. Discovery informatics recognizes that advances in search and retrieval enhance the discovery process.

With more multimedia available online, the discovery process extends to finding content from videos, sound, music, and images to support learning. There is an active research community exploring issues such as the best search parameters, performance improvements, and retrieval based on knowing fragments of both text and other media (see, e.g., Rautiainen, Ojala & Seppänen, 2004).

This same semantic analysis can be exploited in other settings, such as within organizations. It is possible

now to have your email system prompt you based on the content of messages you compose. When you click "Send," the email system may open a dialogue box, "Do you also want to send that to Mary?" The system has analyzed the content of your message, determining that, for messages in the past having similar content, you have also sent them to Mary. So the system is now asking you if you have perhaps forgotten to include her. While this feature can certainly be intrusive and bothersome unless it is wanted, the point is that the same semantic analysis advances are at work here as with the Internet search example.

The "informatics" part of discovery informatics also conveys the breadth of science and technology needed to support discovery. There are commercially available computer systems and special-purpose software dedicated to knowledge discovery (e.g., see listings at http://www.kdnuggets.com/). The informatics support includes comprehensive hardware-software discovery platforms as well as advances in algorithms and data structures, which are core subjects of computer science. The latest developments in data-sharing, application integration, and human-computer interfaces are used extensively in the automated support of discovery. Particularly valuable, because of the voluminous data and complex relationships, are advances in visualization. Commercial visualization packages are widely used to display patterns and enable expert interaction and manipulation of the visualized relationships. There are many dazzling displays on the Internet that demonstrate the benefits of more effective representations of data; see, for example, the visualizations at (Smashing Magazine, 2007).

Discovery across Domains

Discovery informatics encourages a view that spans application domains. Over the past decade, the term has been most often associated with drug discovery in the pharmaceutical industry, mining biological data. The financial industry also was known for employing talented programmers to write highly sophisticated mathematical algorithms for analyzing stock trading data, seeking to discover patterns that could be exploited for financial gain. Retailers were prominent in developing large data warehouses that enabled mining across inventory, transaction, supplier, marketing, and demographic databases. The situation -- marked by drug discovery informatics, financial discovery informatics, et al. -- was evolving into one in which discovery informatics was preceded by more and more words as it was being used in an increasing number of domain areas. One way to see the emergence of discovery informatics is to strip away the domain modifiers and recognize the universality of every application area and organization wanting to take advantage of its data.

Discovery informatics techniques are very influential across professions and domains:

- Industry has been using discovery informatics as a fresh approach to design. The discovery and visualization methods from Purdue University helped Caterpillar to design better rubber parts for its heavy equipment products and Lubrizol to improve its fuel additives. "These projects are success stories about how this unique strategy, called 'Discovery Informatics,' has been applied to real-world, product-design problems" (Center for Catalyst Design, 2007).
- In the financial community, the FinCEN Artificial Intelligence System (FAIS) uses discovery informatics methods to help identify money laundering and other crimes. Rule-based inference is used to detect networks of relationships among people and bank accounts so that human analysts can focus their attention on potentially suspicious behavior (Senator, Goldberg, and Wooton, 1995).
- In the education profession, there are exciting scenarios that suggest the potential for discovery informatics techniques. In one example, a knowledge manager works with a special education teacher to evaluate student progress. The data warehouse holds extensive data on students, their performance, teachers, evaluations, and course content. The educators are pleased that the aggregate performance data for the school is satisfactory. However, with discovery informatics capabilities, the story does not need to end there. The data warehouse permits finer granularity examination, and the discovery informatics tools are able to find patterns that are hidden by the summaries. The tools reveal that examinations involving word problems show much poorer performance for certain students. Further analysis shows that this outcome was also true in previous courses for these students. Now the educators have the specific data enabling them to take action, in the form of targeted tutorials for specific students

to address the problem (Tsantis and Castellani, 2001).

- Bioinformatics requires the intensive use of information technology and computer science to address a wide array of challenges (Watkins, 2001). One example illustrates a multi-step computational method to predict gene models, an important activity that has been addressed to date by combinations of gene prediction programs and human experts. The new method is entirely automated, involving optimization algorithms and the careful integration of the results of several gene prediction programs, including evidence from annotation software. Statistical scoring is implemented with decision trees to show clearly the gene prediction results (Allen, Pertea, and Salzberg, 2004).

TRENDS IN DISCOVERY INFORMATICS

There are many indications that discovery informatics will only grow in relevance. Storage costs are dropping; for example, the cost per gigabyte of magnetic disk storage declined by a factor of 500 from 1990 to 2000 (University of California at Berkeley, 2003). Our stockpiles of data are expanding rapidly in every field of endeavor. Businesses at one time were comfortable with operational data summarized over days or even weeks. Increasing automation led to point-of-decision data on transactions. With online purchasing, it is now possible to know the sequence of clickstreams leading up to the sale. So the granularity of the data is becoming finer, as businesses are learning more about their customers and about ways to become more profitable. This business analytics is essential for organizations to be competitive.

A similar process of finer granular data exists in bioinformatics (Dubitsky, et al., 2007). In the human body, there are 23 pairs of human chromosomes, approximately 30,000 genes, and more than one million proteins (Watkins, 2001). The advances in decoding the human genome are remarkable, but it is proteins that "ultimately regulate metabolism and disease in the body" (Watkins, 2001, p. 27). So the challenges for bioinformatics continue to grow along with the data. An indication of the centrality of data mining to research in the biological sciences is the launching in 2007 of the *International Journal of Data Mining and Bioinformatics*.

THE DISCOVERY INFORMATICS COMMUNITY

As discovery informatics has evolved, there has been a steady growth in the establishment of centers, laboratories, and research programs. The College of Charleston launched the first undergraduate degree program in the field in 2005. The interdisciplinary program addresses the need to gain knowledge from large datasets and complex systems, while introducing problem-solving skills and computational tools that span traditional subjects of artificial intelligence, logic, computer science, mathematics, and learning theory.

In addition to the Laboratory for Discovery Informatics at the Johns Hopkins University, laboratories have emerged at Rochester Institute of Technology and Purdue University. Discovery informatics research at Purdue has highlighted the use of knowledge discovery methods for product design. As a further indication of the broad reach of this discovery informatics approach, the Purdue research has been led by professors from the School of Chemical Engineering in their Laboratory for Intelligent Process Systems.

CONCLUSION

Discovery informatics is an emerging methodology that promotes a crosscutting and integrative view. It looks across both technologies and application domains to identify and organize the techniques, tools, and models that improve data-driven discovery.

There are significant research questions as this methodology evolves. Continuing progress will be eagerly received from efforts in individual strategies for knowledge discovery and machine learning, such as the excellent contributions in (Koza et al., 2003). An additional opportunity is to pursue the recognition of unifying aspects of practices now associated with diverse disciplines. While the anticipation of new discoveries is exciting, the evolving practical application of discovery methods needs to respect individual privacy and a diverse collection of laws and regulations. Balancing these requirements constitutes a significant

and persistent challenge as new concerns emerge and laws are drafted.

Because of its essential role in the drug discovery process, discovery informatics is still associated strongly with the pharmaceutical research and industry. However, more recent explorations have confirmed its value in product design and other domains. Community-building around discovery informatics now includes university degree programs and research laboratories with diverse missions. All of these developments provide further evidence that as the challenges and opportunities of the 21st century unfold, discovery informatics is poised to help people and organizations learn as much as possible from the world's abundant and ever growing data assets.

KEY TERMS

Clickstream: The sequence of mouse clicks executed by an individual during an online Internet session.

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns and relationships such as classification, prediction, estimation, or affinity grouping.

Discovery Informatics: The study and practice of employing the full spectrum of computing and analytical science and technology to the singular pursuit of discovering new information by identifying and validating patterns in data.

Evolutionary Computation: Solution approach guided by biological evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a model that best represents the data.

Knowledge Management: The practice of transforming the intellectual assets of an organization into business value.

Neural Networks: Learning systems, designed by analogy with a simplified model of the neural connections in the brain, which can be trained to find nonlinear relationships in data.

Rule Induction: Process of learning, from cases or instances, if-then rule relationships consisting of an antecedent (if-part, defining the preconditions or coverage of the rule) and a consequent (then-part, stating a classification, prediction, or other expression of a property that holds for cases defined in the antecedent).

Discovery of Protein Interaction Sites

Haiquan Li

Jinyan Li
Nanyang Technological University, Singapore

Xuechun Zhao
The Samuel Roberts Noble Foundation, Inc., USA

INTRODUCTION

Physical interactions between proteins are important for many cellular functions. Since protein-protein interactions are mediated via their interaction sites, identifying these interaction sites can therefore help to discover genome-scale protein interaction map, thereby leading to a better understanding of the organization of living cell. To date, the experimentally solved protein interaction sites constitute only a tiny proportion among the whole population due to the high cost and low-throughput of currently available techniques. Computational methods, including many biological data mining methods, are considered as the major approaches in discovering protein interaction sites in practical applications. This chapter reviews both traditional and recent computational methods such as protein-protein docking and motif discovery, as well as new methods on machine learning approaches, for example, interaction classification, domain-domain interactions, and binding motif pair discovery.

BACKGROUND

Proteins carry out most biological functions within living cells. They interact with each other to regulate cellular processes. Examples of these processes include gene expression, enzymatic reactions, signal transduction, inter-cellular communications and immunoreactions.

Protein-protein interactions are mediated by short sequence of residues among the long stretches of interacting sequences, which are referred to as interaction sites (or binding sites in some contexts). Protein interaction sites have unique features that distinguish them from other residues (amino acids) in protein surface. These interfacial residues are often highly favorable to the counterpart residues so that they can bind together. The favored combinations have been repeatedly applied during evolution (Keskin and Nussinov, 2005), which limits the total number of types of interaction sites. By estimation, about 10,000 types of interaction sites exist in various biological systems (Aloy and Russell, 2004).

To determine the interaction sites, many biotechnological techniques have been applied, such as phage display and site-directed mutagenesis. Despite all these techniques available, the current amount of experimentally determined interaction sites is still very small, less than 10% in total. It should take decades to determine major types of interaction sites using present techniques (Dziembowski and Seraphin, 2004).

Due to the limitation of contemporary experimental techniques, computational methods, especially biological data mining methods play a dominated role in the discovery of protein interaction sites, for example, in the docking-based drug design. Computational methods can be categorized into simulation methods and biological data mining methods. By name, simulation methods use biological, biochemical or biophysical mechanisms to model protein-protein interactions and their interaction sites. They usually take individual proteins as input, as done in protein-protein docking. Recently, data mining methods such as classification and clustering of candidate solutions contributed the accuracy of the approach. Data mining methods learn from large training set of interaction data to induce rules for prediction of the interaction sites. These methods can be further divided into classification methods and pattern mining methods, depending on whether negative data is required. Classification methods require both positive and negative data to develop discriminative features for interaction

sites. In comparison, pattern mining methods learn from a set of related proteins or interactions for over-presented patterns, as negative data are not always available or accurate. Many homologous methods and binding motif pair discovery fall into this category.

MAIN FOCUS

Simulation Methods: Protein-Protein Docking

Protein-protein docking, as a typical simulation method, takes individual tertiary protein structures as input and predicts their associated protein complexes, through simulating the confirmation change such as side-chain and backbone movement in the contact surfaces when proteins are associated into protein complexes. Most docking methods assume that, conformation change terminates at the state of minimal free energy, where free energy is defined by factors such as shape complementarity, electrostatic complementarity and hydrophobic complementarity.

Protein-protein docking is a process of search for global minimal free energy, which is a highly challenging computational task due to the huge search space caused by various flexibilities. This search consists of four steps. In the first step, one protein is fixed and the other is superimposed into the fixed one to locate the best docking position, including translation and rotation. Grid-body strategy is often used at this step, without scaling and distorting any part of the proteins. To reduce the huge search space in this step, various search techniques are used such as, Fast Fourier transformation, Pseudo-Brownian dynamics and molecular dynamics (Mendez et al., 2005). In the second step, the flexibility of side chains is considered. The backbone flexibility is also considered using techniques such as principal component analysis in some algorithms (Bonvin, 2006). Consequently, a set of solutions with different local minima is generated after the first two steps. These solutions are clustered in the third step and representatives are selected (Lorenzen & Zhang, 2007). In the fourth step, re-evaluation is carried out to improve the ranks for nearly native solutions, since the nearly native solutions may not have the best free energy scores due to the flaws of score functions and search algorithms. Supervised data mining techniques have been applied in this step to select the near-native solution, using the accumulative confirmation data for benchmark protein complexes (Bordner and Gorin 2007). Note that in all steps, biological information may be integrated to aid the search process, such as binding sites data (Carter et al., 2005). In the interaction site determination problem, without the guidance of binding sites in docking, the top-ranked interfaces in the final step correspond to the predicted interaction sites. With the guidance of binding sites, the docking algorithms may not contribute remarkably to the prediction of interaction sites since the above steps may be dominated by the guided binding sites.

Although protein-protein docking is the major approach to predict protein interaction sites, the current number of experimentally determined protein structures is much less than that of protein sequences. Even using putative structures, ~ 40% proteins will be failed in protein structure prediction (Aloy et al., 2005), especially for transmembrane proteins. This leaves a critical gap in the protein-protein docking approach.

Classification Methods

Classification methods assume that the features, either in protein sequence or in protein spatial patches, distinguish positive protein interactions from negative non-interactions. Therefore, the distinguishing features correspond to protein interaction sites. The assumption generally holds true but not always.

The first issue in protein interaction classification is to encode protein sequences or structures into features. At least two encoding methods are available. One transforms continuous residues and their associated physicochemical properties in the primary sequence into features (Yan et al., 2004). The other encodes a central residue and its spatially nearest neighbors one time, which is so called spatial patches (Fariselli et al., 2002). The latter encoding is more accurate than the first one because protein structures are more related to interaction sites.

After encoding the features, traditional classification methods such as support vector machine (SVM) and neural networks can be applied to predict interaction sites (Bock & Gough, 2001; Ofran & Rost, 2003). Recently, a two-stage method was proposed (Yan et al., 2004). In the learning phase, both SVM and Bayesian networks produce a model for the continuously encoded residues. In the prediction phase, the SVM model is first applied to predict a class value for each residue, then the Bayesian

model is applied to predict the final class value based on predicted values in SVM model, exploiting the fact that interfacial residues tend to form clusters.

Although classification methods have many advantages, for example, they are good at handling transient complexes which are tough in docking, they have several disadvantages. First, they suffer from unavailability and low quality of the negative data. Second, many classification algorithms apply fixed-length windows in coding, which conflicts with the basic fact that many interaction sites have variable length. Finally, the complicated coding often results in incomprehensibility to the interaction sites from a biological point of view.

Pattern Mining Methods

Pattern mining methods assume that interaction sites are highly conserved in protein homologous data and protein-protein interactions. These conserved patterns about interaction sites are quite different from random expectation and thus, can be revealed even in the absence of negative data. Typical patterns include binding motifs, domain-domain interaction pairs and binding motif pairs.

Binding Motifs from Homologous Proteins

Given a group of homologous proteins, the inherited patterns can be recovered by searching the locally over-represented patterns (so-called motifs) among their sequences, which is often referred to as motif discovery. It is a NP-hard problem and similar to sequential pattern mining but more complicated since its score function is often implicit. The majority of methods discover motifs from primary sequences and can be roughly categorized into pattern-driven, sequence-driven and the combined ones. Pattern-driven methods enumerate all possible motifs with a specific format and output the ones with enough occurrences. For instance, MOTIF (Smith et al., 1990) searches all frequent motifs with three fixed positions and two constant spacings. Sequence-driven methods restrict the candidate patterns to occur at least some times in the group of sequences, for instance, the widely used CLUSTALW (Thompson et al., 1994). Combined methods integrate the strength of pattern-driven and sequence-driven methods. They start from patterns at short lengths and extend them based on conservation of their neighbors in the sequences, for instance, PROTOMAT (Jonassen, 1997). Other motif discovery approaches have also been studied, for example, statistical models such as Hidden Markov models (HMM) and expectation maximization (EM) models.

Motifs can also be discovered from homologous protein structures, which are called structural motifs. Structural motif discovery has been studied from various perspectives, such as frequent common substructure mining (Yan et al., 2005) and multiple structure alignment (Lupyan et al., 2005), impelling by the rapid growth of solved protein structures in recent years.

In general, motif discovery only identifies individual motifs without specifying their interacting partners and thus, can't be considered as complete interaction sites. To reveal both sides of interaction sites, individual motifs can be randomly paired and their correlation can be evaluated by protein-protein interaction data, as done by Wang et al. (2005). Even though, the discovered motif pairs can not guarantee to be interaction sites or binding sites. The rationale is that binding and folding are often interrelated and they could not be distinguished only from homologous proteins. Since homologous proteins share more folding regions than bindings regions, the discovered motifs by sequence or structure conservation are more likely to be folding motifs rather than binding motifs (Kumar et al., 2000). To identify the complete interaction sites, protein interaction information should be taken into consideration in the early stage of learning.

Domain-Domain Pairs from Protein-Protein Interactions

Domain-domain interactions, which are closely related to protein interaction sites, have been widely studied in recent years, due to the well-acknowledged concept of domain and the abundantly available data about protein interactions. Many domains contain regions for interactions and involve in some biological functions.

From a data mining perspective, each protein sequence is a sequence of domains and the target patterns are correlated domain pairs. The correlated pairs have been inferred by various approaches. Sprinzak and Margalit (2001) extracted all over-represented domain pairs in protein interaction data and initially termed them as correlated sequence-signatures. Wojcik and Schachter (2001) generated interacting domain pairs from protein cluster pairs with enough interactions, where the protein clusters are formed by proteins with enough sequence similarities and common interacting partners. Deng et

al. (2002) used maximum-likelihood to infer interacting domain pairs from a protein interaction dataset, by modeling domain pairs as random variables and protein interactions as events. Ng et al. (2003) inferred domain pairs with enough integrated scores, integrating evidences from multiple interaction sources.

Although domain-domain interactions imply abundant information about interaction sites, domains are usually very lengthy, in which only small parts involve binding while most regions contribute to folding. On the contrary, some interaction sites may not occur in any domain. Therefore, the study of domain-domain interactions is not enough to reveal interaction sites, although helpful.

Binding Motif Pairs from Protein-Protein Interactions

To fill the gap left by all above techniques, a novel concept of binding motif pairs has been proposed to define and capture more refined patterns at protein interaction sites hidden among abundant protein interaction data (Li and Li, 2005a). Each binding motif pair consists of two traditional protein motifs, which are usually more specific than domains. Two major methods were developed for the discovery of binding motif pairs.

The first method is based on a fixed-point theorem, which describes the stability under the resistance to some transformation at some special points; that is, the points remain unchanged by a transformation function. Here the stability corresponds to the biochemical laws exhibited in protein-protein interactions. The points of function are defined as protein motif pairs. This transformation function is based on the concept of occurrence and consensus. The discovery of fixed points, or the stable motif pairs, of the function is an iterative process, undergoing a chain of changing but converging patterns (Li and Li, 2005b).

The selection of the starting points for this function is difficult. An experimentally determined protein complex dataset was used to help in identifying meaningful starting points so that the biological evidence is enhanced and the computational complexity is greatly reduced. The consequent stable motif pairs are evaluated for statistical significance, using the unexpected frequency of occurrence of the motif pairs in the interaction sequence dataset. The final stable and significant motif pairs are the binding motif pairs finally targeted (Li and Li, 2005a).

The second method is based on the observation of frequently occurring substructures in protein interaction networks, called interacting protein-group pairs corresponding to maximal complete bipartite subgraphs in the graph theory. The properties of such substructures reveal a common binding mechanism between the two protein sets attributed to all-versus-all interaction between the two sets. The problem of mining interacting protein groups can be transformed into the classical problem of mining closed patterns in data mining (Li et al., 2007). Since motifs can be derived from the sequences of a protein group by standard motif discovery algorithms, a motif pair can be easily formed from an interacting protein group pair (Li et al., 2006).

FUTURE TRENDS

Current approaches to discover interaction sites from protein-protein interactions usually suffer from ineffective models, inefficient algorithms and lack of sufficient data. Many studies can be done in the future exploring various directions of the problem. For example, new machine learning methods may be developed to make full use of existing knowledge on the successfully docked protein complexes. More effective models may be proposed to discover binding motifs from homologous proteins or from domain-domain interacting pairs, through effective distinguishing of binding patterns from folding patterns. Other diverse models such as quasi-bipartite may be developed to discover binding motif pairs. Overall, the focus of studying interactions will then move from protein-protein interactions and domain-domain interactions to motif-motif interactions.

CONCLUSION

In this mini review, we have discussed various methods for the discovery of protein interaction sites. Protein-protein docking is the dominant method but it is constrained by the limited amount of protein structures. Classification methods constitute traditional machine learning methods but suffer from inaccurate negative data. Pattern mining methods are still incapable to distinguish binding patterns from folding patterns, except a few work based on binding motif pairs. Overall, current biological data mining methods are far from perfect. Therefore, it is valuable to develop novel methods in

the near future to improve the coverage rate, specificity and accuracy, especially by using the fast growing protein-protein interaction data, which are closely related to the interaction sites.

KEY TERMS

Binding Motif Pairs: A pair of binding motifs which interact with each other to determine a type of protein interaction.

Binding Motifs: The patterns which describe a group of sequences or structures that bind or interact with a specific target.

Bioinformatics: The research, development, or application of computational tools and approaches for expanding the use of biological, medical, behavioral, or health data, including those used to acquire, store, organize, analyze, or visualize such data.

Domain-Domain Interactions: The binding or association among two or more domains due to their sequence or structure preference.

Protein Interaction Sites: The regions of proteins associated with the other interacting partner during protein-protein interactions.

Protein-Protein Docking: The determination of the molecular structures of complexes formed by two or more proteins without the need for experimental measurement.

Protein-Protein Interactions: The association of protein molecules and the study of these associations from the perspective of biochemistry, signal transduction and networks.

Distance-Based Methods for Association Rule Mining

Vladimír Bartík
Brno University of Technology, Czech Republic

Jaroslav Zendulka
Brno University of Technology, Czech Republic

INTRODUCTION

Association rules are one of the most frequently used types of knowledge discovered from databases. The problem of discovering association rules was first introduced in (Agrawal, Imielinski & Swami, 1993). Here, association rules are discovered from transactional databases –a set of transactions where a transaction is a set of items. An association rule is an expression of a form $A \Rightarrow B$ where A and B are sets of items. A typical application is market basket analysis. Here, the transaction is the content of a basket and items are products. For example, if a rule *milk* $\wedge$ *juice* $\Rightarrow$ *coffee* is discovered, it is interpreted as: "If the customer buys milk and juice, s/he is likely to buy coffee too." These rules are called *single-dimensional Boolean association rules* (Han & Kamber, 2001). The potential usefulness of the rule is expressed by means of two metrics – support and confidence.

A lot of algorithms have been developed for mining association rules in transactional databases. The best known is the Apriori algorithm (Agrawal & Srikant, 1994), which has many modifications, e.g. (Kotásek & Zendulka, 2000). These algorithms usually consist of two phases: discovery of frequent itemsets and generation of association rules from them. A frequent itemset is a set of items having support greater than a threshold called minimum support. Association rule generation is controlled by another threshold referred to as minimum confidence.

Association rules discovered can have a more general form and their mining is more complex than mining rules from transactional databases. In relational databases, association rules are ordinarily discovered from data of one table (it can be the result of joining several other tables). The table can have many columns (attributes) defined on domains of different types. It is useful to distinguish two types of attributes.

A *categorical attribute* (also called nominal) has a finite number of possible values with no ordering among the values (e.g. a country of a customer).

A *quantitative attribute* is a numeric attribute, domain of which is infinite or very large. In addition, it has an implicit ordering among values (e.g. age and salary of a customer).

An association rule (*Age* = [20…30]) $\wedge$ (*Country* = "Czech Rep.") $\Rightarrow$ (Salary = [1000$...2000$]) says that if the customer is between 20 and 30 and is from the Czech Republic, s/he is likely to earn between 1000$ and 2000$ per month. Such rules with two or more predicates (items) containing different attributes are also called *multidimensional association rules*. If some attributes of rules are quantitative, the rules are called quantitative association rules (Han & Kamber, 2001).

If a table contains only categorical attributes, it is possible to use modified algorithms for mining association rules in transactional databases. The crucial problem is to process quantitative attributes because their domains are very large and these algorithms cannot be used. Quantitative attributes must be *discretized*.

This article deals with mining multidimensional association rules from relational databases, with main focus on distance-based methods. One of them is a novel method developed by the authors.

BACKGROUND

There are three basic approaches regarding the treatment of quantitative attributes (Han & Kamber, 2001). First one uses a predefined set of ranges (or, in general, a concept hierarchy) to replace the original numeric values of a quantitative attribute by ranges that represent intervals of values. This discretization occurs prior to applying a mining algorithm. It is *static* and

predetermined. In the second approach, quantitative attributes are initially discretized statically. The resulting ranges are then combined during the mining algorithm. Therefore, the discretization process is *dynamic*. The third approach tries to define ranges based on semantic meaning of the data. This discretization is dynamic too. It considers distance between data points. Discretization and mining methods based on this approach are referred to as *distance-based methods*.

There are two basic methods of *static discretization*: equi-depth and equi-width discretization. Equi-depth discretization lies in creating intervals that contain the same number of values. Equi-width discretization creates ranges of the same size. These methods are very simple, but the result of discretization can be unsuitable because some important associations may be lost. This is caused by the fact that two very near values can be in two different ranges. Sometimes one cluster of values, which might be represented by one predicate in an association rule, is divided into two ranges.

The following two methods are representatives of the second approach mentioned above.

A method for mining quantitative association rules was proposed in (Srikant & Agrawal, 1996). The number of intervals, which will be created, is determined by means of a measure referred to as K-partial completeness, which guarantees the acceptable loss of information. This measure is represented by a number K, which is higher than 1. This value is used to determine number of intervals N:

$$N = \frac{2}{minsup \cdot (K-1)} \qquad (1)$$

where *minsup* is a minimum support threshold.

After initial equi-depth discretization, neighboring intervals are joined together to form intervals having sufficient support. These intervals are then used to discover frequent itemsets.

Zhang extended the method to *fuzzy quantitative association rules* in (Zhang, 1999). Here, association rules can contain fuzzy terms too. In the phase of discretization, creating of intervals is combined with creating of fuzzy terms over quantitative attributes.

A method for mining *optimized association rules* proposed in (Fukuda, Morimoto, Morishita & Tokuyama, 1996) uses no additional measure for the interestingness of an association rule. Because the minimum support and confidence thresholds are antipodal, either rules referred to as optimized support rules or optimized confidence rules are obtained with this method. The goal of the optimized support rules is to find rules with support as high as possible that satisfy minimum confidence. Similarly, the optimized confidence rules maximize confidence of the rule while satisfying the minimum support requirement. The method uses the initial equi-depth discretization of quantitative attributes. Then the method continues with finding optimal interval for a given form of an association rule. The method discovers association rules referred to as constraint-based association rules where the form of rules to be mined must be defined, for example: $(Age \in [v_1, v_2]) \wedge (Country = X) \Rightarrow (Salary \in [v_3, v_4])$. Another method for mining optimized association rules is proposed in (Xiaoyong, Zhibin & Naohiro, 1999).

MAIN FOCUS

Distance-based methods try to respect semantics of data in such a way that the discretization of quantitative attributes reflects the distances between numeric values. The intervals of numeric values are constructed dynamically to contain clusters of values lying close to each other. The main objective of distance-based methods is to minimize loss of information caused by discretization.

The distance-based approach can either be applied as a discretization method or as part and parcel of a mining algorithm.

The first distance-based method was proposed in (Miller & Yang, 1997). Here, the clustering methods are used to create intervals. This algorithm works in two phases; in the first one, interesting clusters over quantitative attributes are found (e.g., with clustering algorithm Birch (Zhang, Ramakrishnan & Livny, 1996) and these clusters are used to generate frequent itemsets of clusters and association rules containing them.

The result of the process is a set of association rules of a form $C_{X1} \wedge \ldots \wedge C_{Xn} \Rightarrow C_{Y1} \wedge \ldots \wedge C_{Yn}$, where C_X and C_Y are clusters over quantitative attributes X and Y. Xi and Yj are pairwise disjoint sets of quantitative attributes. Except minimum support and confidence, an association rule must meet the condition of an *association degree*. To determine the value of the association degree of a rule $C_{Xi} \Rightarrow C_{Yi}$, we need to know if values of the attribute X in the cluster C_{Yi} are inside the cluster C_{Xi}

or close to it. To verify it, we can compute the average value of the attribute X inside the cluster C_{Xi} and inside the cluster C_{Yi} and compare these two values.

The problem of this method appears if there are several quantitative attributes, because they often have very different ranges. We need to normalize them to be comparable. Normalization must be performed before clustering. There are a lot of statistical normalization methods but their use depends on a detailed understanding of data and relationships between them (Milligan, 1995). This method is suitable for mining association rules in a table with only quantitative attributes.

An Adaptive Method for Numerical Attribute Merging was proposed in (Li, Shen & Topor, 1999). The method combines the approach of merging small intervals into larger ones with clustering. At first, each quantitative value is assigned to its own interval (containing only one value). Then, two neighboring intervals with lowest difference are merged together. The criterion that controls the merging process respects both distance and density of quantitative values.

Assume that for each interval, a representative center is defined. The intra-interval distance is defined as the average of distances of the representative center and each individual value inside the interval. The difference of two neighboring intervals can be determined as the intra-interval distance of an interval that is created as a union of them. In every iteration, neighboring intervals with the lowest difference are merged. The process is stopped, if all differences of intervals are higher than a value of $3d$, where d is the average distance of adjacent values of the quantitative attribute being processed.

Another method of interval merging described in (Wang, Tay & Liu, 1998) uses an interestingness measure. The idea is to merge intervals only if the loss of information caused by merging is justified by improved interestingness of association rules. The method uses several interestingness measures. Most of them are based on support and confidence of a resultant association rule.

A method which uses evolutionary algorithm to find optimal intervals was proposed in (Mata, Alvarez & Riquelme, 2002). An evolutionary algorithm is used to find the most suitable size of the intervals that conforms an itemset. The objective is to get high support value without being the intervals too wide. Discretization is performed during the mining of frequent itemsets.

At first, the initial population of frequent itemsets is obtained. Then, the population is improved in each iteration. The quality of discretization is determined by means of a fitness function. The fitness function reflects the width of intervals over quantitative attributes, support and the similarity with another intervals used in other frequent itemsets.

Unfortunately, the methods described above can produce a lot of uninteresting rules that must be eliminated. To cope with this problem, several post-processing methods have been developed to reduce the number of association rules (Li, Shen & Topor, 1999; Gupta, Strehl & Gosh, 1999).

In addition, distance-based methods described above, have some disadvantages. If a relational table contains both categorical and quantitative attributes, the ability to generate association rules containing both categorical and quantitative values is often small.

In next paragraphs, a method called *Average Distance Based Method* (Bartík & Zendulka, 2003), which was designed for mining association rules in a table that can contain both categorical and quantitative attributes, is described.

The method can be characterized by the following important features:

- Categorical and quantitative attributes are processed separately each other.
- Quantitative attributes are discretized dynamically.
- The discretization is controlled by means of two thresholds called maximum average distance and precision. The values of the thresholds are specified for each quantitative attribute.

Assume a quantitative attribute A and its value v. Let I be an interval of N values (data points) v_i ($1 \le i \le N$) of A such that $v \in I$. The *average distance* from v in I is defined as:

$$AD_I(v) = \sum_{i=1}^{N} \frac{(v - v_i)}{N}, \qquad (2)$$

The *maximum average distance* ($maxAD_A$) is a threshold for the average distance measured on values of an attribute A.

A value v of a quantitative attribute A is called an *interesting value* if there is an interval I that includes v with the following two properties:

- It can extend an existing frequent itemset by one item, i.e. the extended itemset satisfies minimum support.
- It holds $AD_I(v) \leq maxAD_A$.

The *precision* P_A is a threshold that determines the granularity of searching for interesting values of an attribute *A*. It is the minimum distance between two successive interesting values of *A*.

If *A* is a quantitative attribute, predicates of association rules containing A have form $(A, = v, maxAD_A)$.

Similarly to many other algorithms, mining association rules is performed in two steps:

1. Finding frequent itemsets, i.e. itemsets satisfying the minimum support threshold *minsup*.
2. Generating strong association rules, i.e. rules that satisfy the minimum confidence threshold *minconf*.

The second step is basically the same as in other well-known algorithms for mining association rules, for example (Agrawal & Srikant, 1994). Therefore, we focus here on the first step only. It can be described in pseudocode as follows:

Algorithm: Average Distance Based Method. Step 1 – finding frequent itemsets.
Input: Table *T* of a relational database; minimum support *minsup*; maximum average distance $maxAD_A$ and precision P_A, for each quantitative attribute of *T*.
Output: *FI*, frequent itemsets in *T*.

```
1.    // process categorical attributes
FI_0 = find_frequent_categorical_itemsets (T, minsup)
2     k = 0
3     // process quantitative attributes one by one
for each quantitative attribute A in T {
3.1     for each frequent itemset fi in FI_k {
3.1.1       V = find_interesting_values (A, minsup,
      maxAD_A, P_A)
3.1.2     for each interesting value v in V {
3.1.2.1       FI_{k+1} = FI_{k+1} ∪ (fi ∪ (A = v, maxAD_A))
          }
        }
      k = k+1
    }
  FI = ⋃_k FI_k
```

First, only categorical attributes are considered and frequent itemsets (referred to as categorical) are found. Any algorithm for mining association rules in transactional data can be used. Quantitative attributes are iteratively processed one by one. For each frequent itemset *fi* the quantitative attribute being processed is dynamically discretized. It means that interesting values of the attribute are found using the average distance measure and the maximum average distance and the precision thresholds.

Assume that a quantitative attribute *A* is being processed. Each frequent itemset discovered in the previous iteration determines the values of *A* that must be taken into account in searching for interesting values of *A*. Each candidate value *v* is determined by means of precision P_A. To satisfy the minimum support threshold *minsup*, the number *N* of considered neighboring values of *v* in an interval *I* used in computation of the average distance (2) is

$$N = minsup * numrows, \qquad (3)$$

where *numrows* is the total number of rows in the mined table. If $AD_I(v) \leq maxAD_A$ then the value *v* is interesting and the frequent itemset can be extended by a new item $(A = v, maxAD_A)$.

The discovered frequent itemsets are dependent on the order, in which quantitative attributes are processed. Therefore, a heuristics for the order that tries to maximize the number of discovered frequent itemsets was designed. For each quantitative attribute *A* in the table, the following function is computed:

$$H(A) = \frac{\max AD_A}{P_A} \cdot (1 - \frac{mis\sin g}{numrows}), \qquad (4)$$

where missing is the number of rows in which the value of the attribute A is missing. The attributes should be processed in descending order of the H(A) values.

FUTURE TRENDS

Methods and algorithms for mining association rules in relational databases are constantly the subject of research. The approach which is often applied – static discretization of quantitative attributes, relies heavily on the experience of the user. Distance-based methods try to discretize quantitative attributes dynamically,

which can increase the chance of discovery all the most important association rules.

There is another challenge for distance-based methods. Nowadays, complex data as object oriented, multimedia data, text and XML documents are constantly used and stored in databases more frequently. Distance-based methods can be adapted, in some cases, for mining such data.

CONCLUSION

The aim of this article was to provide a brief overview of methods for mining multidimensional association rules from relational databases. It was focused mainly on distance-based methods. In addition, a novel method called Average distance based method has been presented. It can be considered as a framework for combination of algorithms for mining association rules over categorical attributes and a new method of dynamic discretization of quantitative attributes. This framework allows using any method for processing of categorical attributes. In addition, it makes it possible to achieve better ability to generate association rules containing both categorical and quantitative attributes (Bartík & Zendulka, 2003).

KEY TERMS

Association Rule: For a database of transactions containing some items, it is an implication of the form $A \Rightarrow B$, where A and B are sets of items. The semantics of the rule is: If a transaction contains items A, it is likely to contain items B. It is also referred to as a single-dimensional association rule.

Average Distance Based Method: A method for mining quantitative association rules. It separates categorical and quantitative attributes processing, and employs dynamic discretization controlled by an average distance measure and maximum average distance and precision thresholds.

Categorical Attribute: An attribute that has a finite number of possible values with no ordering among the values (e.g. a country of a customer)

Discretization: In data mining, it is the process of transferring quantitative attributes into categorical ones by using intervals instead of individual numeric values.

Distance-Based Method: A method for mining association rules in which the discretization of quantitative attributes is performed dynamically, based on the distance between numeric values.

Dynamic Discretization: Discretization that respects the semantics of data. It is usually performed during the run of a mining algorithm..

Multidimensional Association Rule: An association rule with two or more predicates (items) containing different attributes.

Quantitative Association Rule: A synonym for multidimensional association rules containing at least one quantitative attribute.

Quantitative Attribute: A numeric attribute, domain of which is infinite or very large. In addition, it has an implicit ordering among values (e.g. age and salary).

Static Discretization: Discretization based on a predefined set of ranges or conceptual hierarchy.

Distributed Association Rule Mining

INTRODUCTION

Data mining is an iterative and interactive process that explores and analyzes voluminous digital data to discover valid, novel, and meaningful patterns (Mohammed, 1999). Since digital data may have terabytes of records, data mining techniques aim to find patterns using computationally efficient techniques. It is related to a subarea of statistics called exploratory data analysis. During the past decade, data mining techniques have been used in various business, government, and scientific applications.

Association rule mining (Agrawal, Imielinsky & Sawmi, 1993) is one of the most studied fields in the data-mining domain. The key strength of association mining is completeness. It has the ability to discover all associations within a given dataset. Two important constraints of association rule mining are support and confidence (Agrawal & Srikant, 1994). These constraints are used to measure the interestingness of a rule. The motivation of association rule mining comes from market-basket analysis that aims to discover customer purchase behavior. However, its applications are not limited only to market-basket analysis; rather, they are used in other applications, such as network intrusion detection, credit card fraud detection, and so forth.

The widespread use of computers and the advances in network technologies have enabled modern organizations to distribute their computing resources among different sites. Various business applications used by such organizations normally store their day-to-day data in each respective site. Data of such organizations increases in size everyday. Discovering useful patterns from such organizations using a centralized data mining approach is not always feasible, because merging datasets from different sites into a centralized site incurs large network communication costs (Ashrafi, David & Kate, 2004). Furthermore, data from these organizations are not only distributed over various locations, but are also fragmented vertically. Therefore, it becomes more difficult, if not impossible, to combine them in a central location. Therefore, Distributed Association Rule Mining (DARM) emerges as an active subarea of data-mining research.

Consider the following example. A supermarket may have several data centers spread over various regions across the country. Each of these centers may have gigabytes of data. In order to find customer purchase behavior from these datasets, one can employ an association rule mining algorithm in one of the regional data centers. However, employing a mining algorithm to a particular data center will not allow us to obtain all the potential patterns, because customer purchase patterns of one region will vary from the others. So, in order to achieve all potential patterns, we rely on some kind of distributed association rule mining algorithm, which can incorporate all data centers.

Distributed systems, by nature, require communication. Since distributed association rule mining algorithms generate rules from different datasets spread over various geographical sites, they consequently require external communications in every step of the process (Ashrafi, David & Kate, 2004; Assaf & Ron, 2002; Cheung, Ng, Fu & Fu, 1996). As a result, DARM algorithms aim to reduce communication costs in such a way that the total cost of generating global association rules must be less than the cost of combining datasets of all participating sites into a centralized site.

BACKGROUND

DARM aims to discover rules from different datasets that are distributed across multiple sites and intercon-

nected by a communication network. It tries to avoid the communication cost of combining datasets into a centralized site, which requires large amounts of network communication. It offers a new technique to discover knowledge or patterns from such loosely coupled distributed datasets and produces global rule models by using minimal network communication. Figure 1 illustrates a typical DARM framework. It shows three participating sites, where each site generates local models from its respective data repository and exchanges local models with other sites in order to generate global models.

Typically, rules generated by DARM algorithms are considered interesting, if they satisfy both minimum global support and confidence threshold. To find interesting global rules, DARM generally has two distinct tasks: (i) global support count, and (ii) global rules generation.

Let D be a virtual transaction dataset comprised of $D_1, D_2, D_3 \ldots\ldots D_m$ geographically distributed datasets; let n be the number of items and I be the set of items such that $I = \{a_1, a_2, a_3, \ldots\ldots\ldots a_n\}$, where $a_i \subset n$. Suppose N is the total number of transactions and $T = \{t_1, t_2, t_3, \ldots\ldots\ldots t_N\}$ is the sequence of transaction, such that $t_i \subset D$. The support of each element of I is the number of transactions in D containing I and for a given itemset $A \subset I$; we can define its support as follows:

$$Support(A) = \frac{A \subseteq t_i}{N} \quad (1)$$

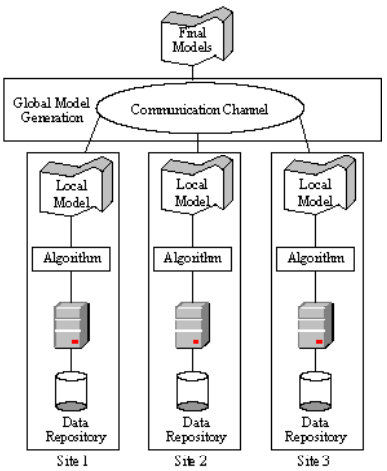
Itemset A is frequent if and only if $Support(A) \geq minsup$, where $minsup$ is a user-defined global support threshold. Once the algorithm discovers all global frequent itemsets, each site generates global rules that have user-specified confidence. It uses frequent itemsets to find the confidence of a rule $R1$ and can be calculated by using the following formula:

$$Confidence(R) = \frac{Support(F_1 \cup F_2)}{Support(F_1)} \quad (2)$$

CHALLENGES OF DARM

All of the DARM algorithms are based on sequential association mining algorithms. Therefore, they inherit all drawbacks of sequential association mining. However, DARM not only deals with the drawbacks of it but also considers other issues related to distributed computing. For example, each site may have different platforms and datasets, and each of those datasets may have different schemas. In the following paragraphs, we discuss a few of them.

Figure 1. A distributed data mining framework



Frequent Itemset Enumeration

Frequent itemset enumeration is one of the main association rule mining tasks (Agrawal & Srikant, 1993; Zaki, 2000; Jiawei, Jian & Yiwen, 2000). Association rules are generated from frequent itemsets. However, enumerating all frequent itemsets is computationally expansive. For example, if a transaction of a database contains 30 items, one can generate up to 2^{30} itemsets. To mitigate the enumeration problem, we found two basic search approaches in the data-mining literature. The first approach uses breadth-first searching techniques that search through the iterate dataset by generating the candidate itemsets. It works efficiently when user-specified support threshold is high. The second approach uses depth-first searching techniques to enumerate frequent itemsets. This search technique performs better when user-specified support threshold is low, or if the dataset is dense (i.e., items frequently occur in transactions). For example, Eclat (Zaki, 2000) determines the support of k-itemsets by intersecting the tidlists (Transaction ID) of the lexicographically first two (k-1) length subsets that share a common prefix. However, this approach may run out of main memory when there are large numbers of transactions.

However, DARM datasets are spread over various sites. Due to this, it cannot take full advantage of those searching techniques. For example, breath-first search performs better when support threshold is high. On the other hand, in DARM, the candidate itemsets are generated by combining frequent items of all datasets; hence, it enumerates those itemsets that are not frequent in a particular site. As a result, DARM cannot utilize the advantage of breath-first techniques when user-specified support threshold is high. In contrast, if a depth-first search technique is employed in DARM, then it needs large amounts of network communication. Therefore, without very fast network connection, depth-first search is not feasible in DARM.

Communication

A fundamental challenge for DARM is to develop mining techniques without communicating data from various sites unnecessarily. Since, in DARM, each site shares its frequent itemsets with other sites to generate unambiguous association rules, each step of DARM requires communication. The cost of communication increases proportionally to the size of candidate itemsets. For example, suppose there are three sites, such as S1, S2, and S3, involved in distributed association mining. Suppose that after the second pass, site S1 has candidate 2-itemsets equal to {AB, AC, BC, BD}, S2 = {AB, AD, BC, BD}, and S3 = {AC, AD, BC, BD}. To generate global frequent 2-itemsets, each site sends its respective candidate 2-itemsets to other sites and receives candidate 2-itemsets from others. If we calculate the total number of candidate 2-itemsets that each site receives, it is equal to 8. But, if each site increases the number of candidate 2-itemsets by 1, each site will receive 10 candidate 2-itemsets, and, subsequently, this increases communication cost. This cost will further increase when the number of sites is increased. Due to this reason, message optimization becomes an integral part of DARM algorithms.

The basic message exchange technique (Agrawal & Shafer, 1996) incurs massive communication costs, especially when the number of local frequent itemsets is large. To reduce message exchange cost, we found several message optimization techniques (Ashrafi et al., 2004; Assaf & Ron, 2002; Cheung et al., 1996). Each of these optimizations focuses on the message exchange size and tries to reduce it in such a way that the overall communication cost is less than the cost of merging all datasets into a single site. However, those optimization techniques are based on some assumptions and, therefore, are not suitable in many situations. For example, DMA (Cheung et al., 1996) assumes the number of disjoint itemsets among different sites is high. But this is only achievable when the different participating sites have vertical fragmented datasets. To mitigate these problems, we found another framework (Ashrafi et al., 2004) in data-mining literature. It partitions the different participating sites into two groups, such as sender and receiver, and uses itemsets history to reduce message exchange size. Each sender site sends its local frequent itemsets to a particular receiver site. When receiver sites receive all local frequent itemsets, it generate global frequent itemsets for that iteration and sends back those itemsets to all sender sites

Privacy

Association rule-mining algorithms discover patterns from datasets based on some statistical measurements. However those statistical measurements have significant meaning and may breach privacy (Evfimievski, Srikant, Agrawal & Gehrke, 2002; Rizvi & Haritsa, 2002). Therefore, privacy becomes a key issue of association rule mining. Distributed association rule-mining algorithms discover association rules beyond the organization boundary. For that reason, the chances of breaching privacy in distributed association mining are higher than the centralized association mining (Vaidya & Clifton, 2002; Ashrafi, David & Kate, 2003), because distributed association mining accomplishes the final rule model by combining various local patterns. For example, there are three sites, S1, S2, and S3, each of which has datasets DS1, DS2, and DS3. Suppose A and B are two items having global support threshold; in order to find rule $A \rightarrow B$ or $B \rightarrow A$, we need to aggregate the local support of itemsets AB from all participating sites (i.e., site S1, S2, and S3). When we do such aggregation, all sites learn the exact support count of other sites. However, participating sites generally are reluctant to disclose the exact support of itemset AB to other sites, because support counts of an itemset has a statistical meaning, and this may thread data privacy.

For the above-mentioned reason, we need secure multi-party computation solutions to maintain privacy of distributed association mining (Kantercioglu & Clifton, 2002). The goal of secure multi-party computation

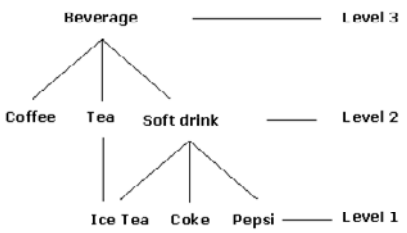
(SMC) in distributed association rule mining is to find global support of all itemsets using a function where multiple parties hold their local support counts, and, at the end, all parties know about the global support of all itemsets but nothing more. And finally, each participating site uses this global support for rule generation.

Partition

DARM deals with different possibilities of data distribution. Different sites may contain horizontally or vertically partitioned data. In horizontal partition, the dataset of each participating site shares a common set of attributes. However, in vertical partition, the datasets of different sites may have different attributes. Figure 2 illustrates horizontal and vertical partition dataset in a distributed context. Generating rules by using DARM becomes more difficult when different participating sites have vertically partitioned datasets. For example, if a participating site has a subset of items of other sites, then that site may have only a few frequent itemsets and may finish the process earlier than others. However, that site cannot move to the next iteration, because it needs to wait for other sites to generate global frequent itemsets of that iteration.

Figure 3. A generalization scenario



Furthermore, the problem becomes more difficult when the dataset of each site does not have the same hierarchical taxonomy. If a different taxonomy level exists in datasets of different sites, as shown in Figure 3, it becomes very difficult to maintain the accuracy of global models.

FUTURE TRENDS

The DARM algorithms often consider the datasets of various sites as a single virtual table. On the other hand, such assumptions become incorrect when DARM uses different datasets that are not from the same domain. Enumerating rules using DARM algorithms on such datasets may cause a discrepancy, if we assume that semantic meanings of those datasets are the same. The future DARM algorithms will investigate how such datasets can be used to find meaningful rules without increasing the communication cost.

CONCLUSION

The widespread use of computers and the advances in database technology have provided a large volume of data distributed among various sites. The explosive growth of data in databases has generated an urgent need for efficient DARM to discover useful information and knowledge. Therefore, DARM becomes one of the active subareas of data-mining research. It not only promises to generate association rules with minimal communication cost, but it also utilizes the resources distributed among different sites efficiently. However,

the acceptability of DARM depends to a great extent on the issues discussed in this article.

KEY TERMS

DARM: Distributed Association Rule Mining.

Data Center: A centralized repository for the storage and management of information, organized for a particular area or body of knowledge.

Frequent Itemset: A set of itemsets that have the user specified support threshold.

Network Intrusion Detection: A system that detects inappropriate, incorrect, or anomalous activity in the private network.

SMC: SMC computes a function $f(x_1, x_2, x_3 \ldots x_n)$ that holds inputs from several parties, and, at the end, all parties know about the result of the function $f(x_1, x_2, x_3 \ldots x_n)$ and nothing else.

Taxonomy: A classification based on a pre-determined system that is used to provide a conceptual framework for discussion, analysis, or information retrieval.

Distributed Data Aggregation Technology for Real-Time DDoS Attacks Detection

Yu Chen
State University of New York – Binghamton, USA

Wei-Shinn Ku
Auburn University, USA

INTRODUCTION

The information technology has revolutionized almost every facet of our lives. Government, commercial, and educational organizations depend on computers and Internet to such an extent that day-to-day operations are significantly hindered when the networks are "down" (Gordon, Loeb, Lucyshyn & Richardson, 2005). The prosperity of the Internet also attracted abusers and attackers motivated for personal, financial, or even political reasons. What attackers aim at currently is beyond obtaining unauthorized network accesses or stealing private information, there have been attacks on Internet infrastructures (Chakrabarti & Manimaran, 2002; Moore, Voelker & Savage, 2001; Naoumov & Ross, 2006).

Distributed Denial of Services (DDoS) attacks is one of such attacks that can lead to enormous destruction, as different infrastructure components of the Internet have implicit trust relationship with each other (Mirkovic & Reiher, 2004; Specht & Lee, 2004). The DDoS attacker often exploits the huge resource asymmetry between the Internet and the victim systems (Chen, Hwang & Ku, 2007; Douligeris & Mitrokosta, 2003).

A comprehensive solution to DDoS attacks requires covering global effects over a wide area of *autonomous system* (AS) domains on the Internet (Mirkovic & Reiher, 2005). Timely detection of the ongoing attacks is the prerequisite of any effective defense scheme (Carl, Kesidis, Brooks & Rai, 2006). It is highly desirable to detect DDoS attacks at very early stage, instead of waiting for the flood to become widespread. It is mandatory for the detection systems to collect real time traffic data from widely deployed traffic monitors and construct the spatiotemporal pattern of anomaly propagation inside the network.

This chapter will introduce a novel distributed real time data aggregation technique named *Change Aggregation Tree* (CAT). The CAT system adopts a hierarchical architecture to simplify the alert correlation and global detection procedures. At intra-domain level, each individual router, which plays the role of traffic monitor, periodically report the local traffic status to the CAT server in the AS. At the inter-domain layer, CAT servers share local detected anomaly patterns with peers located in other ASes, where the potential attack victim is located.

BACKGROUND

To monitor the traffic fluctuations in a real time manner, network devices often play the role of distributed sensor system that collects local data individually. However, as a large scale distributed system without a central administrator, it is challenging to create a spatiotemporal picture covering wide area cross multiple ISP networks. Unfortunately, such a big picture is essential to detect the anomalies embedded in the traffic flows (Chen, Hwang & Ku, 2007; Papadopoulos, Lindell, Mehringer, Hussain & Govindan, 2003). For this reason, efficient distributed data aggregation techniques have become a hot topic in research community. Due to the limited space, here we only provide a brief survey of reported works which are closely relevant to our work.

A couple of overlay based data aggregation techniques have been proposed to monitor local network traffic and detect anomalies and attacks collaboratively (Feinstein, Schnackenberg, Balupari & Kindred, 2003). In WormShield (Cai, Hwang, Pan & Papadopoulos, 2007), a balanced distributed data aggregation tree (DAT) was proposed, which is capable of collecting and aggregating the fingerprint of Internet worms generated locally. Comparing to the original overlay based data aggregation such as Chord (Stoica, Morris, Karger, Kaashoek & Balakrishnan, 2001), DAT

can compute global fingerprint statistics in a scalable and load-balanced fashion. Several data aggregation systems use advanced statistical algorithms to predict lost values (Zhao, Govindan & Estrin, 2003; Madden, Franklin, Hellerstein & Hong, 2002) and try to reduce the sensitivity of large scale data aggregation networks to the loss of data (Huang, Zhao, Joseph & Kubiatowicz, 2006).

MAIN FOCUS

Efficient distributed data aggregation technique is critical to monitor the spatiotemporal fluctuations in Internet traffic status. Chen, Hwang and Ku (2007) have proposed a new distributed aggregation scheme based on change-point detection across multiple network domains. In order to establish an early warning system for DDoS defense across multiple domains, this system adopts a new mechanism called *change aggregation tree* (CAT), which adopts a hierarchical architecture and simplifies the alert correlation and global detection procedures implemented in ISP core networks.

Distributed Change Point Detection

The *Distributed Change-point Detection* (DCD) scheme detects DDoS flooding attacks by monitoring the propagation patterns of abrupt traffic changes at distributed network points. Once a sufficiently large CAT tree is constructed to exceed a preset threshold, an attack is declared. Figure 1 presents the system architecture of the DCD scheme. The system is deployed over multiple AS domains. There is a central CAT server in each domain. The system detects traffic changes, checks flow propagation patterns, aggregates suspicious alerts, and merge CAT subtrees from collaborative servers into a global CAT tree. The root of the global CAT tree is at the victim end. Each tree node corresponds to an *attack-transit routers* (ATR). Each tree edge corresponds to a link between the attack-transit routers.

The DCD system has hierarchical detection architecture. There are three layers in this architecture as shown in Fig. 2. At the lowest layer, individual router functions as a sensor to monitor local traffic fluctuations. Considering the directionality and homing effects in a DDoS flooding attack, routers check how the wavefront changes. A router raises an alert and reports an anomalous traffic pattern to the CAT server. The second layer is at each network domain level. The CAT server constructs a CAT subtree that displays a spatiotemporal pattern of the attack flow in the domain. At the highest layer, the CAT servers at different domains form an overlay network or communicate with each other through *virtual private network* (VPN) channels. All CAT servers send the locally-generated CAT subtrees to

Figure 1. Distributed change detection of DDoS attacks over multiple AS domains

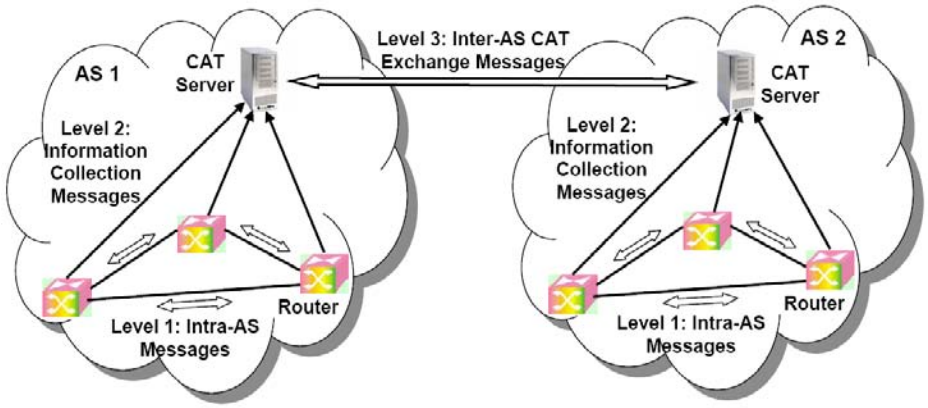
Figure 2. Illustration of 3-level communication between two CAT servers in two AS domains



the server in the destination domain, where the victim is attached. By merging CAT subtrees from cooperative domains, the destination server has a global picture of the attack. The larger is the global CAT tree constructed, the higher is the threat experienced.

Global CAT Aggregation

This section presents the procedure of global change data aggregation. Starting from the single domain subtree construction, we will discuss the global CAT tree merging and analyze the complexity based on real life Internet domain distribution data set.

Constructing Subtrees at Domain Servers

The router reports the identifier of a flow causing the traffic surge. Since all routers are under the same ISP authority and work cooperatively, each router knows their immediate neighbors. The reported message provides the upstream and downstream router identifiers. The main purpose of sending the flow status message is to report where the suspicious flows are captured.

To indicate the location of a suspicious flow, the router identifier must send. We need to identify the flow identifier of the *n*-bit prefix of the destination IP addresses. To construct the CAT, the status report provides the upstream and downstream router identifiers instead of router I/O port numbers. Using the reported status information, the domain server constructs the CAT tree gradually after receiving the alert reports from the ATRs. Table 1 summarizes the information carried in a typical alert message from an ATR.

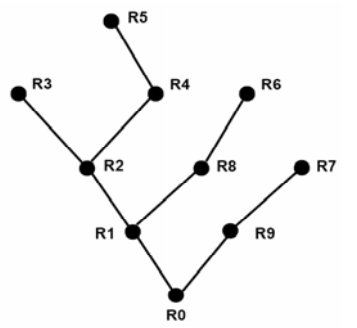
The output of this procedure is a single-domain CAT subtree. Figure 3(a) shows a flooding attack launched from 4 zombies. The ATRs detect abnormal surge of traffic at their I/O ports. The victim is attached with the end router R0 in the Fig. 3(a). All the attack flows form the flow homing towards the end router. Using the data entries listed in Table 1, The CAT tree can be

Table 1. Alert message reported by a router

Parameter	Brief Definition
nd_id	The router ID,
fl_id	The flow ID
up_num	Number of upstream nodes
dn_num	Number of downstream nodes
up_id	node ID of upstream node
dn_id	node ID of downstream node
Router status	Suspicious attack or normal traffic

Figure 3. An example of a single domain subtree construction

(a) An example of traffic flow of a DDoS flooding attack launched from 4 zombies.



(b) A change aggregation tree for the flooding pattern in (a).

specified by a hierarchical data structure. The root node carries the flow ID, the number of routers involved, root node ID, and the count of child nodes at the next level. Figure 3 illustrates how a CAT subtree rooted at the end router is constructed by merging the alert reports from 9 ATRs. The upstream and downstream ATRs report to the CAT server during each monitory cycle.

Global CAT Aggregation

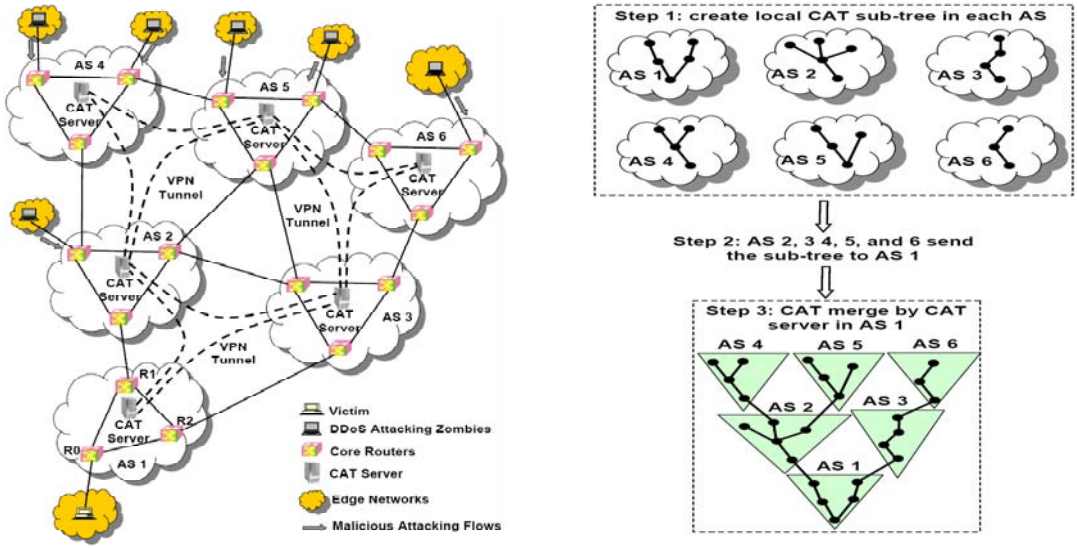
In a DDoS flooding attack, the attacker often recruits many zombies distributed over the Internet. The flooding traffic travels through multiple AS domains before reaching the edge network, where the victim is physically attached. Routers at the upstream domains observe the suspicious traffic flows earlier than routers at the downstream networks. The CAT subtrees constructed at all traversed domains must be merged to yield a global CAT tree at the destination domain. The tree width and height thus reveal the scope of the DDoS attack. On receiving subtrees from upstream CAT servers, the CAT server in the destination domain builds the global CAT tree from its local subtree. Figure 4 shows an example network environment involving six AS domains.

The victim system is located in the AS1 domain. Zombies are scattered widely in Internet outside the illustrated domains. By detecting abnormal traffic changes in each domain, the CAT server creates a CAT subtree locally at each domain. Figure 4(b) shows three steps taken to merge the 6 subtrees generated by 6 CAT servers of 6 AS domain. All 6 subtrees are resulted from checking the packets belonging to the same flow traffic destined for the same domain AS1. Five subtrees generated at AS 2, AS3, AS4, AS5, and AS6 at upstream domains are sent to AS1 at Step 2. Then, the concatenated CAT subtrees are connected to the downstream subtree at AS1. Thus the global CAT tree is finally rooted at the last hop router to an edge network R0 that is attached to the victim system.

Complexity Analysis

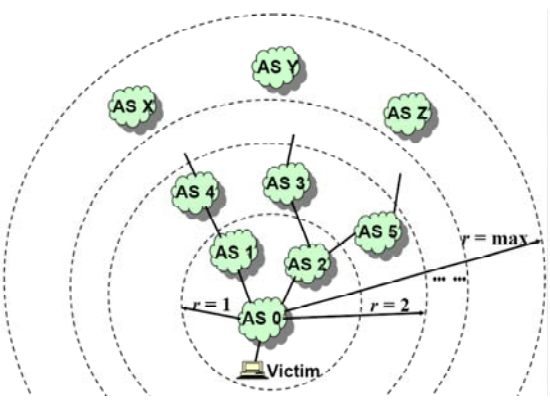
The complexity of the CAT growth is analyzed below based on Internet topology data available from open literature (ISO, 2006; Siganos, M. Faloutsos, P. Faloutsos & C. Faloutsos, 2003). Figure 5 illustrates the process of the CAT tree growth out of merging subtrees from attack-transit domains. Let ***r*** be the number of hops from an AS domain to the destination domain.

Figure 4. An example 6-domain global CAT tree construction environment.



(a) DCD system architecture over 6 domains. *(b) Merging 6 subtrees to yield a global tree*

Figure 5. Merging CAT subtrees from neighboring AS domains to outer domains to build a global CAT tree, where AS_0 is the victim domain and r_{max} = 6 hops



The server checks the received subtrees in increasing order of distance ***r***.

The system first merges the subtrees from ASes located in 1-hop (r = 1) distance to form a partial global tree. Next, it merges the subtrees from domains at 2-hop distance. The merging process repeats with distances r = 3, 4 until all subtrees are merged into the final global CAT tree.

The complexity of global CAT tree merging is highly dependent on the network topology. We model the Internet domains as an undirected graph of M nodes and E edges. The diameter of the graph is denoted by δ. Siganos *et al.* (Siganos, M. Faloutsos, P. Faloutsos & C. Faloutsos, 2003) models the Internet neighborhood as an H-dimensional sphere with a diameter $\boldsymbol{\delta}$. The parameter H is the dimension of the network topology (M. Faloutsos, C. Faloutsos, and P. Faloutsos, 1999). For example, H = 1 specifies a ring topology and H = 2 for a 2-dimensional mesh. Any two nodes are within an effective diameter, δ_{ef} hops away from each other.

In 2002, the dimension of Internet was calculated as H = 5.7 in an average sense. The ceiling of this diameter δ_{ef} is thus set to be 6. Let NN(h) be the number of domains located at distance h from a typical domain in the Internet. Table 2 gives the domain distribution – the probability of an AS domain residing exactly h hops away from a reference domain. The numbers of domains in various distance ranges are given in the

Table 2. Internet domain distribution reported in Feb. 28, 2006 (ISO, 2006)

Hop Count, h	1	2	3	4	5	6	≥ 7
Domain Distribution, p_h	0.04%	8.05%	38.55%	38.12%	12.7%	2.25%	0.29%
Domain Count, $NN(h)$	14	2,818	13,493	13,342	4,445	788	102

second row. It is interesting to note that most communicating domains are within 3 or 4 hops, almost following a normal distribution centered on an average hop count of 3.5.

The number of Internet AS domains keeps increasing in time, the Faloutsos reports (M. Faloutsos, C. Faloutsos, and P. Faloutsos, 1999; Siganos, M. Faloutsos, P. Faloutsos & C. Faloutsos, 2003) indicates that this AS distribution is pretty stable over time. This implies that a packet can reach almost all domains in the Internet by traversing through 6 hops. Therefore, we set the maximum hop count $r_{max} = 6$ in Figure 5.

FUTURE TRENDS

One of the most critical concerns of the real time distributed data aggregation for the security purpose of the Internet traffic monitoring is the scalability. There is limited resources in core routers can be shared to execute security functions. Considering the computational complexity, it is challenging to cope with the high data rate in today's network (multi gigabyte). Especially, it is desired to detect the attacks swiftly before damages caused. In general, most software based security mechanisms are not feasible in high-speed core networks.

We suggest exploring a hardware approach to implementing the CAT mechanism and other real time distributed data aggregation techniques using reconfigurable hardware devices, for instance, network processors or FPGA devices. The ultimate goal is to promote real-time detection and response against DDoS attacks with automatic signature generation. FPGA devices have the flexibility of software combined with a speed of a hardware implementation, providing high performance and fast development cycles. The reconfigurability allows further update of the security system considering the evolution of attacks and defense techniques. The high parallelism makes it capable of handling multi-gigabyte of data rate in the core networks. It pushes security tasks down to the lower level in the packet-processing hierarchy. The suspicious attacking traffic patterns are recognized before the traffic hit the routing fabric. The security monitoring works are performed in parallel with routing jobs and light overhead is incurred. For this purpose, researches on embedded accelerators using network processors or FPGAs have been carried out and solid achievements have been made in recent years (Attig & Lockwood, 2005; Charitakis, Anagnostakis & Markatos, 2004).

CONCLUSION

It is crucial to detect the DDoS flooding attacks at their early launching stage before widespread damages done to legitimate applications on the victim system. We develop a novel distributed data aggregation scheme to monitor the spatiotemporal distribution of changes in Internet traffic. This CAT mechanism helps us to achieve an early DDoS detection architecture based on constructing a global change aggregation tree that describes the propagation of the wavefront of the flooding attacks.

KEY TERMS

Attack Transit Router (ATR): Routers located in the path through which malicious attacking traffic go through towards the victim.

Autonomous Systems: An AS is a connected group of one or more Internet Protocol prefixes run by one or more network operators which has a SINGLE and CLEARLY DEFINED routing policy.

Change Aggregation Tree (CAT): A distributed data structure that describes the spatiotemporal pattern of anomaly traffic surges in a wide area in the network.

Data Aggregation: Data aggregation is any process in which information is gathered and expressed in a summary form, for purposes such as statistical analysis.

DDoS Attacks: On the Internet, a distributed denial-of-service (DDoS) attack is one in which a multitude of compromised systems attack a single target, thereby causing denial of service for users of the targeted system. The flood of incoming messages to the target system essentially forces it to shut down, thereby denying service to the system to legitimate users.

Distributed Change-Point Detection (DCD): A distributed statistical scheme that is design to detect anomalies in a network by monitoring the short term change in the network traffic and comparing it with the long term history average.

FPGA: A field-programmable gate array (FPGA) is an integrated circuit (IC) that can be programmed in the field after manufacture.

Internet: The global internetwork based on the Internet (TCP/IP) architecture, connecting millions of hosts worldwide.

Network Domain: On the Internet, a domain consists of a set of network addresses. This domain is organized in levels. The top level identifies geographic or purpose commonality. The second level identifies a unique place within the top level domain and is, in fact, equivalent to a unique address on the Internet (an IP address). Lower levels of domain may also be used.

Network Processor: A device that is similar to a microprocessor, except that it has been optimized for use in applications involving network routing and packet processing. There is no standard architecture, but many network processors feature multiple RISC CPUs running in parallel. In this configuration, one central processor typically receives and handles network control packets while the others pass data packets through the system at network speeds.

Virtual Private Network (VPN): A communications network tunneled through another network, and dedicated for a specific network. One common application is secure communications through the public Internet, but a VPN need not have explicit security features, such as authentication or content encryption.

Zombie: Zombies are computers that have been compromised by attackers generally through the use of Trojans. Collectively, they are manipulated to create the high traffic flow necessary to create a DDoS attack. In literatures, they are also referred as *agents*.

Distributed Data Mining

INTRODUCTION

The continuous developments in information and communication technology have recently led to the appearance of distributed computing environments, which comprise several, and different sources of large volumes of data and several computing units. The most prominent example of a distributed environment is the Internet, where increasingly more databases and data streams appear that deal with several areas, such as meteorology, oceanography, economy and others. In addition the Internet constitutes the communication medium for geographically distributed information systems, as for example the earth observing system of NASA (*eos.gsfc.nasa.gov*). Other examples of distributed environments that have been developed in the last few years are *sensor networks* for process monitoring and *grids* where a large number of computing and storage units are interconnected over a high-speed network.

The application of the classical knowledge discovery process in distributed environments requires the collection of distributed data in a data warehouse for central processing. However, this is usually either ineffective or infeasible for the following reasons:

(1) *Storage cost*. It is obvious that the requirements of a central storage system are enormous. A classical example concerns data from the astronomy science, and especially images from earth and space telescopes. The size of such databases is reaching the scale of exabytes (10^{18} bytes) and is increasing at a high pace. The central storage of the data of all telescopes of the planet would require a huge data warehouse of enormous cost.
(2) *Communication cost*. The transfer of huge data volumes over network might take extremely much time and also require an unbearable financial cost. Even a small volume of data might create problems in wireless network environments with limited bandwidth. Note also that communication may be a continuous overhead, as distributed databases are not always constant and unchangeable. On the contrary, it is common to have databases that are frequently updated with new data or data streams that constantly record information (e.g remote sensing, sports statistics, etc.).
(3) *Computational cost*. The computational cost of mining a central data warehouse is much bigger than the sum of the cost of analyzing smaller parts of the data that could also be done in parallel. In a grid, for example, it is easier to gather the data at a central location. However, a distributed mining approach would make a better exploitation of the available resources.
(4) *Private and sensitive data*. There are many popular data mining applications that deal with sensitive data, such as people's medical and financial records. The central collection of such data is not desirable as it puts their privacy into risk. In certain cases (e.g. banking, telecommunication) the data might belong to different, perhaps competing, organizations that want to exchange knowledge without the exchange of raw private data.

This article is concerned with Distributed Data Mining algorithms, methods and systems that deal with the above issues in order to discover knowledge from distributed data in an effective and efficient way.

BACKGROUND

Distributed Data Mining (DDM) (Fu, 2001; Park & Kargupta, 2003) is concerned with the application of the classical Data Mining procedure in a distributed computing environment trying to make the best of the available resources (communication network, computing units and databases). Data Mining takes place both

locally at each distributed site and at a global level where the local knowledge is fused in order to discover global knowledge.

A typical architecture of a DDM approach is depicted in Figure 1. The first phase normally involves the analysis of the local database at each distributed site. Then, the discovered knowledge is usually transmitted to a merger site, where the integration of the distributed local models is performed. The results are transmitted back to the distributed databases, so that all sites become updated with the global knowledge. In some approaches, instead of a merger site, the local models are broadcasted to all other sites, so that each site can in parallel compute the global model.

Distributed databases may have homogeneous or heterogeneous schemata. In the former case, the attributes describing the data are the same in each distributed database. This is often the case when the databases belong to the same organization (e.g. local stores of a chain). In the latter case the attributes differ among the distributed databases. In certain applications a key attribute might be present in the heterogeneous databases, which will allow the association between tuples. In other applications the target attribute for prediction might be common across all distributed databases.

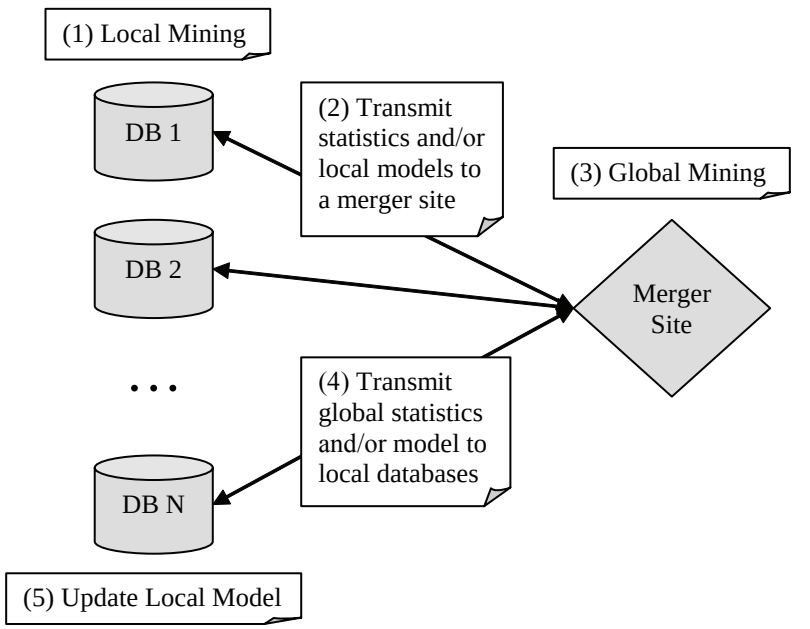
MAIN FOCUS

Distributed Classification and Regression

Approaches for distributed classification and regression are mainly inspired from methods that appear in the area of ensemble methods, such as Stacking, Boosting, Voting and others. Some distributed approaches are straightforward adaptations of ensemble methods in a distributed computing environment, while others extend the existing approaches in order to minimize the communication and coordination costs that arise.

Chan and Stolfo (1993) applied the idea of Stacked Generalization (Wolpert, 1992) to DDM via their meta-learning methodology. They focused on combining distributed data sets and investigated various schemes for structuring the meta-level training examples. They showed that meta-learning exhibits better performance with respect to majority voting for a number of domains. Knowledge Probing (Guo & Sutiwaraphun, 1999) builds on the idea of meta-learning and in addition uses an independent data set, called the probing set, in order to discover a comprehensible model. The output of a meta-learning system on this independent data set together with the attribute value vector of the same

Figure 1. Typical architecture of Distributed Data Mining approaches



data set are used as training examples for a learning algorithm that outputs a final model.

The Collective Data Mining (CDM) framework (Kargupta, Park, Hershberger & Johnson, 2000) allows the learning of classification and regression models over heterogeneous databases. It is based on the observation that any function can be represented using an appropriate set of basis functions. Initially, CDM generates approximate orthonormal basis coefficients at each site. It then moves an appropriately chosen sample of each data set to a single site and generates the approximate basis coefficients corresponding to non-linear cross terms. Finally, it combines the local models and transforms the global model into the user-specified canonical representation.

A number of approaches have been presented for learning a single rule set from distributed data. Hall, Chawla and Bowyer (1997; 1998) present an approach that involves learning decision trees in parallel from disjoint data, converting trees to rules and then combining the rules into a single rule set. Hall, Chawla, Bowyer and Kegelmeyer (2000) present a similar approach for the same case, with the difference that rule learning algorithms are used locally. In both approaches, the rule combination step starts by taking the union of the distributed rule sets and continues by resolving any conflicts that arise. Cho and Wüthrich (2002) present a different approach that starts by learning a single rule for each class from each distributed site. Subsequently, the rules of each class are sorted according to a criterion that is a combination of confidence, support and deviation, and finally the top k rules are selected to form the final rule set. Conflicts that appear during the classification of new instances are resolved using the technique of relative deviation (Wüthrich, 1997).

Fan, Stolfo and Zhang (1999) present d-sampling AdaBoost, an extension to the generalized AdaBoost learning algorithm (Schapire and Singer, 1999) for DDM. At each round of the algorithm, a different site takes the role of training a weak model using the locally available examples weighted properly so as to become a distribution. Then, the update coefficient α_t is computed based on the examples of all distributed sites and the weights of all examples are updated. Experimental results show that the performance of the proposed algorithm is in most cases comparable to or better than learning a single classifier from the union of the distributed data sets, but only in certain cases comparable to boosting that single classifier. The distributed boosting algorithm of Lazarevic and Obradovic (2001) at each round learns a weak model in each distributed site in parallel. These models are exchanged among the sites in order to form an ensemble, which takes the role of the hypothesis. Then, the local weight vectors are updated at each site and their sums are broadcasted to all distributed sites. This way each distributed site maintains a local version of the global distribution without the need of exchanging the complete weight vector. Experimental results show that the proposed algorithm achieved classification accuracy comparable or even slightly better than boosting on the union of the distributed data sets.

Distributed Association Rule Mining

Agrawal and Shafer (1996) discuss three parallel algorithms for mining association rules. One of those, the Count Distribution (CD) algorithm, focuses on minimizing the communication cost, and is therefore suitable for mining association rules in a distributed computing environment. CD uses the Apriori algorithm (Agrawal and Srikant, 1994) locally at each data site. In each pass k of the algorithm, each site generates the same candidate k-itemsets based on the globally frequent itemsets of the previous phase. Then, each site calculates the local support counts of the candidate itemsets and broadcasts them to the rest of the sites, so that global support counts can be computed at each site. Subsequently, each site computes the k-frequent itemsets based on the global counts of the candidate itemsets. The communication complexity of CD in pass k is $O(|C_k|n^2)$, where C_k is the set of candidate k-itemsets and n is the number of sites. In addition, CD involves a synchronization step when each site waits to receive the local support counts from every other site.

Another algorithm that is based on Apriori is the Distributed Mining of Association rules (DMA) algorithm (Cheung, Ng, Fu & Fu, 1996), which is also found as Fast Distributed Mining of association rules (FDM) algorithm in (Cheung, Han, Ng, Fu & Fu, 1996). DMA generates a smaller number of candidate itemsets than CD, by pruning at each site the itemsets that are not locally frequent. In addition, it uses polling sites to optimize the exchange of support counts among sites, reducing the communication complexity in pass k to $O(|C_k|n)$, where C_k is the set of candidate k-itemsets and n is the number of sites. However, the performance enhancements of DMA over CD are based on the as-

sumption that the data distributions at the different sites are skewed. When this assumption is violated, DMA actually introduces a larger overhead than CD due to its higher complexity.

The Optimized Distributed Association rule Mining (ODAM) algorithm (Ashrafi, Taniar & Smith, 2004) follows the paradigm of CD and DMA, but attempts to minimize communication and synchronization costs in two ways. At the local mining level, it proposes a technical extension to the Apriori algorithm. It reduces the size of transactions by: i) deleting the items that weren't found frequent in the previous step and ii) deleting duplicate transactions, but keeping track of them through a counter. It then attempts to fit the remaining transaction into main memory in order to avoid disk access costs. At the communication level, it minimizes the total message exchange by sending support counts of candidate itemsets to a single site, called receiver. The receiver broadcasts the globally frequent itemsets back to the distributed sites.

Distributed Clustering

Johnson and Kargupta (1999) present the Collective Hierarchical Clustering (CHC) algorithm for clustering distributed heterogeneous data sets, which share a common key attribute. CHC comprises three stages: i) local hierarchical clustering at each site, ii) transmission of the local dendrograms to a facilitator site, and iii) generation of a global dendrogram. CHC estimates a lower and an upper bound for the distance between any two given data points, based on the information of the local dendrograms. It then clusters the data points using a function on these bounds (e.g. average) as a distance metric. The resulting global dendrogram is an approximation of the dendrogram that would be produced if all data were gathered at a single site.

Samatova, Ostrouchov, Geist and Melechko (2002), present the RACHET algorithm for clustering distributed homogeneous data sets. RACHET applies a hierarchical clustering algorithm locally at each site. For each cluster in the hierarchy it maintains a set of descriptive statistics, which form a condensed summary of the data points in the cluster. The local dendrograms along with the descriptive statistics are transmitted to a merging site, which agglomerates them in order to construct the final global dendrogram. Experimental results show that RACHET achieves good quality of clustering compared to a centralized hierarchical clustering algorithm, with minimal communication cost.

Januzaj, Kriegel and Pfeifle (2004) present the Density Based Distributed Clustering (DBDC) algorithm. Initially, DBDC uses the DBSCAN clustering algorithm locally at each distributed site. Subsequently, a small number of representative points that accurately describe each local cluster are selected. Finally, DBDC applies the DBSCAN algorithm on the representative points in order to produce the global clustering model.

Database Clustering

Real-world, physically distributed databases have an intrinsic data skewness property. The data distributions at different sites are not identical. For example, data related to a disease from hospitals around the world might have varying distributions due to different nutrition habits, climate and quality of life. The same is true for buying patterns identified in supermarkets at different regions of a country. Web document classifiers trained from directories of different Web portals is another example.

Neglecting the above phenomenon, may introduce problems in the resulting knowledge. If all databases are considered as a single logical entity then the idiosyncrasies of different sites will not be detected. On the other hand if each database is mined separately, then knowledge that concerns more than one database might be lost. The solution that several researchers have followed is to cluster the databases themselves, identify groups of similar databases, and apply DDM methods on each group of databases.

Parthasarathy and Ogihara (2000) present an approach on clustering distributed databases, based on association rules. The clustering method used, is an extension of hierarchical agglomerative clustering that uses a measure of similarity of the association rules at each database. McClean, Scotney, Greer and Páircéir (2001) consider the clustering of heterogeneous databases that hold aggregate count data. They experimented with the Euclidean metric and the Kullback-Leibler information divergence for measuring the distance of aggregate data. Tsoumakas, Angelis and Vlahavas (2003) consider the clustering of databases in distributed classification tasks. They cluster the classification models that are produced at each site based on the differences of their predictions in a validation data set. Experimental results show that the combining of the classifiers within each cluster leads to better performance compared to

combining all classifiers to produce a global model or using individual classifiers at each site.

FUTURE TRENDS

One trend that can be noticed during the last years is the implementation of DDM systems using emerging distributed computing paradigms such as Web services and the application of DDM algorithms in emerging distributed environments, such as mobile networks, sensor networks, grids and peer-to-peer networks.

Cannataro and Talia (2003), introduced a reference software architecture for knowledge discovery on top of computational grids, called *Knowledge Grid*. Datta, Bhaduri, Giannela, Kargupta and Wolff (2006), present an overview of DDM applications and algorithms for P2P environments. McConnell and Skillicorn (2005) present a distributed approach for prediction in sensor networks, while Davidson and Ravi (2005) present a distributed approach for data pre-processing in sensor networks.

CONCLUSION

DDM enables learning over huge volumes of data that are situated at different geographical locations. It supports several interesting applications, ranging from fraud and intrusion detection, to market basket analysis over a wide area, to knowledge discovery from remote sensing data around the globe.

As the network is increasingly becoming the computer, the role of DDM algorithms and systems will continue to play an important role. New distributed applications will arise in the near future and DDM will be challenged to provide robust analytics solutions for these applications.

KEY TERMS

Data Skewness: The observation that the probability distribution of the same attributes in distributed databases is often very different.

Distributed Data Mining (DDM): A research area that is concerned with the development of efficient algorithms and systems for knowledge discovery in distributed computing environments.

Global Mining: The combination of the local models and/or sufficient statistics in order to produce the global model that corresponds to all distributed data.

Grid: A network of computer systems that share resources in order to provide a high performance computing platform**.**

Homogeneous and Heterogeneous Databases: The schemata of Homogeneous (Heterogeneous) databases contain the same (different) attributes.

Local Mining: The application of data mining algorithms at the local data of each distributed site.

Sensor Network: A network of spatially distributed devices that use sensors in order to monitor environment conditions.

Document Indexing Techniques for Text Mining

José Ignacio Serrano

Mª Dolore del Castillo
Instituto de Automática Industrial (CSIC), Spain

INTRODUCTION

Owing to the growing amount of digital information stored in natural language, systems that automatically process text are of crucial importance and extremely useful. There is currently a considerable amount of research work (Sebastiani, 2002; Crammer et al., 2003) using a large variety of machine learning algorithms and other Knowledge Discovery in Databases (KDD) methods that are applied to Text Categorization (automatically labeling of texts according to category), Information Retrieval (retrieval of texts similar to a given cue), Information Extraction (identification of pieces of text that contains certain meanings), and Question/Answering (automatic answering of user questions about a certain topic). The texts or documents used can be stored either in ad hoc databases or in the World Wide Web. Data mining in texts, the well-known Text Mining, is a case of KDD with some particular issues: on one hand, the features are obtained from the words contained in texts or are the words themselves. Therefore, text mining systems faces with a huge amount of attributes. On the other hand, the features are highly correlated to form meanings, so it is necessary to take the relationships among words into account, what implies the consideration of syntax and semantics as human beings do. KDD techniques require input texts to be represented as a set of attributes in order to deal with them. The text-to-representation process is called text or document indexing, and the attributes and called indexes. Accordingly, indexing is a crucial process in text mining because indexed representations must collect, only with a set of indexes, most of the information expressed in natural language in the texts with the minimum loss of semantics, in order to perform as well as possible.

BACKGROUND

The traditional "bag-of-words" representation (Sebastiani, 2002) has shown that a statistical distribution of word frequencies, in many text classification problems, is sufficient to achieve high performance results. However, in situations where the available training data is limited by size or by quality, as is frequently true in real-life applications, the mining performance decreases. Moreover, this traditional representation does not take into account the relationships among the words in the texts so that if the data mining task required abstract information, the traditional representation would not afford it. This is the case of the textual informal information in web pages and emails, which demands a higher level of abstraction and semantic depth to perform successfully.

In the end-nineties, word hyperspaces appeared on the scene and they are still updating and improving nowadays. These kind of systems build a representation, a matrix, of the linguistic knowledge contained in a given text collection. They are called word hyperspaces because words are represented in a space of a high number of dimensions. The representation, or hyperspace, takes into account the relationship between words and the syntactic and semantic context where they occur and store this information within the knowledge matrix. This is the main difference with the common "bag of words" representation. However, once the hyperspace has been built, word hyperspace systems represent the text as a vector with a size equal to the size of the hyperspace by using the information hidden in it, and by doing operations with the rows and the columns of the matrix corresponding to the words in the texts.

LSA (Latent Semantic Analysis) (Landauer, Foltz & Laham, 1998; Lemaire & Denhière, 2003) was the first

one to appear. Given a text collection, LSA constructs a term-by-document matrix. The A_{ij} matrix component is a value that represents the relative occurrence level of term *i* in document *j*. Then, a dimension reduction process is applied to the matrix, concretely the SVD (Singular Value Decomposition) (Landauer, Foltz & Laham, 1998). This dimension-reduced matrix is the final linguistic knowledge representation and each word is represented by its corresponding matrix row of values (vector). After the dimension reduction, the matrix values contain the latent semantic of all the other words contained in all each document. A text is then represented as a weighted average of all the vectors corresponding to the words it contains and the similarity between two texts is given by the cosine distance between the vectors that represent them.

Hyperspace Analogue to Language (HAL) (Burgess, 2000) followed LSA. In this method, a matrix that represents the linguistic knowledge of a text collection is also built but, in this case, is a word-by-word matrix. The A_{ij} component of the matrix is a value related to the number of times the word *i* and the word *j* co-occur within the same context. The context is defined by a window of words, of a fixed size. The matrix is built by sliding the window over all the text in the collection, and by updating the values depending on the distance, in terms of position, between each pair of words in the window. A word is represented by the values corresponding to its row concatenated with the values corresponding to its column. This way, not only the information about how is the word related to each other is considered, but also about how the other words are related to it. The meaning of a word can be derived from the degrees of the relations of the word with each other. Texts are also represented by the average of the vectors of the words it contains and compared by using the cosine distance.

Random Indexing (Kanerva, Kristofersson & Holst, 2000) also constructs a knowledge matrix but in a distributed fashion and with a strong random factor. A fixed number of contexts (mainly documents) in which words can occur, is defined. Each context is represented by a different random vector of a certain size. The vector size is defined by hand and corresponds to the number of columns, or dimensions, of the matrix. Each row of the matrix makes reference to one of the words contained in the text collection from which the linguistic knowledge was obtained. This way, each time a word occurs in one of the predefined contexts, the context vector is summed up to the row referent to the word. At the end of the construction of the knowledge matrix, each word is represented as a vector resulting from the sum of all the vectors of the contexts where it appears. Other advantage relies on the flexibility of the model, because the incorporation of a new context or word only implies a new random vector and a sum operation. Once again, texts are represented as the average (or any other statistical or mathematical function) of the vector of the words that appear in it.

Unlike the previous systems, in WAS (Word Association Space) (Steyvers, Shiffrin & Nelson, 2004) the source of the linguistic knowledge is not a text collection but data coming from human subjects. Although the associations among words are represented as a word-by-word matrix, they are not extracted from the co-occurrences within texts. The association norms are directly queried humans. A set of human subjects were asked to write the first word that come out in their mind when each of the words in a list were presented to them, one by one, so that the given words correspond to the rows of the matrix and the answered words correspond to the columns of the matrix. Finally, the SVD dimension reduction is applied to the matrix. The word and text representations are obtained the same way as the systems above.

The FUSS (Featural and Unitary Semantic Space) system (Vigliocco, Vinson, Lewis & Garrett, 2004), the knowledge source also comes from human subjects. It is based on the state that words are not only associated to their semantic meaning but also to the way humans learn them when perceive them. Then, human subjects are asked to choose which conceptual features are useful to describe each entry of a word list. So a word-by-conceptual feature matrix is constructed, keeping the *k* most considered features and discarding the others, and keeping the *n* most described words by the selected features. Once the matrix is bounded, a SOM (Self Organizing Map) algorithm is applied. A word is represented by the most activated unit of the maps, when the feature vector which corresponds to the word is taken as the input of the map. The texts are then represented by the most activated units which correspond to the words that appear inside it.

In Sense Clusters system (Pedersen & Kulkarni, 2005), the authors propose two different representations for the linguistic knowledge, both of them matrix-like, called representation of first order and second order, respectively. In the first representations, matrix values

correspond to the frequency of occurring for the words, bigrams and n-grams represented by the columns, in the contexts of the rows. In the other representation, a square matrix collects the associations among the words that belong to all the bigrams and n-grams. The SVD dimension reduction method is applied to both matrices and then a clustering algorithm is run over them. This way, the semantics topics are described by the clusters obtained. A new text is represented as a vector separately for each cluster. Finally, the decisions are taken following the similarity criterion of the text to each cluster.

The system that stands for NLS (Non-Latent Similarity) (Cai, McNamara, Louwerse, Hu, Rowe & Graesser, 2004) is one of the few that deals with syntax in an explicit way. A set of features is defined by an expert, as well as a set of significance weights for the features. The features are sequences of POS (Part Of Speech) tags. For each word in the text collection, a vector of size equal to the number of defined features is created. Then a word-by-word matrix is built. An SVD dimension reduction is finally applied to the matrix. Texts are represented as a function of the vectors of the words it contains.

Besides the systems briefly described above, there exist other techniques, also different from the traditional indexing, that do not use a matrix to collect the background linguistic knowledge. Instead of that, PMI (Pointwise Mutual Information) (Turney, 2001), the most representative example of this kind of systems, represents the word associations as a probabilistic model. The frequencies of co-occurrence are obtained from the World Wide Web, by asking the Altavista Advanced Search, so that if a word is not in the probabilistic model, the co-occurrence relationships with the other words in the model are obtained in real time from web search results, opposite to the classical statistical models which fail when missing words appear.

The CDSA (Context Dependent Sentence Abstraction) model (Ventura, Hu, Graesser, Louwerse & Olney, 2004) does not use a matrix either. For each word, a list of the words with which it co-occurrs ("neighbours") is stored together with a weight for each component of the list. The weights represent the frequencies of co-occurrence. This way, the similarity between two words is a function on the weights of their shared neighbours.

MAIN FOCUS

All the systems described above improve the traditional "bag of words" representation. They have provided great advances to text mining in terms of depth and richness for text representation. In spite of the progress made with word hyperspaces and probabilistic models, human beings keep doing text mining tasks much better than machines, although of course more slowly. So, in order to certainly obtain good results a brining near human cognition is required. However, it is hard to believe that linguistic knowledge is represented as a matrix in the human mind and that text reading is carried out by mathematical operations on this matrix. Although many of the systems try to be close to humans, by searching the psychological plausibility for some of the internal processes, they do not achieve it in fact. Let us put attention in some of the features that characterize a computational model of linguistic representation (Lemaire & Denhière, 2004):

1. **Input:** The source from which the linguistic knowledge is constructed. A corpus of heterogeneous documents, mixing different topics, styles and spoken and writing texts, is psychologically more plausible than small sets of association norms or sublanguages.
2. **Representation:** The formalism to store and operate with words and texts. Vectors allow to easily compute similarity among words and texts. However, it makes difficult to find out the most related words or texts to a given one. Moreover, the asymmetric condition of the similarity function among vectors is not psychologically plausible, and neither the use of the same representation for vectors and words.
3. **Knowledge updating:** The way in which the linguistic knowledge can be modified when new texts need to be added. The incremental models are close to humans. In some of the methods described above, updating is very time-consuming because it implies the reconstruction of all the knowledge representation from the beginning.
4. **High-order co-occurrences:** The indirect associations or associations of the words that are associated to other and so on. Only a few of the models take several levels of indirect associations into account, what is showed to be very significant

in human language cognition.

5. **Compositionality:** The process to represent the text from the words it contains. A direct composition, such as vector average or sum, is very efficient in computational terms. However, humans do not create the representation of a text in mind by a direct function on the words of the texts.

There is only one system that introduces a structural representation: ICAN (Incremental Construction of an Associative Network) (Lemaire & Denhière, 2004). ICAN does not store linguistic knowledge as a matrix but as a net of associated words. These associations have a weight calculated from probabilities of co-occurrence and non-co-occurrence between word pairs. In this model words and texts do not share the same structure of representation, unlike the systems mentioned above. This model makes it possible to incrementally add new words without retraining and recalculating the knowledge, which is psychologically more plausible. This approach proposes a connectionist model, by representing linguistic knowledge as a net of concepts associated by context. However, texts are simply represented by subnets of the global knowledge net, formed by the nodes corresponding to the words in the texts and their associations.

However, humans represent texts in mind after an indirect process: reading. Human reading is a process of sequential perception over time, during which the mind builds mental images and inferences which are reinforced, updated or discarded until the end of the text (Perfetti, 1999). At that moment, this mental image allows humans to summarize and classify the text, to retrieve similar texts or simply to talk about the text by expressing opinions. Thus, the target of the research should be the construction of text representations as a result of a process over time, with a structure that makes it possible to indirectly describe the salience and relations of words at every instant during the reading process. There are some research works referring to computational models of reading (Ram & Moorman, 1999) in terms of human cognition. However, these systems are used in a closed linguistic environment with a very limited sublanguage and very specific targets. They are theoretical models rather than applications to real data mining problems.

FUTURE TRENDS

Future research is intended to bring together different research fields, such as cognitive science, cognitive linguistics, cognitive neuroscience, computational linguistics, artificial intelligence and machine learning among others. Word hyperspaces and probabilistic systems for indexing documents will be given of psychological plausibility so that they approximate to human cognition. Hybrid systems will be developed, which will make use of the models of cognitive theories but keeping the capacity of hyperspaces and probabilistic models to deal with data-intensive real problems. With this leaning to human cognition, the techniques for representing documents will intend to also model individual user behavior in order to obtain customized representations and to optimize the performance of text mining tasks.

CONCLUSION

On one hand, word hyperspaces and probabilistic systems have been shown to highly improve traditional "bag-of-words" representation of texts, what implies an increasing of the performance of text mining systems. Although they include information about syntax and semantics and they are able to deal with a huge amount of texts, they still produce representations as vectors without structure, in a direct fashion. Humans represent texts in mind as a result of a process of reading over time. On the other hand, models of cognitive reading deal with these mental processes but in closed environments and oriented to very specific tasks. Hybrid approaches that bring together hyperspaces and cognition, as well as the real world application and the theory, will be the future systems for indexing documents in order to optimize text mining tasks by user-customized representations.

KEY TERMS

Bag of Words: Traditional representation of documents stored electronically in which texts are represented by the list of the words they contains together with some measurement of the local and global frequency of the words.

Context: Continuous fragment or unit of text in which the words that constitute it are considered to be semantically or syntactically associated to each other in some manner.

Document Indexing: Representation of texts stored electronically by a set of features called indexes, mainly words or sequences of words, which try to collect most of the information contained in the natural language of the text, in order to be dealt by text mining methods.

Information Retrieval: Process of automatic searching, collecting and ranking a set of texts or fragments of text in natural language from a corpus, semantically related to an input query stated by the user also in natural language.

Latent Semantic: Relationship among word meanings given by the context in which words co-occur and

by the indirect relationships between the words.

Text Classification: Process of automatic representation and labeling of texts that intends to characterize the documents as belonging, in some degree, to one or more predefined thematic categories.

Text Mining: Knowledge discovery process on data given as text in natural language by the analysis of the textual information in many different ways. It is a kind of data mining which deals with a huge amount of a special type of information where preprocessing and feature selection steps are of crucial importance with this type of data. It is also known as text data mining, knowledge discovery in text or intelligent text analysis.

Word Hyperspace: Mathematical space with a high number of dimensions in which words are unequivocally compared and represented as vectors with a number of components equal to the number of dimensions. Word hyperspaces are usually constructed automatically from examples of natural language texts by statistical and mathematical methods.

Dynamic Data Mining

Richard Weber
University of Chile, Chile

INTRODUCTION

Since the First KDD Workshop back in 1989 when "Knowledge Mining" was recognized as one of the top 5 topics in future database research (Piatetsky-Shapiro 1991), many scientists as well as users in industry and public organizations have considered data mining as highly relevant for their respective professional activities.

We have witnessed the development of advanced data mining techniques as well as the successful implementation of knowledge discovery systems in many companies and organizations worldwide. Most of these implementations are static in the sense that they do not contemplate explicitly a changing environment. However, since most analyzed phenomena change over time, the respective systems should be adapted to the new environment in order to provide useful and reliable analyses.

If we consider for example a system for credit card fraud detection, we may want to segment our customers, process stream data generated by their transactions, and finally classify them according to their fraud probability where fraud pattern change over time. If our segmentation should group together homogeneous customers using not only their current feature values but also their trajectories, things get even more difficult since we have to cluster vectors of functions instead of vectors of real values. An example for such a trajectory could be the development of our customers' number of transactions over the past six months or so if such a development tells us more about their behavior than just a single value; e.g., the most recent number of transactions.

It is in this kind of applications is where dynamic data mining comes into play!

Since data mining is just one step of the iterative KDD (Knowledge Discovery in Databases) process (Han & Kamber, 2001), dynamic elements should be considered also during the other steps. The entire process consists basically of activities that are performed before doing data mining (such as: selection, pre-processing, transformation of data (Famili et al., 1997)), the actual data mining part, and subsequent steps (such as: interpretation, evaluation of results).

In subsequent sections we will present the background regarding dynamic data mining by studying existing methodological approaches as well as already performed applications and even patents and tools. Then we will provide the main focus of this chapter by presenting dynamic approaches for each step of the KDD process. Some methodological aspects regarding dynamic data mining will be presented in more detail. After envisioning future trends regarding dynamic data mining we will conclude this chapter.

BACKGROUND

In the past a diverse terminology has been used for emerging approaches dealing with "dynamic" elements in data mining applications. Learning from data has been defined as *incremental* if the training examples used become available over time, usually one at a time; see e.g., (Giraud-Carrier, 2000). Mining *temporal* data deals with the analysis of streams of categorical data (e.g., events; see e.g., Domingos, Hulten, 2003) or the analysis of time series of numerical data (Antunes, Oliveira 2001; Huang, 2007). Once a model has been built, *model updating* becomes relevant. According to the CRISP-DM methodology such updating is part of the monitoring and maintenance plan to be performed after model construction.

The following listing provides an overview on applications of dynamic data mining.

- Intrusion detection (Caulkins et al., 2005).
- Traffic state identification (Crespo, Weber, 2005).
- Predictive maintenance (Joentgen et al., 1999).
- Scenario analysis (Weber 2007).
- Time series prediction (Kasabov, Song, 2002)

Dynamic data mining has also been patented already, e.g., the dynamic improvement of search engines in internet which use so-called rating functions in order to measure the relevance of search terms. "Based upon a historical profile of search successes and failures as well as demographic/personal data, technologies from artificial intelligence and other fields will optimize the relevance rating function. The more the tool is used (especially by a particular user) the better it will function at obtaining the desired information earlier in a search. ... The user will just be aware that with the same input the user might give a static search engine, the present invention finds more relevant, more recent and more thorough results than any other search engines." (Vanderveldt, Black 2001).

MAIN FOCUS

As has been shown above dynamic data mining can be seen as an area within data mining where dynamic elements are considered. This can take place in any of the steps of the KDD process as will be introduced next.

Feature Selection in Dynamic Data Mining

Feature selection is an important issue of the KDD process before the actual data mining methods are applied. It consists in determining the most relevant features given a set of training examples (Famili et al., 1997). If, however, this set changes dynamically over time the selected feature set could do so as well. In such cases we would need a methodology that helps us to dynamically update the set of selected features. A dynamic wrapper approach for feature selection has been proposed in (Guajardo et al., 2006) where feature selection and model construction is performed simultaneously.

Preprocessing in Dynamic Data Mining

If in certain applications feature trajectories instead of feature values are relevant for our analysis we are faced with specific requirements for data preprocessing. In such cases it could be necessary to determine distances between trajectories within the respective data mining algorithms (as e.g., in Weber, 2007) or alternatively to apply certain preprocessing steps in order to reduce the trajectories to real-valued feature vectors.

Dynamic Clustering

Clustering techniques are used for data mining if the task is to group similar objects in the same classes (segments) whereas objects from different classes should show different characteristics (Beringer, Hüllermeier 2007). Such clustering approaches could be generalized in order to treat different dynamic elements, such as e.g., dynamic objects and/or dynamic classes. Clustering of **dynamic objects** could be the case where trajectories of feature vectors are used as input for the respective data mining algorithms. If the class structure changes over time we speak about **dynamic classes**. We present first approaches for clustering of dynamic objects and then a methodology to determine dynamic classes.

In order to be able to cluster dynamic objects, we need a distance measure between two vectors where each component is a trajectory (function) instead of a real number. Functional fuzzy c-means (FFCM) is a fuzzy clustering algorithm where the respective distance is based on the similarity between two trajectories which is determined using membership functions (Joentgen et al., 1999).

Applying this distance measure between functions FFCM determines classes of dynamic objects. The respective class centers are composed of the most representative trajectories in each class; see the following figure.

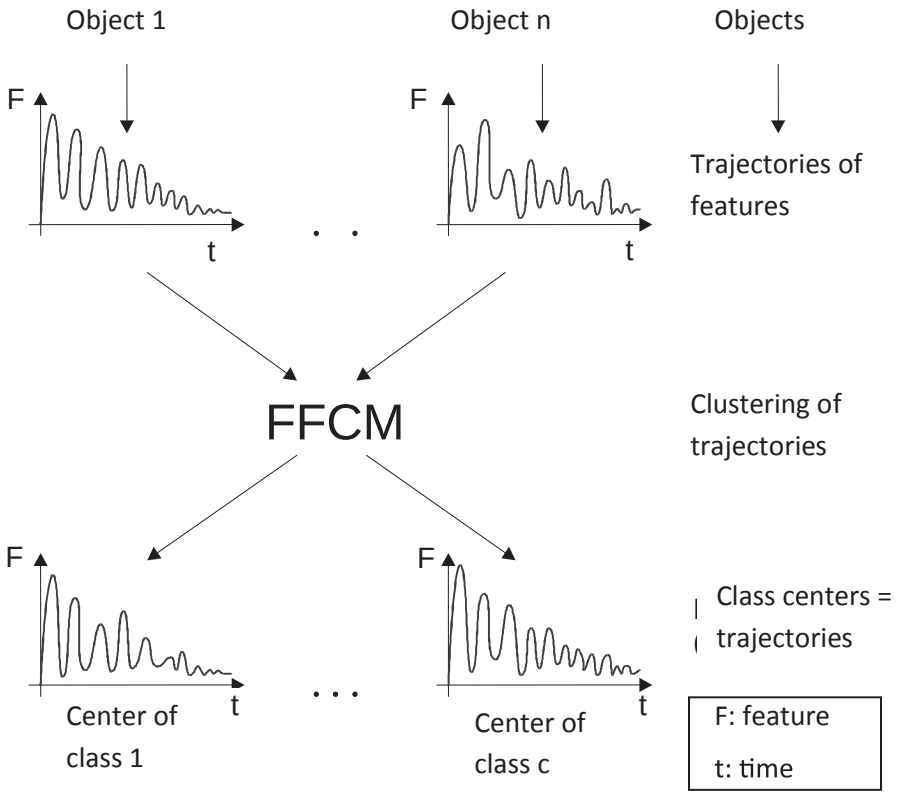
Determine dynamic classes could be the case when classes have to be created, eliminated or simply moved in the feature space. The respective methodology applies the following five steps in order to detect these changes.

Here we present just the methodology's main ideas; a detailed description can be found e.g., in (Crespo, Weber, 2005). It starts with a given classifier; in our case we chose Fuzzy c-means since the respective membership values provide a strong tool for classifier updating.

Step I: Identify Objects that Represent Changes

For each new object we want to know if it can be explained well by the given classifier. With other words

Figure 1. Functional fuzzy c-means (FFCM)



we want to identify objects that represent possible changes in the classifier structure because they are not well classified. If there are many objects that represent such possible changes we proceed with Step II, in the other case we go immediately to Step III.

Step II: Determine Changes of Class Structure

In Step I we have identified the objects that could not be well classified. Now we want to decide if we have to change the classifier structure (i.e. create new classes) or if it is sufficient to just move the existing classes. If "many new objects" are identified in Step I to represent changes we have to create a new class, in the other case we just move the existing classes in the feature space.

Step III: Change the Class Structure

Here we perform the changes according to Steps I and II (move or create classes).

Step III.1 Move Classes

We update the position of the existing class centers having the new objects and knowing that they do not ask for a structural change.

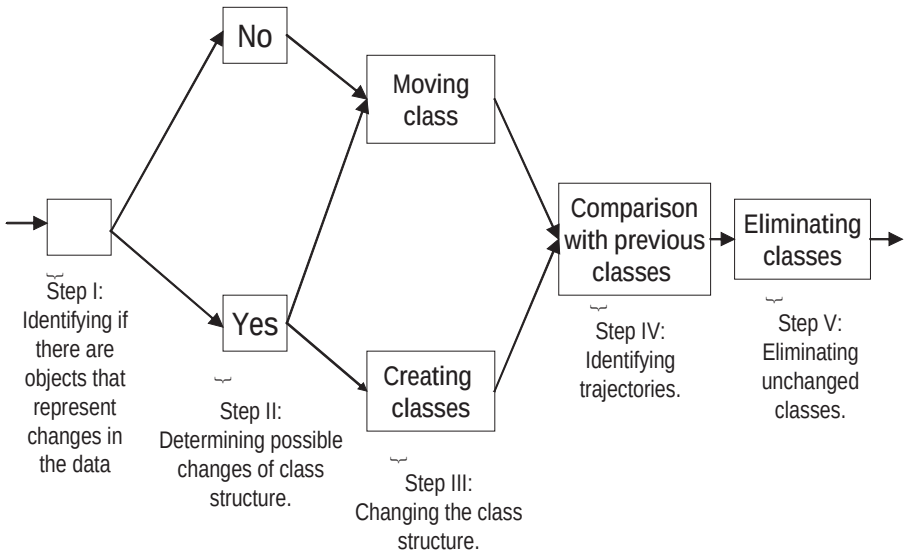
Step III.2 Create Classes

If we know that classes have to be created, we first determine an appropriate class number. Then we apply fuzzy c-means with the new class number to the available data set.

Step IV: Identify Trajectories of Classes

We identify trajectories of the classes from the previous cycles in order to decide if they received new objects. Classes that did not receive new objects during several cycles have to be eliminated.

Figure 2. Methodology for dynamic clustering



Step V: Eliminate Unchanged Classes

Based on the result of Step IV we eliminate classes that did not receive new objects during an "acceptable period".

Figure 2 provides a general view of the proposed methodology.

Dynamic Regression and Classification

Regression or classification models have to be updated over time when new training examples represent different pattern. A methodology proposed for updating forecasting models based on Support Vector Regression (SVR) changes constantly the composition of the data sets used for training, validation, and test (Weber, Guajardo, 2008). The basic idea is to add always the most recent examples to the training set in order to extract this way the most recent information about pattern changes. We suppose the series to be characterized by seasonal patterns (cycles) of length *c*.

In the static case we sequentially split data into training, validation and test sets whereas in the dynamic approach these sets are changed periodically as shown in the following figure.

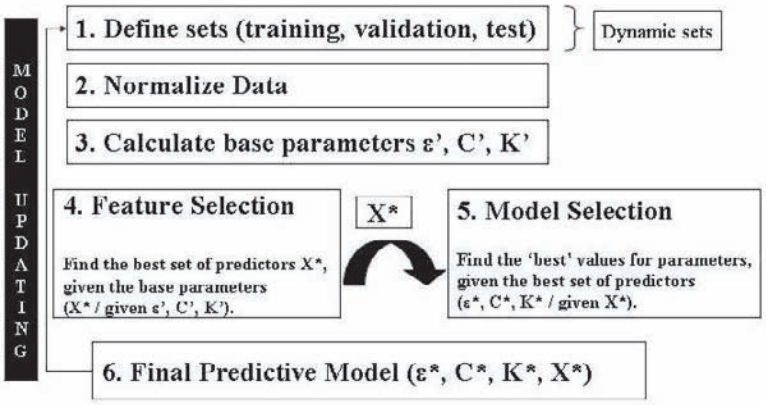
The proposed model updating strategy is designed to deal with time series with seasonal patterns. We will refer to a complete seasonal pattern as a cycle; examples are e.g., monthly data with yearly seasonality, where a cycle is defined by a year.

First, we have to identify the length of the cycles of the series. For this purpose, graphical inspection, autocorrelation analysis or spectral analysis can be carried out. Then we define a test set containing at least two cycles. This test set is divided into subsets, each one containing a single cycle. Let there be k cycles of length c belonging to the test set in the static case. In the static case, we construct just one model to predict all the observations contained in the test set, as well as for future observations, maintaining this model throughout the entire procedure unchanged. The main idea of our updating approach consists of developing different predictive models for each cycle of the test set, as well as for any future cycle by using the most recent information for model construction.

Next, we have to define the configuration of the training and validation sets for predicting the first cycle of the test set. Training data contains two parts where the first part is a set of past (or historical) data and the second part contains the most recent information. The idea of integrating the most recent information into the training set is to obtain more accurate estimations by taking into account the most recent patterns in model construction, while the proportion of data belonging to training and validation is kept stable over time.

To predict the second cycle of the test set, we add the first cycle of the test set (this data is now part of the

Figure 3. Methodology for updating regression-based forecasting using SVR



past) to the training set, and build a different predictive model. By doing so, we ensure again that most recent information has influence in model construction.

As we want to keep the proportion of data belonging to the training and validation sets stable over time, we move data from the historical part of the training set to the validation set. The amount of data to be moved is determined according to the original proportion of data in each subset. This same strategy will be applied to build predictive models for the rest of the cycles of the test set, as well as for any future observations.

Approaches for updating classification models have been presented e.g., in (Aggarwal et al., 2005, Aggarwal, 2007) where a combination of clustering and classification detects changes in stream data.

FUTURE TRENDS

In the future more *methods* for dynamic data mining addressing different steps of the KDD process will be developed. We will also see many interesting *applications* since most phenomena in real-world applications possess inherently dynamic elements.

Consequently, tool providers are supposed to add such modules to their *commercial products* in order to assist their customers more efficiently. A first though simple tool exists already on the market: the CLEO module from SPSS that deploys the entire KDD process for dynamic data mining that can be quickly adapted to changes in the analyzed phenomena. In the case of data stream mining it would also be interesting to develop special *hardware tools* in order to optimize processing speed of the respective mining tasks.

At the annual KDD conferences a particular workshop dedicated to *standards* for data mining has been established and reports since 2003 about maturing standards, including the following:

- Predictive Model Markup Language (PMML)
- XML for Analysis and OLE DB for Data Mining
- SQL/MM Part 6: Data Mining
- Java Data Mining (JDM)
- CRoss Industry Standard Process for Data Mining (CRISP-DM)
- OMG Common Warehouse Metadata (CWM) for Data Mining

The rising need for dynamic data mining will lead also to standards regarding the respective models in order to be "transferable" between tools from different providers and "usable" for various users.

A recent theoretical development which promises a huge potential is the *combination of dynamic data mining with game theory*. While data mining analyzes the behavior of agents in a real-world context via an analysis of data they generated, game theory tries to explain theoretically the behavior of such agents. If these agents "play" several times their game it will not be sufficient to just apply static data mining. Dynamic data mining will reveal the specific patterns in a changing environment. First experiments in this direction have shown already very promising results (Bravo, Weber, 2007).

CONCLUSION

Dynamic data mining will become one of the key elements of future knowledge discovery applications. Phenomena in real-world applications are dynamic in nature and so should be the models that we apply to extract useful information. This chapter presented an overview on recent developments as well as future trends related to this area.

KEY TERMS

Dynamic Data Mining: Area within data mining that deals with dynamic aspects in any of the steps of the KDD process.

Evolving Stream Data Mining: Mining data streams that change their pattern unexpectedly.

Incremental Data Mining: Mining data that become available over time, usually one at a time.

Model Updating: Adaptation of an existing data mining model when undesired deviations during the monitoring of performed applications occur.

Stream Data Mining: We refer to stream data mining when it comes to mine in data that arrives in enormous quantities under memory constraints thus making it necessary to process data in only one direction.

Temporal Data Mining: Temporal data is classified to either categorical event streams or numerical time series.

Dynamical Feature Extraction from Brain Activity Time Series

INTRODUCTION

Neurologists typically study the brain activity through acquired biomarker signals such as Electroencephalograms (EEGs) which have been widely used to capture the interactions between neurons or groups of neurons. Detecting and identifying the abnormal patterns through visual inspection of EEG signals are extremely challenging and require constant attention for well trained and experienced specialists. To resolve this problem, data mining techniques have been successfully applied to the analysis for EEG recordings and other biomarker data sets. For example, Chaovalitwongse et al., (2006; 2007), Prokopyev et al., (2007) and Pardalos et al., (2007) reported the EEG patterns can be classified through dynamical features extracted from the underlying EEG dynamical characteristics. Moreover, in the area of cancer research, Busygin et al., (2006) showed promising results via Bi-clustering data classification technique using selected features from DNA microarrays. Ceci et al., (2007); Krishnamoorthy et al., (2007) also reported that data mining techniques enable protein structure characterization and protein structure prediction. From data mining aspects, feature extraction and selection for time series data sets not only play an important role in data preprocessing but also provide opportunities to uncover the underlying mechanisms of data under study. It also keeps the essential data structure and makes a better representation of acquired data sets that need to be classified.

In this work, the properties and descriptions of the most common neurological biomarker namely EEG data sets will be given as well as the motivations and challenges for abnormal EEG classification. The dynamical features for EEG classification will be reviewed and described in the second part of this work. The described dynamical features can also be applied to other types of classification applications for discovering the useful knowledge from obtained data sets. Finally, the potential applications for EEG classification will be discussed and comments for further research directions will be given in the future trends and conclusion sections.

BACKGROUND

Epilepsy is a common neurological disorder, affecting about 50 million people worldwide (WHO, 2005). Anti antiepileptic drugs (AEDs) are the mainstay of contemporary treatment for epilepsy, it can reduce frequency of seizure and prevent seizure recurrence in most cases. For subjects with uncontrolled seizures, ablative surgery is considered after two or more AEDs have failed to result for seizure freedom. The EEG (see Fig. 1 for an example) is a key tool in diagnosing seizure disorders and contributing tremendously to surgical decisions in patients with intractable epilepsy. The EEG recordings provide information about underlying interactions among neurons around the recording electrodes as a function of time. By carefully investigating EEG patterns, the spatio-temporal neuronal electrical activities can be decoded and abnormal patterns can be captured for diagnostic purposes (Berger, 1929). Through nonlinear dynamical features, data mining techniques have

Figure 1. An example of 10 second, 32-channel intracranial EEG display

made progresses in shedding light on hidden patterns in EEG recordings for such neurological disorders (Chaovalitwongse et al., 2006; 2007).

Nonlinear nature of EEG recordings has been shown by multiple researchers (Casdagli et al., 1997; Liu et al., 2007), features generated from nonlinear dynamics have also been shown to have high applicability for EEG analysis with promising results both on classifying and predicting epileptic seizures in EEG recordings (Iasemidis et al., 1990, 2003(a),2003(b), 2004; Le Van Quyen et al., 1998, 2005; Sackellares et al., 2006; Chaovalitwongse et al., 2006, 2007; Pardalos et al., 2006, 2007). The abnormal activities detected by nonlinear dynamical methods which are not able to achieve by traditional linear measurements. Classifying through these nonlinear characteristics in the feature space, the abnormal EEG pattern can be exploited and distinguished from the normal activity in the brain.

MAIN FOCUS

The spatio-temporal nonlinear dynamics has been steadily involved in EEG analysis from its conception in the 1970s, to proof-of-principle experiments in the late 1980s and 1990s, to its current place as an area of vigorous, clinical and laboratory investigation. A specific standard for future epilepsy research was to validate the presences of abnormal brain activities and eventually link them with treatment strategies that interrupt the abnormal activities (Seref et al., 2007). Results from many studies in data mining fluctuate broadly from their theoretical approaches to the problem, the amount of data analyzed and validation of the results. Relative weaknesses in this field include the lack of extensive testing on baseline data, the lack of technically rigorous validation and quantification of algorithm performance in many published studies, and the lack of methods for extracting the useful information from multi-channel and multi-feature data sets for the data per-processing. Classifications through constructed feature space, the domain of the system and solution to

that problem are given more insightful comprehension about the underlying processes under study. Using novel dynamical features from field of nonlinear dynamics, our group has successfully reported on predicting incoming seizures, detecting abnormal brain activities and capturing the effects of therapeutic interventions. Other researchers have also documented the usefulness of nonlinear dynamics for conducting brain research (Elger et al., 1998; Lehnertz et al., 2007; L.V. Quyen et al., 1998, 2005; Mormann et al., 2005, 2006).). In this section, three dynamical features will be described together with computational results obtained from real EEG data sets obtained from patients with epilepsy.

Lyapunov exponent: The maximum Lyapunov exponent is one of the most commonly used methods for estimating the stability of nonlinear chaotic systems like EEG recordings. Lyapunov exponents quantify the rate of divergence or convergence of two nearby initial points of a dynamical system, in a global sense. A positive Lyapunov exponent measures the average exponential divergence of two nearby trajectories, whereas a negative Lyapunov exponent measures exponential convergence of two nearby trajectories. If a system is chaotic, its largest Lyapunov exponent Lmax would be positive. The Lmax is defined as the average of local Lyapunov exponents L_{ij} in the state space, defined as follows:

$$L_{max} = \frac{1}{N_\alpha} \cdot \sum_{\alpha} L_{ij},$$

where N_α is the total number of the local Lyapunov exponents that are estimated from the evolution of adjacent points (vectors), $Y_{i=}Y(t_i)$ and $Y_{j=}Y(t_j)$ in the state space such that

$$L_{ij} = \frac{1}{\Delta t} \cdot \log_2 \frac{|Y(t_i + \Delta t) - Y(t_j + \Delta t)|}{|Y(t_i) - Y(t_j)|},$$

where Δt is the evolution time allowed for the vector difference $\delta_{xk}^{(\lambda)} = |X(t_i) - X(t_j)|$ to evolve to the new difference $\delta k\,(x_k) = |Y(t_i + \Delta t) - Y(t_j + \Delta t)|$, where $\lambda = 1...$ $N\alpha - 1$ and $\Delta t = k \cdot dt$ and dt is the sampling period of the original time series. If Δt is given in second, Lmax is in bits/sec.

Iasemidis et al. (1990) first introduced Lyapunov exponent for analyzing the EEG data sets recorded from patients with epilepsy. The Lyapunov exponent has been reported to have the ability to predict epileptic seizures about 1 hour prior to seizure onset (Iasemidis et al., 2003, 2004, 2005).

Minimum Embedding Dimension: Dynamical systems processing d degrees of freedom may choose to evolve on a manifold of much lower dimension, so that only fractions of the total number of degrees of

Figure 2. A plot demonstrates the values of the Lmax start decreasing 2 hours prior to seizure onset

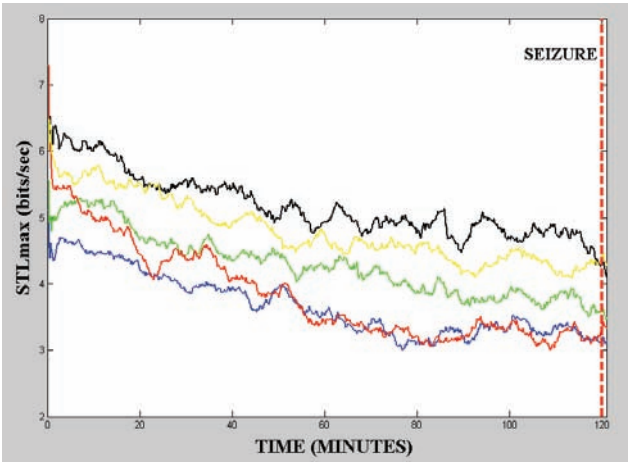

Figure 1. The steps for finding Lmax on an attractor

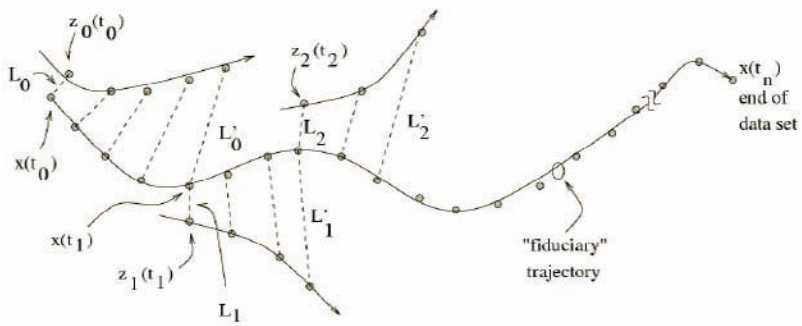


freedom are active. In such case it is useful to know how many degrees of freedom are actually active, and it is obvious that this information can be obtained from that dimension of attractor of the corresponding system. Choosing a too low value of the embedding dimension will result in points that are far apart in the original phase space being moved closer together in the reconstruction space. Takens' delay embedding theorem (Taken, 1980) states that a pseudo-state space can be reconstructed from infinite noiseless time series (when one chooses d>2dA) and can be used when reconstructing the delay vector. The classical approaches usually require huge computation power and vast amounts of data. We evaluated the minimum embedding dimension of the EEG recordings by using modified false neighbor method (Cao et al., 1997). Suppose that we have a time series $\{X_1, X_2 \ldots X_n\}$. By applying the method of delay we obtain the time delay vector, we can obtain the time-delay vector:

$$y_i(d) = (x_i, x_{i+\tau}, \ldots, x_{i+(d-1)\tau}) \text{ for i= } 1,2 \ldots N(d-1)\tau,$$

where d is the embedding dimension and τ is the time-delay and $y_i(d)$ means the i^{th} reconstructed vector with embedding dimension d. Similar to the idea of the false neighbor methods, defining

$$a(i,d) = \frac{\|y_i(d+1) - y_{n(i,d)}(d+1)\|}{\|y_i(d) - y_{n(i,d)}(d)\|} \text{ for } i = 1,2,\ldots,N - d\tau$$

where $\|\cdot\|$ is some measurement of Euclidian distance and given in this paper is the maximum norm. Define the mean value of all $a(i,d)$'s as

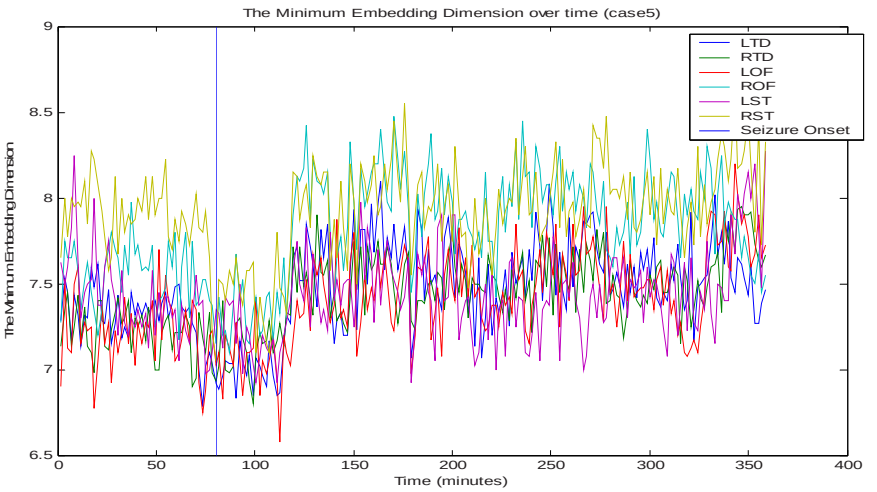
$$E(d) = \frac{1}{N-d\tau}\sum_{i=1}^{N-d\tau} a(i,d)$$

.

$E(d)$ will only depend on the dimension d and the time delay τ. The minimum embedding dimension is determined (when $E1(d) = \frac{E(d+1)}{E(d)}$ close to 1) when d is greater than some value d_0. If the time series comes from an attractor, then $d_0 + 1$ is the minimum embedding dimension. Liu et al. (2007) reported encouraging results for early seizure detection for the data sets acquired from patients with temporal lobe epilepsy.

Approximate Entropy: The Approximate entropy (ApEn) is a measure of complexity for systems. It was introduced by Pincus (1991) and has been widely applied in medical data. It can be used to differentiate between normal and abnormal data in instances where moment statistics (e.g. mean and variance) approaches fail to show a significant difference. Applications include heart rate analysis in the human neonate and in epileptic activity in electrocardiograms (Diambra, 1999). Mathematically, as part of a general theoretical framework, ApEn has been shown to be the rate of approximating a Markov chain process (Pincus, 1993). Most importantly, compared with Kolmogorov-Sinai (K-S) entropy (Kolmogorov, 1958), ApEn is generally finite and has been shown to classify the complexity of a system via fewer data points using theoretical analyses

Figure 3. The minimum embedding dimension generated from EEG data sets over 350 minutes, the vertical line denote an onset of an epileptic seizure



of both stochastic and deterministic chaotic processes and clinical applications (Pincus er al., , 1991; Kaplan et al., 1991; Rukhin et al., 2000).

The calculation of ApEn of a signal s of finite length N is performed as follows. First fix a positive integer m and a positive real number r_f. Next, from the signal s the N–m+1 vectors $x_m(i) = \{s(i), s(i + 1), ..., s(i + m – 1)\}$ are formed. For each i, $1 \le i \le (N – m + 1)$the quantity $C_i^m(r_f)$ is generated as:

$$C_i^m(r_f) \frac{Number\ of\ such\ j\ that\ d(\{(i),x_m(i),x_m(j)\}\le r_f}{N-m+1} ,$$

where the distance d between vectors $x_m(i)$ and $x_m(j)$ is defined as:

$$d[x_m(i),x_m(j)] = \max_{k=1,2,...,m}\{|(s(i+k-1)-s(j+k-1)|\}$$

Next the quantity $\Phi(r_f)$ is calculated as:

$$\Phi^m(r_f) = \frac{1}{N-m+1}\sum_{i=1}^{N-m+1}\log C_i^m(r_f)$$

Finally the ApEn is defined as:

$$ApEn(m,r_f,N) = \Phi^m(r_f) - \Phi^{m+1}(r_f)$$

The parameter r_f corresponds to an a priori fixed distance between neighboring trajectory points and frequently, r_f is chosen according to the signal's standard deviation (SD). Hence, r_f can be viewed as a filtering level and the parameter m is the embedding dimension determining the dimension of the phase space.

An example figure shows *ApEn* generated from EEG data sets over 100 minutes, the vertical dash lines denote an epileptic seizure.

FUTURE TRENDS

Electroencephalographic recordings are among the most accessible neurological continuous time series data. They contain many complex and hidden patterns that might link to different neurological disorders. The main message of this chapter is the importance of extracting useful dynamical features in the analysis of EEG classification. Dynamical feature extraction techniques have been shown capable of characterizing EEG patterns at the microscopic level (Pardalos et al., 2002). With advanced high frequency EEG acquisition devices, the sampling rate can be easily set to as high as 10 KHz allowing us to capture 10,000 data points of neuronal activity per second. For longer EEG data sets, the amount of data and the computational time for analysis will not only increase dramatically but also make it almost impossible to analyze the entire data sets. Extraction of dynamical features offers a lower dimensional feature space, in contrast to work on raw EEG data sets directly. The use of dynamical features may allow the data mining techniques to operate efficiently in a nonlinear transformed feature space without being adversely affected by dimensionality of the feature space. Moreover, through specific and suitable computational data mining analysis the dynamical features will allow us to link mining results to EEG patterns with neurological disorders. In the future, it is important to bridge the classification results with clinical outcomes as this has been one of the most important tasks for conceiving automatic diagnoses schemes and controlling the progression of diseases through data mining techniques.

CONCLUSION

In this chapter, we used several dynamical features on the acquired EEG data sets to identify the abnormal patterns that were most important for discriminating between normal and abnormal brain activities. Moreover, results from our classification showed the dynamical features are also resulted in more meaningful outcomes for interpreting brain disorders.

KEY TERMS

Attractor: An attractor is defined as a phase space point or a set of points representing the various possible steady-state conditions of a system; an equilibrium state or a group of states to which a dynamical system converges and cannot be decomposed into two or more attractors with distinct basins of attraction.

Degree of Freedom: In the context of dynamical systems, the degree of freedom is the number of variables needed to describe the underlying system.

Fixed Point: A point to which different trajectories in phase space tend to at rest is called a fixed point.

Limit Cycle: A limit-cycle is a closed trajectory in phase space having the property that at least one other trajectory spirals into it either as time approaches infinity.

Phase Space: Phase space is the collection of possible states of a dynamical system. In general, the phase space is identified with a topological manifold. An n-dimensional phase space is spanned by a set of n-dimensional "embedding vectors", each one defining a point in the phase space, thus representing the instantaneous state of the system.

Strange Attractor: A strange attractor is defined as an attractor that shows sensitivity to initial conditions (exponential divergence of neighboring trajectories) and that, therefore, occurs only in the chaotic domain. While all chaotic attractors are strange, not all strange attractors are chaotic. In other words, the chaoticity condition is necessary, but not sufficient, for the strangeness condition of attractors.

Trajectory: Trajectory or orbit of the dynamical system is the path connecting points in chronological order in phase space traced out by a solution of an initial value problem. If the state variables take real values in a continuum, the orbit of a continuous time system is a curve, while the orbit of a discrete-time system is a sequence of points.

Efficient Graph Matching

Diego Reforgiato Recupero
University of Catania, Italy

INTRODUCTION

Application domains such as bioinformatics and web technology represent complex objects as graphs where nodes represent basic objects (i.e. atoms, web pages etc.) and edges model relations among them. In biochemical databases proteins are naturally represented as labeled graphs: the nodes are atoms and the edges are chemical links. In computer vision, graphs can be used to represent images at different levels of abstraction. In a low-level representation (Pailloncy, Deruyver, & Jolion, 1999), the nodes of a graph correspond to pixels and the edges to spatial relations between pixels. At higher levels of description (Hong & Huang, 2001), nodes are image regions and edges are spatial relations among them. In a Web graph (Deutsch, Fernandez, Florescu, Levy, & Suciu, 1999) nodes are web pages and edges are links between them. In all these domains, substructure queries that search for all exact or approximate occurrences of a given query graph in the graphs of the database can be useful.

Research efforts in graph searching have taken three directions: the first is to study matching algorithms for particular graph structures (planar graphs, bounded valence graphs and association graphs); the second is to use elaborate tricks to reduce the number of generated matching maps (Cordella, Foggia, Sansone, & Vento, 2004); and the third is, since graph searching problem is NP-complete, to provide polynomial approximate algorithms. In the context of querying in a database of graphs many of the existing methods are designed for specific applications. For example, several querying methods for semi-structured databases have been proposed. In addition, commercial products and academic projects (Kelley 2002) for subgraph searching in biochemical databases are available. These two examples have a different underlying data model (a web-page database is a large graph whereas a biochemical database is a collection of graphs). In these two applications regular path expressions and indexing methods are used during query time to respectively locate substructures in the database and to avoid unnecessary traversals of the database. In general graph databases, there are some searching methods where the data graph and the query graph must have the same size. Other methods allow the query to be considerably smaller than the database graphs. A common idea in the above algorithms is to index the subgraph matches in the database and organize them in suitable data structures.

BACKGROUND

A graph database can be viewed as either a single (large) labeled graph (e.g. web) or a collection of labeled graphs (e.g., chemical molecules). By keygraph searching it is intended graph or subgraph matching in a graph database. Although (sub)graph-to-graph matching algorithms can be used for keygraph searching, efficiency considerations suggest the use of indexing techniques to reduce the search space and the time complexity especially in large databases. Keygraph searching in databases consists of three basic steps:

1. Reduce the search space by filtering. For a database of graphs a filter finds the most relevant graphs; for a single-graph database it identifies the most relevant subgraphs. In this work, the attention is restricted to filtering techniques based on the structure of the labeled graphs (paths, subgraphs). Since searching for subgraph structures is quite difficult, most algorithms choose to locate paths of node labels.
2. Formulate query into simple structures. The query graph can be given directly as a set of nodes and edges or as the intersection of a set of paths. Furthermore the query can contain wildcards (representing nodes or paths) to allow more general searches. This step normally reduces the query graph to a collection of small paths.

3. Match. Matching is implemented by either traditional (sub)graph-to-graph matching techniques, or combining the set of paths resulting from processing the path expressions in the query through the database.

A well-known graph-based data mining algorithm able to mine structural information is Subdue (Ketkar, Holder, Cook, Shah, & Coble, 2005). Subdue has been applied to discovery and search for subgraphs in protein databases, image databases, Chinese character databases, CAD circuit data and software source code. Furthermore, an extension of Subdue, SWSE (Rakhshan, Holder & Cook, 2004), has been applied to hypertext data. Yan et al. (Yan, Yu & Han, 2004) proposed a novel indexing technique for graph databases based on reducing the space dimension with the most representative substructures chosen by mining techniques. However, Subdue based systems accept one labeled graph at a time as input.

GRACE, (Srinivasa, Maier & Mutalikdesai, 2005) is a system where a data manipulation language is proposed for graph database and it is integrated with structural indexes in the DB.

Daylight (James, Weininger & Delany, 2000) is a system used to retrieve substructures in databases of molecules where each molecule is represented by a graph. Daylight uses fingerprinting to find relevant graphs from a database. Each graph is associated with a fixed-size bit vector, called the fingerprint of the graph. The similarity of two graphs is computed by comparing their fingerprints. The search space is filtered by comparing the fingerprint of the query graph with the fingerprint of each graph in the database. Queries can include wildcards. For most queries, the matching is implemented using application-specific techniques. However queries including wildcards may require exhaustive graph traversals. A free and efficient academic emulation of Daylight, called Frowns (Kelley, 2002), uses the compacted hashed paths vector filtering of Daylight and the subgraph matching algorithm VF (Cordella, Foggia, Sansone, & Vento, 2004).

In character recognition, a practical optical character reader is required to deal with both fonts and complex designed fonts; authors in (Omachi, Megawa, & Aso, 2007) proposed a graph matching technique to recognize decorative characters by structural analysis. In image recognition, an improved exact matching method using a genetic algorithm is described in (Auwatanamongkol, 2007).

One way to use a simple theoretical enumeration algorithm to find the occurrences of a query graph Ga in a data graph Gb is to generate all possible maps between the nodes of the two graphs and to check whether each generated map is a match. All the maps can be represented using a state-space representation tree: a node represents a pair of matched nodes; a path from the root down to a leaf represents a map between the two graphs. In (Ullmann, 1976) the author presented an algorithm for an exact subgraph matching based on state space searching with backtracking. Based on the Ullmann's algorithm, Cordella et al. (Cordella, Foggia, Sansone, & Vento, 2004) proposed an efficient algorithm for graph and subgraph matching using more selective feasibility rules to cut the state search space. Foggia et al. (Foggia, Sansone, & Vento, 2001) reported a performance comparison of the above algorithm with other different algorithms in literature. They showed that, so far, no one algorithm is more efficient than all the others on all kinds of input graphs.

MAIN FOCUS

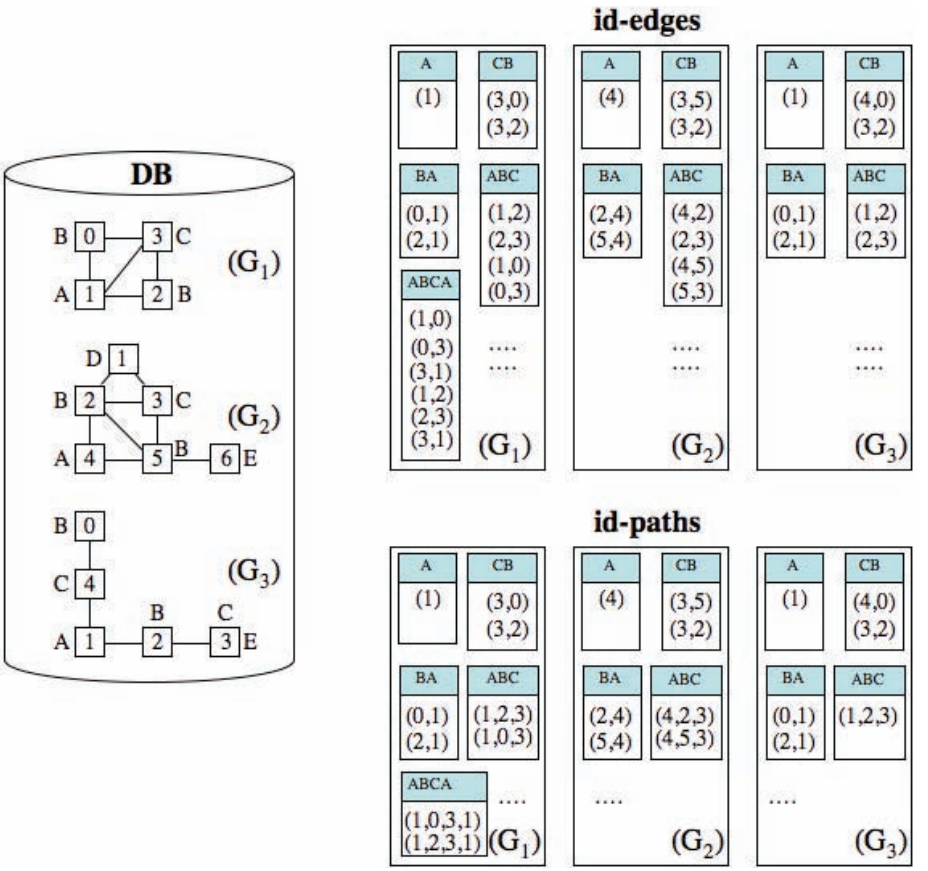
The idea of an efficient method for graph matching is to first represent the label paths and the label edges of each graph of the database as compacted hash functions; then, given the query graph, the paths of the database graphs not matching the query paths will be pruned out in order to speed up the searching process.

The proposed method models the nodes of data graphs as having an identification number (node-id) and a label (node-label). An id-path of length n is a list of $n+1$ node-ids with an edge between any two consecutive nodes. A label-path of length n is a list of $n+1$ node-labels. An id-path of length 1 is called id-edge. The label-paths and the id-paths of the graphs in a database are used to construct the index of the database and to store the data graphs. Figure 1 shows three input graphs with id-paths and id-edges.

Indexing Construction

Let l_p be a fixed positive integer (in practice, 4 is often used). For each graph in the database and for each node, all paths that start at this node and have length from one up to l_p are found. The index is implemented using a hash table. The keys of the hash table are the hash values of the label-paths. Collisions are solved

Figure 1. Three input graphs in Berkeley DB with their id-edges and id-paths for l_p=3.



by chaining, that is, each hash table bucket contains the linked list of the label-paths together with the number of their occurrences in each database graph. This hash table will be referred as the fingerprint of the database.

Path Representation of a Graph

Since several paths may contain the same label sequence, the id-edges of all the paths representing a label sequence are grouped into a label-path-set. The collection of such label-path-sets is called the path-representation of a graph.

Data Storing

The Berkeley DB (Berkeley) is used as the underlying database to store the massive data resulting from data graph representation and indexing construction. The fingerprint is stored as a dynamic Berkeley DB hash table of linked lists whose keys are the hashed label-path values. This allows efficient execution of the subgraph queries. Each graph is stored in a set of Berkeley DB tables each corresponding to a path and containing the set of id-edges comprising the occurrences of that path (label-path-set).

Queries Decomposition

The execution of a query is performed by first filtering out those graphs in the database which cannot contain the query. To do this, the query is parsed to build its fingerprint (hashed set of paths). Moreover, the query is decomposed into a set of intersecting paths in the following way: the branches of a depth-first traversal tree of the graph query are decomposed into sequences of overlapping label paths, called patterns, of length less than or equal to l_p. Overlaps may occur in the following cases:

- For consecutive label-paths, the last node of a pattern coincides with the first node of the next pattern (e.g. A/B/C/B/, with l_p=2, is decomposed into two patterns: A/B/C/ and C/B/);
- If a node has branches it is included in the first pattern of every branch;
- The first node visited in a cycle appears twice: in the beginning of the first pattern of the cycle and at the end of the last pattern of the cycle (the first and last pattern can be identical.) (See Figure 2.)

GrepVS Database Filtering

A first filtering is performed by comparing the fingerprint of the query with the fingerprint of the database. A graph, for which at least one value in its fingerprint is less than the corresponding value in the fingerprint of the query, is filtered out. The remaining graphs are candidates for matching. See Figure 3.

Then, parts of the candidate graphs are filtered as follows:

- decomposing the query into patterns;
- selecting only those Berkeley DB tables associated with patterns in the query.

The restored edge-ids correspond to one or several subgraphs of candidate graphs. Those subgraphs are the only ones that are matched with the query. Notice that the time complexity of filtering is linear in the size of the database. Figure 4 shows the subgraph filtering for the obtained graph in Figure 3.

The above method requires finding all the label-paths up to a length l_p starting from each node in the query graph. Depending on the size of the query the expected online querying time may result in a rather expensive task. In order to avoid that cost, one may choose to modify the fingerprint construction procedure as follows: only label-paths (patterns) found in the

Figure 2. A query graph (a); its depth first tree (b); patterns obtained with l_p=3. Overlapping labels are marked with asterisks and underlines. Labels with same mark represent the same node.

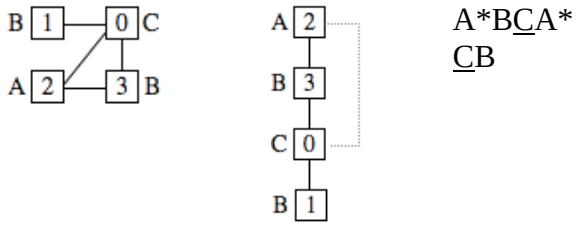


Figure 3. Filtering for graphs of Figure 1 and query of Figure 2

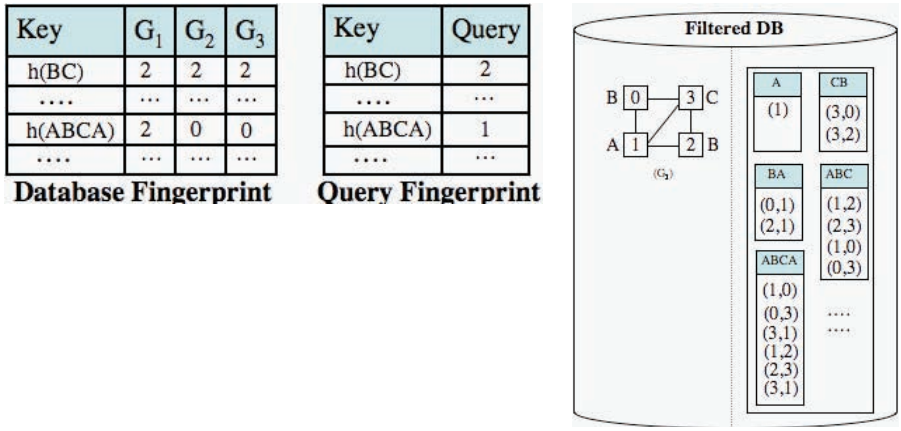

Figure 4. Subgraph filtering for graph in Figure 3.

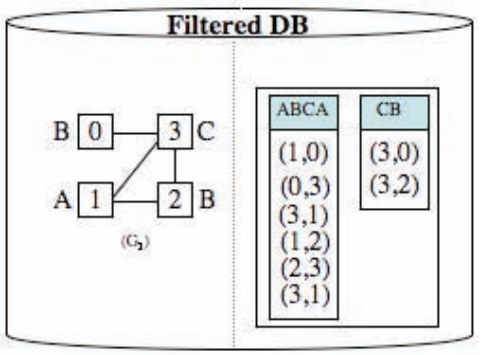


decomposition step are used. In the proposed method, a single fingerprint value is associated to each pattern. Obviously, this method requires less time and space to filter, but is less selective. However, it may be required in some applications. The performance test considers this modified method.

GrepVS Subgraph Matching

After filtering, a collection of subgraph candidates is left (see Figure 4) which may contain matches with the query. Subgraph matching is performed by the VF (Cordella, Foggia, Sansone, & Vento. 2004) algorithm. VF algorithm is a refinement of Ullmann's subgraph isomorphism algorithm with a more selective feasibility rules to prune the state search space. Given a query graph *Q* and data graph *G*, the matching process is carried out by using the state space representation where a state is partial mapping, whereas a transition between two states corresponds to the addition of a new pair of matched nodes. The aim of the matching process is the determination of a mapping which is a bijection and consists of a set of node pairs covering all the query graph nodes. When a node pair is added to the partial mapping, coherence conditions are checked. If the new pair produces an incoherent state, then any further exploration of that path is avoided. The introduction of feasibility rules allows the pruning of the search space, reducing significantly the computational cost of the matching process. The feasibility rules are divided into semantic rules which guarantee the semantic coherence (they are satisfied if the labels of nodes corresponding in the mapping are equal) and three syntactic rules which guarantee the syntactic coherence. They are described in (Cordella, Foggia, Sansone, & Vento. 2004), where it is also stated that the computational complexity in the worst case of the VF algorithm is $\Theta(N!N)$ whereas its spatial complexity is $\Theta(N)$ where $N = |V1|+|V2|$.

Performance Analysis

GrepVS is implemented in ANSI C++ and it uses Berkeley DB as the underlying database.

To evaluate GrepVS both query and preprocessing time have been measured varying database size, number of nodes, edges and node labels on the input dataset, degree of the nodes, efficiency of filtering, and the parameter l_p.

Three kinds of databases have been considered:

1. Synthetic databases of size 1000 to 5000 graphs generated by (Kuramochi & Karypis. 2001). They are generated by a set of potentially frequent connected subgraphs; the number of distinct vertex labels is specified by a parameter; for each frequent connected subgraph, its topology as well as its vertex labels are randomly generated. (These will be referred to as random graphs).
2. Synthetic 2D mesh databases of size 1000 to 5000 graphs from (Foggia, Sansone, & Vento. 2001). (These will be referred to as mesh graphs).
3. Databases containing 10000 up to 50000 molecules available at (National Cancer Institute). (These will be referred to as AIDS graphs).

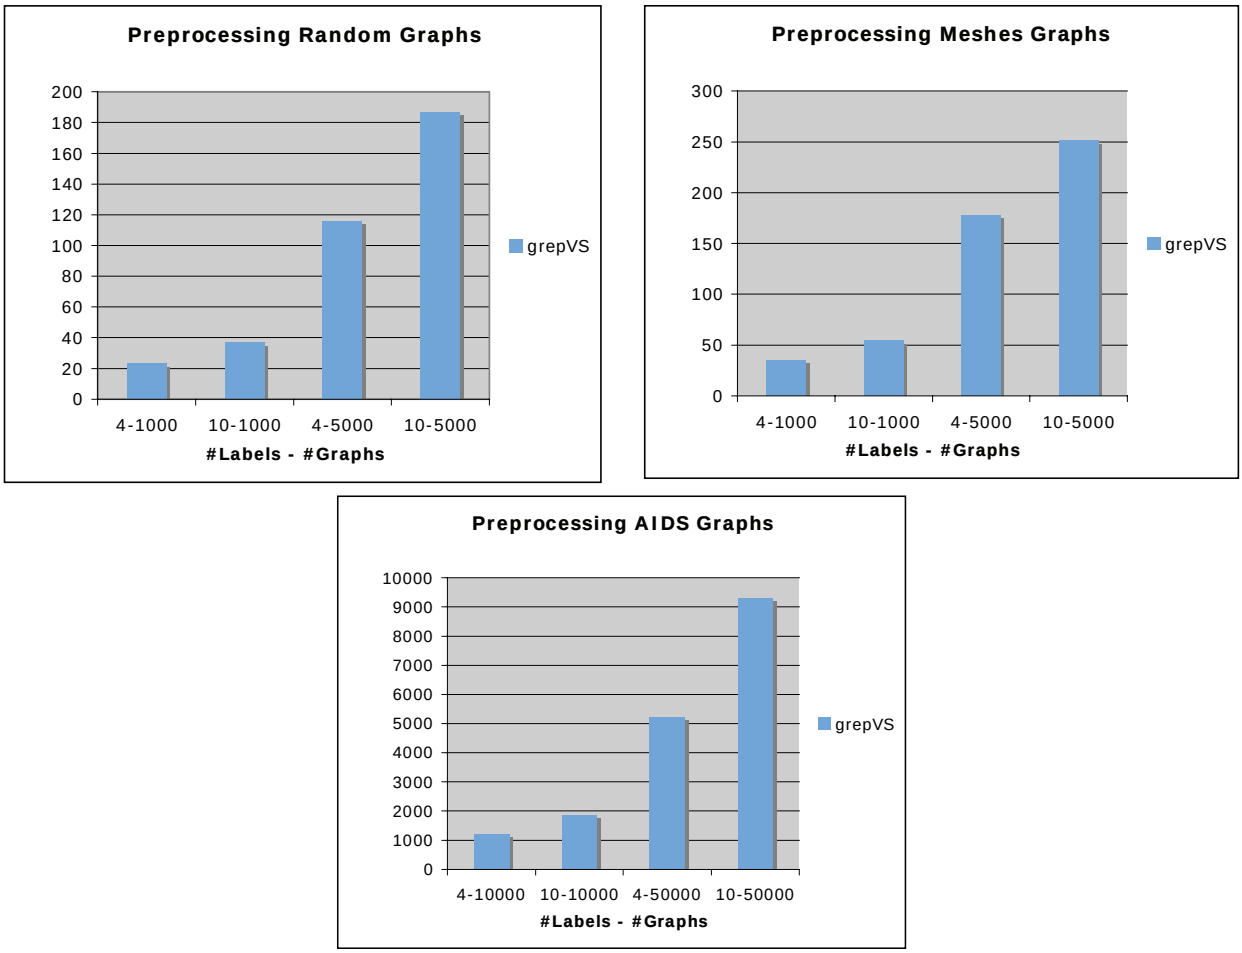
Building the database requires finding all the id-paths of length up to l_p and it is independent of the number of different labels in the graphs. Figure 5 shows the preprocessing time for each type of dataset considered.

On the other hand, the query running time is strongly influenced by the number of different labels. Increasing the number of labels in the graphs implies that fingerprints are more selective and the number of matches decreases.

Results

GrepVS has been compared against Subdue, Frowns, Daylight, and Grace for both single-graph databases and multi-graphs databases.

Figure 5. GrepVS preprocessing for the types of graphs considered.



GrepVS performs in a matter of seconds query searches that take Subdue more than 10 minutes. Moreover, GrepVS performs significantly better than Frowns, Daylight, and Grace. In each experiment four graphs with different numbers of nodes and edges have been generated. For meshes and random graph datasets each graph had a number of nodes ranging from 100 to 200, whereas the number of different labels ranged from 4 to 10. For AIDS graph datasets each graph had a number of nodes ranging from 100 to 5000, whereas the number of different labels was over 50. For AIDS databases the running times are faster due to the number of labels. On the latter the filtering process is much more effective.

FUTURE TRENDS

Graph matching techniques will become key components of any data mining instrument.

There are still a number of open issues that need further research. There are many applications in computer vision and pattern recognition where the full representational power of graphs may not be required. Focusing on special subclasses of graphs may result in more efficient matching procedures. Moreover, the design of efficient matching algorithms for very large graph queries will be of primary interest for graph matching of big graphs. For example, aligning a large protein interaction network against a set of other protein interaction networks.

CONCLUSION

GrepVS is an application-independent method for finding all the occurrences of a query graph within a database of graphs. This is an important problem in many applications from computer vision to chemistry. Several searching systems exist for chemical databases but not much research has been done for application-independent searching in database of graphs. GrepVS incorporates efficient searching algorithms and selective filtering techniques and allows inexpensive data analysis across many domains. It has been extensively tested on both synthetic databases and molecular databases. It appears to outperform the best-known alternative methods, from which it borrows many ideas and sometimes code.

KEY TERMS

Approximate Graph Search: Given a query graph G with wildcards it is the problem of looking in each graph of a given dataset for possible sub-graphs matching G and satisfying the wildcards.

Exact Graph Search: Given a query graph G it is the problem of looking in each graph of a given dataset for possible sub-graphs matching G.

Filtering: A step consisting of removing irrelevant graphs from a given dataset.

Fingerprint: A data structure (usually a compacted hash-table) representing a database of graphs.

Graph Matching Problem: Given two graphs $G_a(V_a,E_a)$ and $G_b(V_b,E_b)$ the problem is to find a one-to-one mapping $f:V_a \rightarrow V_b$ such that $(u,v) \varepsilon E_s$ iff $(f(u),f(v)) \varepsilon E_b$.

Id-Path: A list of n+1 node-ids with an edge between any consecutive nodes.

Keygraph Searching: A graph or subgraph matching in a graph database.

Label-Path: A list of n+1 node labels.

Meshes Graphs: Graphs in which each node is connected to its 4 neighborhood nodes.

Semantic Coherence: The mapping of the labels of corresponding nodes of two graphs.

Syntactic Coherence: The mapping of the nodes and edges of two graphs.

INTRODUCTION

As known to us, the cognition process is the instinct learning ability of the human being. This process is perhaps one of the most complex human behaviors. It is a highly efficient and intelligent information processing process. For a cognition process of the natural world, humans always transfer the feature information to the brain through their perception, and then the brain processes the feature information and remembers it. Due to the invention of computers, scientists are now working toward improving its artificial intelligence, and they hope that one day the computer could have its intelligent "brain" as human does. However, it is still a long way for us to go in order to let a computer truly "think" by itself.

Currently, artificial intelligence is an important and active research topic. It imitates the human brain using the idea of function equivalence. Traditionally, the neural computing and neural networks families are the majority parts of the direction (Haykin, 1994). By imitating the working mechanism of the human-brain neuron, scientists have built the neural networks theory following experimental research such as perception neurons and spiking neurons (Gerstner & Kistler, 2002) in order to understand the working mechanism of neurons.

Neural-computing and neural networks (NN) families (Bishop, 1995) have made great achievements in various aspects. Recently, statistical learning and support vector machines (SVM) (Vapnik, 1995) have drawn extensive attention and shown better performances in various areas (Li, Wei & Liu, 2004) than NN, which implies that artificial intelligence can also be made via advanced statistical computing theory. Nowadays, these two methods tend to merge under the statistical learning theory framework.

BACKGROUND

It should be noted that, for NN and SVM, the function imitation happens at microscopic view. Both of them utilize the mathematic model of neuron working mechanism. However, the whole cognition process can also be summarized as two basic principles from the macroscopical point of view (Li, Wei & Liu, 2004): the first is that **humans always cognize things of the same kind**, and the second is that **humans recognize and accept things of a new kind easily**.

In order to clarify the idea, the function imitation explanation of NN and SVM is first analyzed. The function imitation of human cognition process for pattern classification (Li & Wei, 2005) via NN and SVM can be explained as follows:

The training process of these machines actually imitates the learning processes of human being, which is called "cognizing process", While the testing process of an unknown sample actually imitates the recognizing process of human being, which is called "recognizing process".

From a mathematical point of view, the feature space is divided into many partitions according to the selected training principles (Haykin, 1994). Each feature space partition is then linked with a corresponding class. Given an unknown sample, NN or SVM detects its position and then assigns the indicator. For more details, the reader should refer to (Haykin, 1994 & Vapnik, 1995).

Now, suppose a sample database is given, if a totally unknown new sample comes, both SVM and NN will not naturally recognize it correctly and will consider it to the closest known in the learned classes (Li & Wei, 2005).

The root cause of this phenomenon lies in the fact that the learning principle of the NN or SVM is based on

feature space partition. This kind of learning principle may amplify each class's distribution region especially when the samples of different kinds are small due to incompleteness. Thus it is impossible for NN or SVM to detect the unknown new samples successfully.

However, this phenomenon is quite easy for humans to handle. Suppose that we have learned some things of the same kind before, and then if given similar things we can easily recognize them. And if we have never encountered with them, we can also easily tell that they are fresh things. Then we can remember their features in the brain. Sure, this process will not affect other learned things. This point surely makes our new learning paradigm different from NN or SVM.

MAIN FOCUS

Humans generally cognize things of one kind and recognize totally unknown things of a new kind easily. So why not let the learning machine "cognize" or "recognize" like humans (Li, Wei & Liu, 2004). Thus our intention is only focused on learning each single class instead of separating them. To learn each class, we can **let each class be cognized or described by a cognitive learner** to imitate the "cognizing process". Therefore, the false alarm zone is now greatly cut down for small samples case. After training, each minimum volume bounding cognitive learner scatters in the feature space. And all learners' boundaries consist of the whole knowledge to the learned classes. If given an unknown sample, the cognitive recognizer then detects **whether the unknown sample is located inside a cognitive learner's boundary** to imitate the "recognizing process". If the sample is totally new (i.e., none of the trained cognitive learner contains the sample), it can be again described by a new cognitive learner and the new obtained learner can be added to the feature space without affecting others. This concludes the basic process of our proposed enclosing machine learning paradigm (Wei, Li & Li, 2007A).

Mathematic Modeling

In order to make previously mentioned ideas practical, they have to be linked with concrete mathematical models (Wei, Li & Li, 2007A). Actually the first principle can be modeled as a minimum volume enclosing problem. The second principle can be ideally modeled as a point detection problem. Generally, the minimum volume enclosing problem is quite hard to handle samples generated in arbitrary distribution and especially if such the distribution shape might be rather complex to be calculated directly. Therefore, an alternative is to use regular shapes such as sphere, ellipsoid and so on to enclose all samples of the same class with the minimum volume objective (Wei, Löfberg, Feng, Li & Li, 2007). Moreover, the approximation method can be easily formulated and efficiently solved as a convex optimization problem.

Enclosing Machine Learning Concepts

The new learning methodology has three aspects. The first is to learn each class respectively, and it is called cognitive learning. The second is to detect the unknown samples' location and determine their indicator, and it is called cognitive classification. While the third is to conduct a new cognitive learning process, and it is called feedback self-learning. The third is to imitate learning samples from an unknown new kind. The whole process is depicted in Figure 1.

Cognitive Learner: A cognitive learner is defined as the bounding boundary of a minimum volume set which encloses all the given samples. The cognitive learner can be either a sphere or an ellipsoid or their combinations. Figure 2 and Figure 3 depict the examples of sphere learner, ellipsoid learner, and combinational ellipsoid learner in 2D.

We conclude that the basic geometric shapes are the best choices, because they have many commendable features: (1) regular to make calculation easier. (2) convex bodies, which guarantee the optimality. (3) fault tolerance to assure generalization performance. And thus operations like intersection, union or complement of them can be implemented easily within convex optimization framework. Then the volume of them can be minimized to enclose the given samples. This is the most important reason why we call it enclosing machine learning.

Remarks: As for the illustrated three type learner, obviously the sphere learner has the biggest volume. Next is single ellipsoid learner. The combinational ellipsoid learner has the smallest volume.

Figure 1. Enclosing machine learning process: The real line denotes the cognizing process. The dotted line denotes the recognizing process. The dash-dotted line denotes the feedback self-learning process.

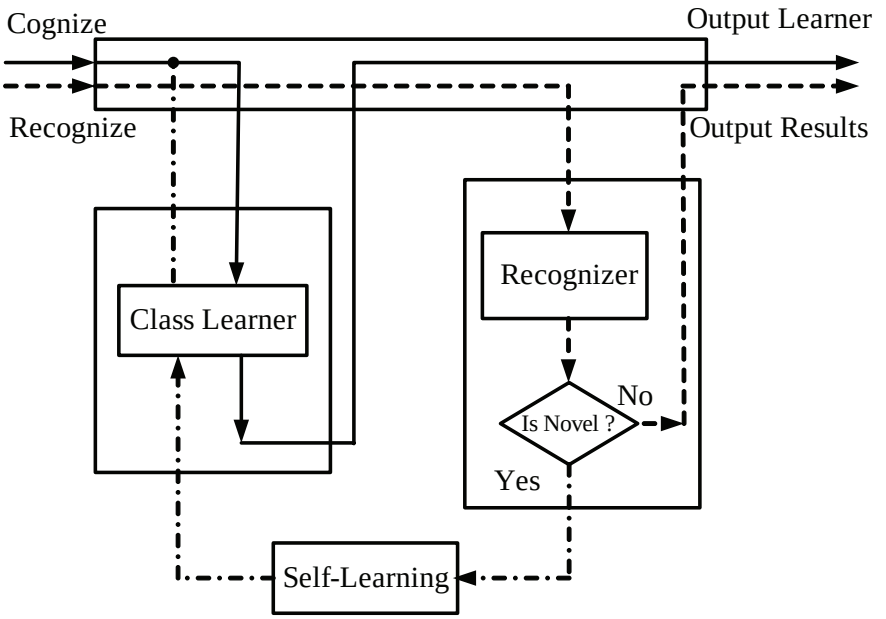

Figure 2. Single cognitive learner illustrations: (a) A sphere learner. (b) An ellipsoid learner

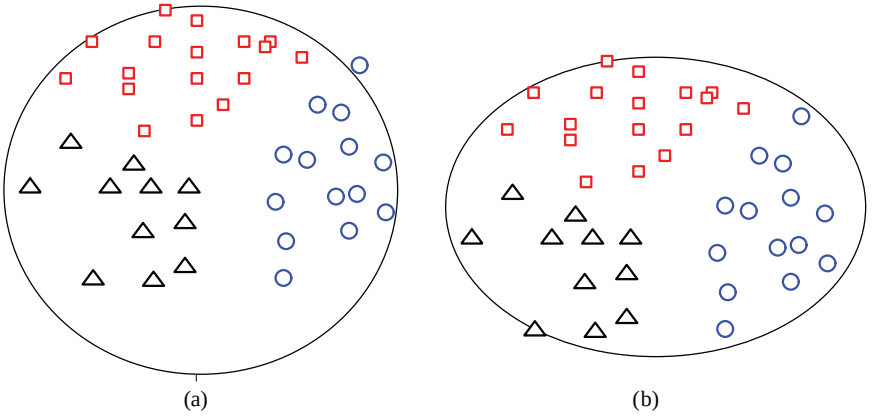

Figure 3. A combinational ellipsoid learner illustration

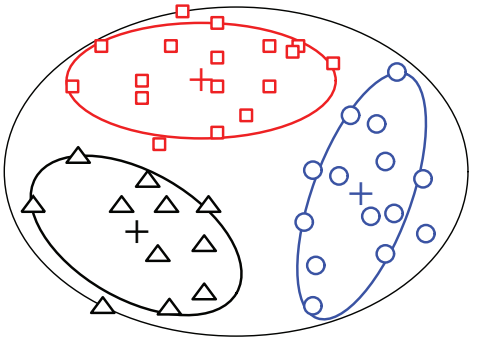


Cognitive Recognizer: A cognitive recognizer is defined as the point detection and assignment algorithm. For example, it is a distance metric with true or false output.

Cognitive Learning and Classification Algorithms

Firstly, the differences between enclosing machine learning and other feature space partition based methods are investigated. Figure 4 gives a geometric illustration of the differences. As for enclosing machine learning, each class is described by a cognitive learner in the cognitive learning process. But for the partition based learning paradigm such as SVM, every two classes are separated by a hyperplane (or other boundary forms, such as hypersphere etc.). Obviously, the partition based learning paradigm amplifies the real distribution regions of each class, while the enclosing machine learning paradigm obtains more reasonable approximated distribution regions.

Figure 4. A geometric illustration of learning a three class samples via enclosing machine learning vs. feature space partition learning paradigm. (a) For the depicted example, the cognitive learner is the bounding minimum volume ellipsoid, while the cognitive recognizer is actually the point location detection algorithm of the testing sample. (b) All the three classes are separated by three hyperplanes.

In enclosing machine learning, the most important step is to obtain a proper description of each single class. From a mathematical point of view, our cognitive learning methods actually are the same as the so-called one class classification methods (OCCs) (Schölkopf, Platt, Shawe-Taylor, 2001). It is reported that OCCs can efficiently recognize the new samples that resemble the training set and detect uncharacteristic samples, or outliers, which justifies feasibility of our initial idea of the cognizing imitation method.

By far, the well-known examples of OCCs are studied in the context of SVM. Support vector domain description (SVDD) proposed by Tax & Duin (1999) tries to seek the minimum hypersphere that encloses all the data of the target class in a feature space.

However, traditional Euclidean distance based OCCs are often sub-optimal and scale variant. To overcome this, Tax & Juszczak (2003) propose a KPCA based technique to rescale the data in a kernel feature space to unit variance. Except this, Mahalanobis distance based OCCs (Tsang, Kwok, & Li, S., 2006) are reported scale invariant and more compact than traditional ones. What's more, to alleviate the undesirable effects of estimation error, a priori knowledge with an uncertainty model can be easily incorporated.

Utilizing virtues of Mahalanobis distance, our progresses towards "cognizing" are that a new minimum volume enclosing ellipsoid learner is developed and several Mahalanobis distance based OCCs are proposed, i.e. a dual QP ellipsoidal learner (Wei, Huang & Li, 2007A), a dual QP hyperplane learner (Wei, Huang & Li, 2007B), and a primal second order cone programming representable ellipsoidal learner (Wei, Li, Feng & Huang, 2007A). According to the new learners, several practical learning algorithms are developed.

Minimum Volume Enclosing Ellipsoid (MVEE) Learner

Towards the state-of-the-arts MVEE algorithms, they include solving the SDP primal, solving the lndet dual using interior point algorithm and solving the SOCP primal (Wei, Li, Feng, & Huang, 2007B). The minimum volume enclosing ellipsoid center at the origin is only considered for simplicity. As for this point, the reader may check the paper (Wei, Li, Feng & Huang, 2007A) for more details.

Given sample $X \in R^{m \times n}$, suppose $\mathrm{E}(c,\Sigma) := \{x : (x-c)^T \Sigma^{-1} (x-c) \le 1\}$ is the demanded ellipsoid, then the minimum volume enclosing ellipsoid problem can be formulated as

$$\min_{A,b} -\ln\det\Sigma^{-1}$$
$$s.t. \begin{cases} (x_i - c)^T \Sigma^{-1} (x_i - c) \le 1 \\ \Sigma^{-1} \succ 0 \end{cases} \quad (1)$$

However, this is not a convex optimization problem. Fortunately, it can be transformed into the following convex optimization problem:

$$\min_{A,b} -\ln\det A$$
$$s.t. \begin{cases} (Ax_i - b)^T (Ax_i - b) \le 1 \\ A \succ 0, \forall i = 1,2,\cdots,n \end{cases} \quad (2)$$

via matrix transform $\begin{cases} A = \Sigma^{-\frac{1}{2}} \\ b = \Sigma^{-\frac{1}{2}} c \end{cases}$.

In order to allow errors, (2) can be represented in following SDP form

$$\begin{aligned} &\min_{A,b,\zeta_i} -\ln\det A + \Theta\sum_{i=1}^{n}\zeta_i \\ &s.t.\begin{bmatrix} I & (Ax_i - b) \\ (Ax_i - b)^T & 1+\zeta_i \end{bmatrix} \geq 0 \end{aligned} \tag{3}$$

Solving (3), the minimum volume enclosing ellipsoid is then obtained. Yet, SDP is quite demanded especially for large scale or high dimensional data learning problem.

As for $\mathrm{E}(c,\Sigma) := \{x : (x-c)^T \Sigma^{-1} (x-c) \leq R^2\}$, the primal of minimum volume enclosing ellipsoid problem can be reformulated as following SOCP form:

$$\begin{aligned} &\min_{A,b,\zeta_i} -\ln\det A + \Theta\sum_{i=1}^{n}\zeta_i \\ &s.t.\begin{bmatrix} I & (Ax_i - b) \\ (Ax_i - b)^T & 1+\zeta_i \end{bmatrix} \geq 0 \end{aligned} \tag{4}$$

Accordingly, it can be kernelized as:

$$\begin{aligned} &\min_{\mathbf{w},R,\xi_i \geq 0} R + \Theta\sum_{i=1}^{n}\xi_i \\ &s.t.\begin{cases} \sqrt{n}\left\|\mathbf{\Omega}^{-1}\mathbf{Q}(\mathbf{k} - \mathbf{K}\mathbf{w})\right\|_2 \leq R + \xi_i, \\ R > 0, \xi_i \geq 0, i = 1,2,\cdots,n. \end{cases} \end{aligned} \tag{5}$$

where **c** is the center of the ellipsoid, R is the generalized radius, n is number of samples, and $\mathbf{K}_C = \mathbf{Q}^T \Omega \mathbf{Q}$, ξ_i is slack variable, Θ is tradeoff between volume and errors, Σ is covariance matrix.

Except previously mentioned primal based methods, the minimum volume enclosing ellipsoid centered at the origin can also be reformulated as following:

$$\begin{aligned} &\min_{U,\zeta_i} -\ln\det\Sigma^{-1} + \Theta\sum_{i=1}^{n}\zeta_i \\ &s.t.\begin{cases} x_i^T\Sigma^{-1}x_i \leq 1+\zeta_i \\ \zeta_i \geq 0, \forall i = 1,2,\cdots,n \end{cases} \end{aligned} \tag{4}$$

Via optimality and KKT conditions, the dual as following can be efficiently solved

$$\begin{aligned} &\max_{\alpha} \ln\det\sum_{i=1}^{n}\alpha_i x_i x_i^T - \sum_{i=1}^{n}\alpha_i \\ &s.t.\begin{cases} 0 \leq \alpha_i \leq \Theta \\ i = 1,\cdots,n \end{cases} \end{aligned} \tag{5}$$

where α is dual variable.

See that (5) cannot be kernelized directly, therefore it is necessary to use some tricks (Wei, Li, & Dong, 2007) to get the kernelized version:

$$\begin{aligned} &\max_{\alpha} \ln\det \mathrm{K}^{\frac{1}{2}}\Gamma\mathrm{K}^{\frac{1}{2}} - \sum_{i=1}^{n}\alpha_i \\ &s.t.\begin{cases} 0 \leq \alpha_i \leq \Theta \\ i = 1,\cdots,n \end{cases} \end{aligned} \tag{6}$$

where α is the dual variable, $\Gamma := \begin{bmatrix} \alpha_1 & & \\ & \ddots & \\ & & \alpha_n \end{bmatrix}$,

$$\mathrm{K} := \begin{bmatrix} k(x_1,x_1) & \cdots & k(x_1,x_n) \\ \vdots & \ddots & \vdots \\ k(x_n,x_1) & \cdots & k(x_n,x_n) \end{bmatrix}$$

Multiple Class Classification Algorithms

For a multiple class classification problem, a naturally solution is first to use minimum volume geometric shapes to approximate each class samples' distribution separately. But this is for ideal case, where no overlaps occur. When overlaps occur, two multiple class classification algorithms are proposed to handle this case (Wei, Huang & Li, 2007C).

For the first algorithm, a distance based metric is adopted, i.e. assign it to the closest class. This multiple class classification algorithm can be summarized as:

$$f(x) = \arg \min_{k\in\{1,2,\cdots,m\}} \|x-c\|_{\Sigma} - R \tag{7}$$

where $\|\bullet\|_{\Sigma}$ denotes Mahalanobis norm.

Another multiple class classification algorithm is to use optimum Bayesian decision theory, and assign it to the class with maximum posterior probability:

$$f(x) = \arg \max_{k\in\{1,2,\cdots,m\}} \frac{P_k}{(2\pi R_k^2)^{\frac{d}{2}}} \exp(-\frac{\|\mathbf{x}-\mathbf{c}_k\|_M^2}{R_k^2}) \tag{8}$$

where d is the dimension of the feature space and $P_k = \frac{1}{N}\sum_{i=1}^{N} 1_{y_i=k}$ is the prior distribution of class k.

According to (8) the decision boundary between class 1 and 2 is given by

$$\frac{P_1(2\pi R_1^2)^{-\frac{d}{2}} \exp(-\frac{\|\mathbf{x}-\mathbf{c}_1\|_M^2}{R_1^2})}{P_2(2\pi R_2^2)^{-\frac{d}{2}} \exp(-\frac{\|\mathbf{x}-\mathbf{c}_2\|_M^2}{R_2^2})} = 1 \tag{9}$$

And this is equivalent to

$$\frac{\|\mathbf{x}-\mathbf{c}_1\|_M^2}{R_1^2} + T_1 = \frac{\|\mathbf{x}-\mathbf{c}_2\|_M^2}{R_2^2} + T_2 \tag{10}$$

Therefore a new decision rule is given by

$$f(x) = \arg \max(\frac{\|\mathbf{x}-\mathbf{c}_k\|_M^2}{R_k^2} + T_k) \tag{11}$$

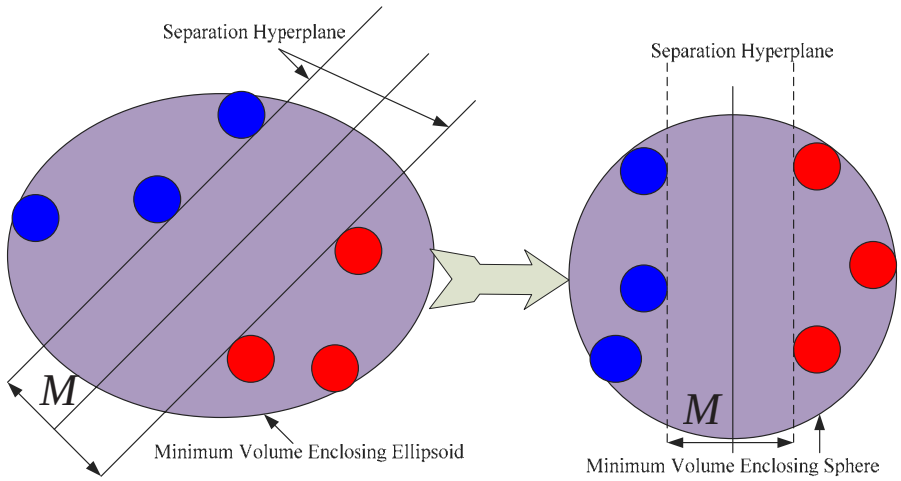
where $T_k = d \log R_k - P_k$ can be estimated from the training samples.

Remarks: A single MVEE learner based two-class classification algorithm (Wei, Li, Feng & Huang, 2007A) is also proposed, which owns both features of MVEE description and SVM discrimination. Then via one-vs-one or one-against-one strategy, a multiple class classification algorithm can be extended. Except this, we recently get an idea of solving a multiple class classification algorithm learning at complexity of a two-class classification algorithm, which is expected to obtain promising performances.

Gap Tolerant SVM Design

In this section, a new gap tolerant SVM design algorithm based on minimum volume enclosing ellipsoid is briefly reviewed. We first find the MVEE around all the samples and thus obtain a Mahalanobis transform. We then use the Mahalanobis transform to whiten all the given samples and map them to a unit sphere distribution (see Figure 5). Then we construct standard SVM there.

Figure 5. MVEE gap tolerant classifier illustration



The MVEE gap tolerant classifier design algorithm can be summarized as:

Step1: Solve MVEE and obtain Σ and center c

Step2: Whiten data using Mahalanobis transformand $t_i = \Sigma^{-\frac{1}{2}}(x_i - c)$ get new sample pairs $(t_i, y_i)_{i=1}^{n}$

Step3: Train standard SVM and get the decision function $y(x) = \text{sgn}(w^T t + b)$.

Remarks: This algorithm is very concise and has several commendable features worth noted: (1) less VC dimension compared with traditional ones. (2) scale invariant. For more details, the reader should refer to (Wei, Li & Dong, 2007).

FUTURE TRENDS

In the future, more basic learner algorithms such as box, convex hull etc, and more compact learner such as set based combinational learner algorithm (Wei, & Li, 2007; Wei, Li, & Li, 2007B) will be developed.

More classification algorithms will be focused, such as vector value reproducing kernel Hilbert space based one. This new algorithm is expected to solve multiple class classification problems efficiently while with single class complexity.

Another topic is how to scale up to large problems. The coreset idea will be introduced for speedup.

Except theoretical developments, various applications such as novelty detection, face detection, and many other possible applications are also expected.

CONCLUSION

In this article, the enclosing machine learning paradigm is introduced. Its concept definitions and progresses in modeling the cognizing process via minimum volume enclosing ellipsoid are reported. Then, several learning and classification algorithms based on MVEE are introduced. And a new gap tolerant SVM design method based MVEE is also reported.

E

KEY TERMS

Cognitive Learner: It is defined as the bounding boundary of a minimum volume set which encloses all the given samples to imitate the learning process.

Cognition Process: In this chapter, it refers to the cognizing and recognizing process of the human brain.

Cognitive Recognizer: It is defined as the point detection and assignment algorithm to imitate the recognizing process.

Enclosing Machine Learning: It is a new machine learning paradigm which is based on function imitation of human being's cognizing and recognizing process using minimum enclosing set approximation.

Minimum Enclosing Set: It is a bounding boundary with minimum volume, which encloses all the given points exactly.

MVEE: It is an ellipsoidal minimum enclosing set, which encloses all the given points with minimum volume.

MVEE Gap Tolerant Classifier: A MVEE Gap Tolerant Classifier is specified by an ellipsoid, and by two hyperplanes, with parallel normals. The set of points lying in between (but not on) the hyperplanes is called the margin set. Points that lie inside the ellipsoid but not in the margin set are assigned a class, $\{\pm 1\}$, depending on which side of the margin set they lie on. All other points are defined to be correct: they are not assigned a class. A MVEE gap tolerant classifier is in fact a special kind of support vector machine which does not count data falling outside the ellipsoid containing the training data or inside the margin as an error.

Enhancing Web Search through Query Expansion

Daniel Crabtree
Victoria University of Wellington, New Zealand

INTRODUCTION

Web search engines help users find relevant web pages by returning a result set containing the pages that best match the user's query. When the identified pages have low relevance, the query must be refined to capture the search goal more effectively. However, finding appropriate refinement terms is difficult and time consuming for users, so researchers developed query expansion approaches to identify refinement terms automatically.

There are two broad approaches to query expansion, automatic query expansion (AQE) and interactive query expansion (IQE) (Ruthven et al., 2003). AQE has no user involvement, which is simpler for the user, but limits its performance. IQE has user involvement, which is more complex for the user, but means it can tackle more problems such as ambiguous queries.

Searches fail by finding too many irrelevant pages (low precision) or by finding too few relevant pages (low recall). AQE has a long history in the field of information retrieval, where the focus has been on improving recall (Velez et al., 1997). Unfortunately, AQE often decreased precision as the terms used to expand a query often changed the query's meaning (Croft and Harper (1979) identified this effect and named it query drift). The problem is that users typically consider just the first few results (Jansen et al., 2005), which makes precision vital to web search performance. In contrast, IQE has historically balanced precision and recall, leading to an earlier uptake within web search. However, like AQE, the precision of IQE approaches needs improvement. Most recently, approaches have started to improve precision by incorporating semantic knowledge.

BACKGROUND

While AQE and IQE use distinctly different user interfaces, they use remarkably similar components. Both involve three components: the retrieval model, term weighting, and term selection. The four main retrieval models are the Boolean model, the vector space model, the probabilistic model, and the logical model (Ruthven et al., 2003). Term weighting is dependent on the retrieval model. For the Boolean model, the selected terms simply extend the query. For the vector space model, Rocchio (1971) developed the most common weighting scheme, which increases the weight of relevant terms and decreases the weight of irrelevant terms. The remaining models use richer weighting schemes.

Historically, query expansion approaches targeted specific retrieval models and focused on optimizing the model parameters and the selection of term weights. However, these issues have largely been resolved. The best approaches add a small subset of the most discriminating expansion terms. For web-scale data sets (those involving billions of pages), selecting about 25 terms performs best and selecting more terms decreases precision (Yue et al., 2005). Once selected, the terms are relatively easy to incorporate into any retrieval model and weighting scheme. Therefore, our focus lies on term selection.

The selected terms must address a variety of search problems. A well-known problem is low recall, typically caused by the vocabulary gap (Smyth, 2007), which occurs when some relevant pages do not contain the query terms. For example, a search for "data mining algorithms" may not find relevant pages such as one that discussed "decision trees", which used the term "machine learning" instead of "data mining". Fortunately, AQE and IQE approaches adequately address low recall for web search when the precision of the highest ranked pages is high. That makes precision improvement paramount and the focus of both recent research and this chapter.

Another well-known problem is query ambiguity, which hurts precision and arises when there are multiple interpretations for a query. For example, "jaguar" may refer to the car or the animal. As the user must clarify

their intent, AQE approaches cannot help refine these queries, but for simple cases, many IQE approaches work well. The trouble is distinguishing interpretations that use very similar vocabulary.

A recent TREC workshop identified several problems that affect precision, half involved the aspect coverage problem (Carmel et al., 2006) and the remainder dealt with more complex natural language issues. The aspect coverage problem occurs when pages do not adequately represent all query aspects. For example, a search for "black bear attacks" may find many irrelevant pages that describe the habitat, diet, and features of black bears, but which only mention in passing that sometimes bears attack – in this case, the result set underrepresents the attacks aspect. Interestingly, addressing the aspect coverage problem requires no user involvement and the solution provides insights into distinguishing interpretations that use similar vocabulary.

Query ambiguity and the aspect coverage problem are the major causes of low precision. Figure 1 shows four queries, "regular expressions" (an easy single-aspect query that is not ambiguous), "jaguar" (an easy single-aspect query that is ambiguous), "transportation tunnel disasters" (a hard three-aspect query that is not ambiguous), and "black bear attacks" (a hard two-aspect query that is ambiguous). Current search engines easily solve easy, non-ambiguous queries like "regular expressions" and most IQE approaches address easy, ambiguous queries like "jaguar". The hard queries like "transportation tunnel disasters" are much harder to refine, especially when they are also ambiguous like "black bear attacks".

Predicting query difficulty has been a side challenge for improving query expansion. Yom-Tov et al. (2005) proposed that AQE performance would improve by only refining queries where the result set has high precision. The problem is that users gain little benefit from marginal improvements to easy queries that already have good performance. Therefore, while predicting query difficulty is useful, the challenge is still to improve the precision of the hard queries with low initial precision. Fortunately, the most recent query expansion approaches both improve the precision of hard queries and help predict query difficulty.

MAIN FOCUS

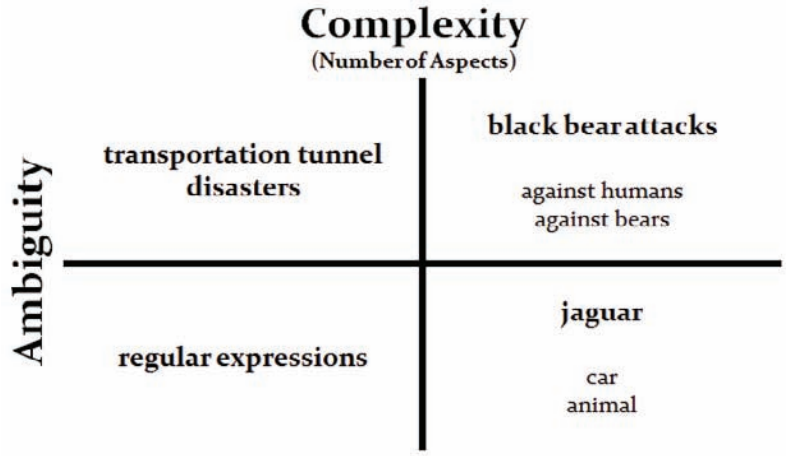
There are a variety of approaches for finding expansion terms, each with its own advantages and disadvantages.

Relevance Feedback (IQE)

Relevance feedback methods select expansion terms based on the user's relevance judgments for a subset of the retrieved pages. Relevance feedback implementations vary according to the use of irrelevant pages and the method of ranking terms.

Normally, users explicitly identify only relevant pages; Ide (1971) suggested two approaches for de-

Figure 1. Query examples and factors affecting precision



termining the irrelevant ones. Ide-regular considers pages irrelevant when they are not relevant and occur earlier in the result set than the last relevant page. For example, when pages four and five are relevant, pages one, two, and three are irrelevant, and positions six and later are neither relevant nor irrelevant. Ide-dec-hi considers just the first non-relevant page irrelevant. While not outperforming Ide-regular, Ide-dec-hi is more consistent and improves more queries (Ruthven et al., 2003).

The most important factor for performance is selecting the most valuable terms. Researchers considered many approaches, including all combinations of document frequency (DF), term frequency (TF), and inverse document frequency (IDF). Experiments consistently confirm that TF•IDF performs the best (Drucker et al., 2002).

Relevance feedback approaches frequently improve query performance when at least some of the initially retrieved pages are relevant, but place high demands on the user. Users must waste time checking the relevance of irrelevant documents and performance is highly dependent on judgment quality. In fact, Magennis & Rijsbergen (1997) found that while user selections improve performance, they were not optimal and often fell short of completely automatic expansion techniques such as pseudo-relevance feedback.

Pseudo-Relevance Feedback (AQE+IQE)

Pseudo-Relevance Feedback, also called blind or ad-hoc relevance feedback is nearly identical to relevance feedback. The difference is that instead of users making relevance judgments, the method assumes the first N pages are relevant. Using approximately N=10 provides the best performance (Shipeng et al., 2003).

Pseudo-relevance feedback works well for AQE when the query already produces good results (high precision). However, for the hard queries, with poor initial results (low precision), pseudo-relevance feedback often reduces precision due to query drift. Crabtree et al. (2007) recently confirmed the problem and found that on balance, pseudo-relevance feedback does not provide any significant improvement over current search engines.

Pseudo-relevance feedback can be adapted for IQE by presenting users with the top ranked terms, and letting them select which terms to use for query expansion. Like relevance feedback, this relies on user judgments, but the user's decision is simpler and performance is potentially greater: Crabtree et al. (2007) found that adding the single best refinement term suggested by interactive pseudo-relevance feedback outperformed relevance feedback when given optimal relevance judgments for five pages.

Thesauri Based Expansion (AQE+IQE)

Thesauri provide semantically similar terms and the approaches based on them expand the query with terms closely related to existing query terms. Human constructed thesauri like WordNet expose an assortment of term relationships. Since many relationships are unsuitable for direct query expansion, most approaches use only a few relationships such as synonyms and hyponyms. Hsu et al. (2006) changed this, by combining several relationships together into a single model for AQE. As with pseudo-relevance feedback, thesauri approaches can present users with thesauri terms for IQE (Sihvonen et al., 2004).

A useful alternative to human constructed thesauri is global document analysis, which can provide automatic measures of term relatedness. Cilibrasi and Vitanyi (2007) introduced a particularly useful measure called Google distance that uses the co-occurrence frequency of terms in web pages to gauge term relatedness.

Human constructed thesauri are most helpful for exploring related queries interactively, as knowledge of term relationships is invaluable for specializing and generalizing refinements. However, descriptively related terms such as synonyms perform poorly for query expansion, as they are often polysemous and cause query drift. Co-occurrence information is more valuable, as good refinements often involve descriptively obscure, but frequently co-occurring terms (Crabtree et al., 2007). However, simply adding co-occurring terms en-mass causes query drift. The real advantage comes when coupling co-occurrence relatedness with a deeper analysis of the query or result set.

Web Page Clustering (IQE)

Web page clustering approaches group similar documents together into clusters. Researchers have developed many clustering algorithms: hierarchical (agglomerative and divisive), partitioning (probabilistic, k-means), grid-based and graph-based clustering (Berkhin, 2002). For web page clustering, algorithms

extend these by considering text or web specific characteristics. For example, Suffix Tree Clustering (Zamir and Etzioni, 1998) and Lingo (Osinski et al., 2004) use phrase information and Menczer (2004) developed an approach that uses the hyperlinked nature of web pages. The most recent trend has been incorporating semantic knowledge. Query Directed Clustering (Crabtree et al., 2006) uses Google distance and other co-occurrence based measures to guide the construction of high quality clusters that are semantically meaningful.

Normally, clustering algorithms refine queries indirectly by presenting the pages within the cluster. However, they can just as easily generate terms for query expansion. Many text-oriented clustering algorithms construct intentional descriptions of clusters comprised of terms that are ideal for query expansion. For the remainder, relevance feedback applies at the cluster level, for instance, by treating all pages within the selected cluster as relevant. Query Directed Clustering additionally computes cluster-page relevance; a particularly nice property for weighting page terms when used for relevance feedback.

Web page clustering enables users to provide feedback regarding many pages simultaneously, which reduces the likelihood of users making relevance judgment mistakes. Additionally, it alleviates the need for users to waste time examining irrelevant pages. The performance is also superior to the alternatives: Crabtree et al. (2007) showed that the best clustering algorithms (Lingo and Query Directed Clustering) outperform the relevance feedback and interactive pseudo-relevance approaches. However, clustering approaches do not adequately address queries where the vocabulary of the relevant and irrelevant documents is very similar, although they do significantly outperform the alternatives discussed previously (Crabtree et al., 2007a).

Query Aspect Approaches (AQE+IQE)

Query aspect approaches (Crabtree et al., 2007) use an in-depth analysis of the query to guide the selection of expansion terms. Broadly, the approach identifies query aspects, determines how well the result set represents each aspect, and finally, finds expansion terms that increase the representation of any underrepresented aspects.

Query aspect approaches identify query aspects by considering the query word ordering and the relative frequencies of the query subsequences; this works as queries with the same intent typically preserve the ordering of words within an aspect. For example, a user wanting "Air New Zealand" would not enter "Zealand Air New". Determining aspect representation involves examining the aspect's vocabulary model, which consists of terms that frequently co-occur with the aspect. The degree of aspect representation is roughly the number of terms from the aspect's vocabulary model in the result set; this works as different aspects invoke different terms. For example, for the query "black bear attacks", the "black bear" aspect will invoke terms like "Animal", "Mammal", and "Diet", but the "attacks" aspect will invoke terms like "Fatal", "Maul", and "Danger". The terms selected for query expansion are terms from the vocabulary models of underrepresented aspects that resolve the underrepresentation of query aspects.

Query aspects help predict query difficulty: when the result set underrepresents an aspect, the query will have poor precision. Additionally, query aspect approaches can improve exactly those queries that need the most improvement. AbraQ (Crabtree et al., 2007) provides a very efficient approach that solves the aspect coverage problem by using the query aspect approach for AQE. AbraQ without any user involvement produces higher precision queries than the alternatives given optimal user input. Qasp (Crabtree et al., 2007a) coupled the query aspect approach with hierarchical agglomerative clustering to provide an IQE approach that works when the vocabulary of the relevant and irrelevant documents is very similar. Furthermore, with a trivial extension, query aspect approaches can improve queries that find few or no results.

Query Log Analysis (IQE)

Query log analysis examines the search patterns of users by considering the pages visited and the sequences of queries performed (Cui, 2002). Query log analysis then presents the user with similar queries as possible expansions. As of October 2007, Google offered a similar queries feature presented as search navigation through the experimental search feature of Google Labs (http://www.google.com/experimental/).

The approach currently works best for short queries repeated by many users (Crabtree et al., 2007). However, there is great potential for cross-fertilization between query log analysis and other query expansion techniques. Unfortunately, this research is constrained

to large search engines, as the query log data has commercial value and is not widely available to other researchers.

FUTURE TRENDS

Over the last few years, the trend has been the increased incorporation of semantic knowledge and the coupling of distinct approaches. These trends will continue into the future and if search companies make at least some query log data publicly available, the coupling between query log analysis and other approaches is likely to be particularly fruitful. Additionally, with the aspect coverage problem addressed, it is likely that the less common natural language problems identified in TREC will become the focus of future efforts.

CONCLUSION

Many approaches select useful terms for query expansion. Relevance feedback and pseudo-relevance feedback help when the initially retrieved documents are reasonably relevant. Thesauri based approaches help users explore the space around their query and boost the performance of other approaches by providing semantic knowledge. Clustering methods help users ignore the irrelevant documents and reduce the amount of feedback required from users. Query aspect approaches identify many problematic queries and improve them without user involvement, additionally query aspect approaches aid clustering by showing how to identify clusters when all documents share similar vocabulary. Query log analysis helps for short and frequent queries, but could potentially improve other approaches in the future.

KEY TERMS

Automatic Query Expansion: Adding additional query terms to improve result set quality without user involvement.

Interactive Query Expansion: Finding additional query terms to improve result set quality and then presenting them to the user.

Pseudo-relevance Feedback: Selecting refinement terms based on assuming the top N pages are relevant.

Query Aspect: Sequence of query words that form a distinct semantic component of a query. For example, searching for information on holidays has one query aspect (holidays), whereas searching for travel agents in Los Angeles who deal with cruises involves three different query aspects (travel agents, Los Angeles, and cruises).

Query Log Analysis: Mining the collective queries of users for similar queries by finding temporal patterns in the search sequences across user search sessions.

Relevance Feedback: Selecting refinement terms based on the relevancy judgments of pages from the user.

Vocabulary: The terms expected to co-occur in the context of another term.

Web Page Clustering: Automatically grouping together semantically similar pages into clusters by analyzing the contents of pages such as text, page structure, and hyperlinks.

Enhancing Web Search through Query Log Mining

Ji-Rong Wen
Microsoft Research Asia, China

INTRODUCTION

Web query log is a type of file keeping track of the activities of the users who are utilizing a search engine. Compared to traditional information retrieval setting in which documents are the only information source available, query logs are an additional information source in the Web search setting. Based on query logs, a set of Web mining techniques, such as log-based query clustering, log-based query expansion, collaborative filtering and personalized search, could be employed to improve the performance of Web search.

BACKGROUND

Web usage mining is an application of data mining techniques to discovering interesting usage patterns from Web data, in order to understand and better serve the needs of Web-based applications. Since the majority of usage data is stored in Web logs, usage mining is usually also referred to as log mining. Web logs can be divided into three categories based on the location of data collecting: server log, client log, and proxy log. Server log provides an aggregate picture of the usage of a service by all users, while client log provides a complete picture of usage of all services by a particular client, with the proxy log being somewhere in the middle (Srivastava, Cooley, Deshpande, & Tan, 2000).

Query log mining could be viewed as a special kind of Web usage mining. While there is a lot of work about mining Website navigation logs for site monitoring, site adaptation, performance improvement, personalization and business intelligence, there is relatively little work of mining search engines' query logs for improving Web search performance. In early years, researchers have proved that relevance feedback can significantly improve retrieval performance if users provide sufficient and correct relevance judgments for queries (Xu & Croft, 2000). However, in real search scenarios, users are usually reluctant to explicitly give their relevance feedback. A large amount of users' past query sessions have been accumulated in the query logs of search engines. Each query session records a user query and the corresponding pages the user has selected to browse. Therefore, a query log can be viewed as a valuable source containing a large amount of users' implicit relevance judgments. Obviously, these relevance judgments can be used to more accurately detect users' query intentions and improve the ranking of search results.

One important assumption behind query log mining is that the clicked pages are "relevant" to the query. Although the clicking information is not as accurate as explicit relevance judgment in traditional relevance feedback, the user's choice does suggest a certain degree of relevance. In the long run with a large amount of log data, query logs can be treated as a reliable resource containing abundant implicit relevance judgments from a statistical point of view.

MAIN THRUST

Web Query Log Preprocessing

Typically, each record in a Web query log includes the IP address of the client computer, timestamp, the URL of the requested item, the type of Web browser, protocol, etc. The Web log of a search engine records various kinds of user activities, such as submitting queries, clicking URLs in the result list, getting HTML pages and skipping to another result list. Although all these activities reflect, more or less, a user's intention, the query terms and the Web pages the user visited are the most important data for mining tasks. Therefore, a query session, the basic unit of mining tasks, is defined as a query submitted to a search engine together with the Web pages the user visits in response to the query.

Since the HTTP protocol requires a separate connection for every client-server interaction, the activities of multiple users usually interleave with each other. There are no clear boundaries among user query sessions in the logs, which makes it a difficult task to extract individual query sessions from Web query logs (Cooley, Mobasher, & Srivastava, 1999). There are mainly two steps to extract query sessions from query logs: user identification and session identification. User identification is the process of isolating from the logs the activities associated with an individual user. Activities of the same user could be grouped by their IP addresses, agent types, site topologies, cookies, user IDs, etc. The goal of session identification is to divide the queries and page accesses of each user into individual sessions. Finding the beginning of a query session is trivial: a query session begins when a user submits a query to a search engine. However, it is difficult to determine when a search session ends. The simplest method of achieving this is through a timeout, where if the time between page requests exceeds a certain limit, it is assumed that the user is starting a new session.

Log-Based Query Clustering

Query clustering is a technique aiming at grouping users' semantically (not syntactically) related queries in Web query logs. Query clustering could be applied to FAQ detecting, index-term selection and query reformulation, which are effective ways to improve Web search. First of all, FAQ detecting means to detect Frequently Asked Questions (FAQs), which can be achieved by clustering similar queries in the query logs. A cluster being made up of many queries can be considered as a FAQ. Some search engines (e.g. Askjeeves) prepare and check the correct answers for FAQs by human editors, and a significant majority of users' queries can be answered precisely in this way. Second, inconsistency between term usages in queries and those in documents is a well-known problem in information retrieval, and the traditional way of directly extracting index terms from documents will not be effective when the user submits queries containing terms different from those in the documents. Query clustering is a promising technique to provide a solution to the word mismatching problem. If similar queries can be recognized and clustered together, the resulting query clusters will be very good sources for selecting additional index terms for documents. For example, if queries such as "atomic bomb", "Manhattan Project", "Hiroshima bomb" and "nuclear weapon" are put into a query cluster, this cluster, not the individual terms, can be used as a whole to index documents related to atomic bomb. In this way, any queries contained in the cluster can be linked to these documents. Third, most words in the natural language have inherent ambiguity, which makes it quite difficult for user to formulate queries with appropriate words. Obviously, query clustering could be used to suggest a list of alternative terms for users to reformulate queries and thus better represent their information needs.

The key problem underlying query clustering is to determine an adequate similarity function so that truly similar queries can be grouped together. There are mainly two categories of methods to calculate the similarity between queries: one is based on query content, and the other on query session. Since queries with the same or similar search intentions may be represented with different words and the average length of Web queries is very short, content-based query clustering usually does not perform well.

Using query sessions mined from query logs to cluster queries is proved to be a more promising method (Wen, Nie, & Zhang, 2002). Through query sessions, "query clustering" is extended to "query session clustering". The basic assumption here is that the activities following a query are relevant to the query and represent, to some extent, the semantic features of the query. The query text and the activities in a query session as a whole can represent the search intention of the user more precisely. Moreover, the ambiguity of some query terms is eliminated in query sessions. For instance, if a user visited a few tourism Websites after submitting a query "Java", it is reasonable to deduce that the user was searching for information about "Java Island", not "Java programming language" or "Java coffee". Moreover, query clustering and document clustering can be combined and reinforced with each other (Beeferman & Berger, 2000).

Log-Based Query Expansion

Query expansion involves supplementing the original query with additional words and phrases, which is an effective way to overcome the term-mismatching problem and to improve search performance. Log-based query expansion is a new query expansion method based on query log mining. Taking query sessions in query logs

as a bridge between user queries and Web pages, probabilistic correlations between terms in queries and those in pages can then be established. With these term-term correlations, relevant expansion terms can be selected from the documents for a query. For example, a recent work by Cui, Wen, Nie, and Ma (2003) shows that, from query logs, some very good terms, such as "personal computer", "Apple Computer", "CEO", "Macintosh" and "graphical user interface", can be detected to be tightly correlated to the query "Steve Jobs", and using these terms to expand the original query can lead to more relevant pages.

Experiments by Cui, Wen, Nie, and Ma (2003) show that mining user logs is extremely useful for improving retrieval effectiveness, especially for very short queries on the Web. The log-based query expansion overcomes several difficulties of traditional query expansion methods because a large number of user judgments can be extracted from user logs, while eliminating the step of collecting feedbacks from users for ad-hoc queries. Log-based query expansion methods have three other important properties. First, the term correlations are pre-computed offline and thus the performance is better than traditional local analysis methods which need to calculate term correlations on the fly. Second, since user logs contain query sessions from different users, the term correlations can reflect the preference of the majority of the users. Third, the term correlations may evolve along with the accumulation of user logs. Hence, the query expansion process can reflect updated user interests at a specific time.

Collaborative Filtering and Personalized Web Search

Collaborative filtering and personalized Web search are two most successful examples of personalization on the Web. Both of them heavily rely on mining query logs to detect users' preferences or intentions.

Collaborative Filtering

Collaborative filtering is a method of making automatic predictions (filtering) about the interests of a user by collecting taste information from many users (collaborating). The basic assumption of collaborative filtering is that users having similar tastes on some items may also have similar preferences on other items. From Web logs, a collection of items (books, music CDs, movies, etc.) with users' searching, browsing and ranking information could be extracted to train prediction and recommendation models. For a new user with a few items he/she likes or dislikes, other items meeting the user's taste could be selected based on the trained models and recommended to him/her (Shardanand & Maes, 1995; Konstan, Miller, Maltz, Herlocker, & Gordon, L. R., et al., 1997). Generally, vector space models and probabilistic models are two major models for collaborative filtering (Breese, Heckerman, & Kadie, 1998). Collaborative filtering systems have been implemented by several e-commerce sites including Amazon.

Collaborative filtering has two main advantages over content-based recommendation systems. First, content-based annotations of some data types are often not available (such as video and audio) or the available annotations usually do not meet the tastes of different users. Second, through collaborative filtering, multiple users' knowledge and experiences could be remembered, analyzed and shared, which is a characteristic especially useful for improving new users' information seeking experiences.

The original form of collaborative filtering does not use the actual content of the items for recommendation, which may suffers from the scalability, sparsity and synonymy problems. Most importantly, it is incapable of overcoming the so-called first-rater problem. The first-rater problem means that objects newly introduced into the system have not been rated by any users and can therefore not be recommended. Due to the absence of recommendations, users tend to not be interested in these new objects. This in turn has the consequence that the newly added objects remain in their state of not being recommendable. Combining collaborative and content-based filtering is therefore a promising approach to solving the above problems (Baudisch, 1999).

Personalized Web Search

While most modern search engines return identical results to the same query submitted by different users, personalized search targets to return results related to users' preferences, which is a promising way to alleviate the increasing information overload problem on the Web. The core task of personalization is to obtain the preference of each individual user, which is called user profile. User profiles could be explicitly provided

by users or implicitly learned from users' past experiences (Hirsh, Basu, & Davison, 2000; Mobasher, Cooley, & Srivastava, 2000). For example, Google's personalized search requires users to explicitly enter their preferences. In the Web context, query log provides a very good source for learning user profiles since it records the detailed information about users' past search behaviors. The typical method of mining a user's profile from query logs is to first collect all of this user's query sessions from logs, and then learn the user's preferences on various topics based on the queries submitted and the pages viewed by the user (Liu, Yu, & Meng, 2004).

User preferences could be incorporated into search engines to personalize both their relevance ranking and their importance ranking. A general way for personalizing relevance ranking is through query reformulation, such as query expansion and query modification, based on user profiles. A main feature of modern Web search engines is that they assign importance scores to pages through mining the link structures and the importance scores will significantly affect the final ranking of search results. The most famous link analysis algorithms are PageRank (Page, Brin, Motwani, & Winograd, 1998) and HITS (Kleinberg, 1998). One main shortcoming of PageRank is that it assigns a static importance score to a page, no matter who is searching and what query is being used. Recently, a topic-sensitive PageRank algorithm (Haveliwala, 2002) and a personalized PageRank algorithm (Jeh & Widom, 2003) are proposed to calculate different PageRank scores based on different users' preferences and interests. A search engine using topic-sensitive PageRank and Personalized PageRank is expected to retrieve Web pages closer to user preferences.

FUTURE TRENDS

Although query log mining is promising to improve the information seeking process on the Web, the number of publications in this field is relatively small. The main reason might lie in the difficulty of obtaining a large amount of query log data. Due to lack of data, especially lack of a standard data set, it is difficult to repeat and compare existing algorithms. This may block knowledge accumulation in the field. On the other hand, search engine companies are usually reluctant to make pubic of their log data because of the costs and/or legal issues involved. However, to create such a kind of standard log dataset will greatly benefit both the research community and the search engine industry, and thus may become a major challenge of this field in the future.

Nearly all of the current published experiments were conducted on snapshots of small to medium scale query logs. In practice, query logs are usually continuously generated and with huge sizes. To develop scalable and incremental query log mining algorithms capable of handling the huge and growing dataset is another challenge.

We also foresee that client-side query log mining and personalized search will attract more and more attentions from both academy and industry. Personalized information filtering and customization could be effective ways to ease the deteriorated information overload problem.

CONCLUSION

Web query log mining is an application of data mining techniques to discovering interesting knowledge from Web query logs. In recent years, some research work and industrial applications have demonstrated that Web log mining is an effective method to improve the performance of Web search. Web search engines have become the main entries for people to exploit the Web and find needed information. Therefore, to keep improving the performance of search engines and to make them more user-friendly are important and challenging tasks for researchers and developers. Query log mining is expected to play a more and more important role in enhancing Web search.

KEY TERMS

Collaborative Filtering: A method of making automatic predictions (filtering) about the interests of a user by collecting taste information from many users (collaborating).

Log-Based Query Clustering: A technique aiming at grouping users' semantically related queries collected in Web query logs.

Log-Based Query Expansion: A new query expansion method based on query log mining. Probabilistic correlations between terms in the user queries and those in the documents can then be established through user logs. With these term-term correlations, relevant expansion terms can be selected from the documents for a query.

Log-Based Personalized Search: Personalized search targets to return results related to users' preferences. The core task of personalization is to obtain the preference of each individual user, which could be learned from query logs.

Query Log: A type of file keeping track of the activities of the users who are utilizing a search engine.

Query Log Mining: An application of data mining techniques to discover interesting knowledge from Web query logs. The mined knowledge is usually used to enhance Web search.

Query Session: a query submitted to a search engine together with the Web pages the user visits in response to the query. Query session is the basic unit of many query log mining tasks.

Enhancing Web Search through Web Structure Mining

Ji-Rong Wen
Microsoft Research Asia, China

INTRODUCTION

The Web is an open and free environment for people to publish and get information. Everyone on the Web can be either an author, a reader, or both. The language of the Web, *HTML (Hypertext Markup Language)*, is mainly designed for information display, not for semantic representation. Therefore, current Web search engines usually treat Web pages as unstructured documents, and traditional information retrieval (IR) technologies are employed for Web page parsing, indexing, and searching. The unstructured essence of Web pages seriously blocks more accurate search and advanced applications on the Web. For example, many sites contain structured information about various products. Extracting and integrating product information from multiple Web sites could lead to powerful search functions, such as comparison shopping and business intelligence. However, these structured data are embedded in Web pages, and there are no proper traditional methods to extract and integrate them. Another example is the link structure of the Web. If used properly, information hidden in the links could be taken advantage of to effectively improve search performance and make Web search go beyond traditional information retrieval (Page, Brin, Motwani, & Winograd, 1998, Kleinberg, 1998).

Although *XML (Extensible Markup Language)* is an effort to structuralize Web data by introducing semantics into tags, it is unlikely that common users are willing to compose Web pages using XML due to its complication and the lack of standard schema definitions. Even if XML is extensively adopted, a huge amount of pages are still written in the HTML format and remain unstructured. Web structure mining is the class of methods to automatically discover structured data and information from the Web. Because the Web is dynamic, massive and heterogeneous, automated Web structure mining calls for novel technologies and tools that may take advantage of state-of-the-art technologies from various areas, including machine learning, data mining, information retrieval, and databases and natural language processing.

BACKGROUND

Web structure mining can be further divided into three categories based on the kind of structured data used.

- **Web graph mining:** Compared to a traditional document set in which documents are independent, the Web provides additional information about how different documents are connected to each other via hyperlinks. The Web can be viewed as a (directed) graph whose nodes are the Web pages and whose edges are the hyperlinks between them. There has been a significant body of work on analyzing the properties of the Web graph and mining useful structures from it (Page et al., 1998; Kleinberg, 1998; Bharat & Henzinger, 1998; Gibson, Kleinberg, & Raghavan, 1998). Because the Web graph structure is across multiple Web pages, it is also called *interpage structure*.
- **Web information extraction (Web IE):** In addition, although the documents in a traditional information retrieval setting are treated as plain texts with no or few structures, the content within a Web page does have inherent structures based on the various HTML and XML tags within the page. While Web content mining pays more attention to the content of Web pages, Web information extraction has focused on automatically extracting structures with various accuracy and granularity out of Web pages. Web content structure is a kind of structure embedded in a single Web page and is also called *intrapage structure*.
- **Deep Web mining:** Besides Web pages that are accessible or crawlable by following the hyperlinks, the Web also contains a vast amount of noncrawlable content. This hidden part of the

Web, referred to as the *deep Web* or the *hidden Web* (Florescu, Levy, & Mendelzon, 1998), comprises a large number of online Web databases. Compared to the static surface Web, the deep Web contains a much larger amount of high-quality structured information (Chang, He, Li, & Zhang, 2003). Automatically discovering the structures of Web databases and matching semantically related attributes between them is critical to understanding the structures and semantics of the deep Web sites and to facilitating advanced search and other applications.

MAIN THRUST

Web Graph Mining

Mining the Web graph has attracted a lot of attention in the last decade. Some important algorithms have been proposed and have shown great potential in improving the performance of Web search. Most of these mining algorithms are based on two assumptions. (a) Hyperlinks convey human endorsement. If there exists a link from page A to page B, and these two pages are authored by different people, then the first author found the second page valuable. Thus the importance of a page can be propagated to those pages it links to. (b) Pages that are co-cited by a certain page are likely related to the same topic. Therefore, the popularity or importance of a page is correlated to the number of incoming links to some extendt, and related pages tend to be clustered together through dense linkages among them.

Hub and Authority

In the Web graph, a *hub* is defined as a page containing pointers to many other pages, and an *authority* is defined as a page pointed to by many other pages. An authority is usually viewed as a good page containing useful information about one topic, and a hub is usually a good source to locate information related to one topic. Moreover, a *good* hub should contain pointers to many good authorities, and a *good* authority should be pointed to by many good hubs. Such a mutual reinforcement relationship between hubs and authorities is taken advantage of by an iterative algorithm called HITS (Kleinberg, 1998). HITS computes authority scores and hub scores for Web pages in a subgraph of the Web, which is obtained from the (subset of) search results of a query with some predecessor and successor pages.

Bharat and Henzinger (1998) addressed three problems in the original HITS algorithm: mutually reinforced relationships between hosts (where certain documents "conspire" to dominate the computation), automatically generated links (where no human's opinion is expressed by the link), and irrelevant documents (where the graph contains documents irrelevant to the query topic). They assign each edge of the graph an authority weight and a hub weight to solve the first problem and combine connectivity and content analysis to solve the latter two. Chakrabarti, Joshi, and Tawde (2001) addressed another problem with HITS: regarding the whole page as a hub is not suitable, because a page always contains multiple regions in which the hyperlinks point to different topics. They proposed to disaggregate hubs into coherent regions by segmenting the DOM (document object model) tree of an HTML page.

PageRank

The main drawback of the HITS algorithm is that the hubs and authority score must be computed iteratively from the query result on the fly, which does not meet the real-time constraints of an online search engine. To overcome this difficulty, Page et al. (1998) suggested using a random surfing model to describe the probability that a page is visited and taking the probability as the importance measurement of the page. They approximated this probability with the famous PageRank algorithm, which computes the probability scores in an iterative manner. The main advantage of the PageRank algorithm over the HITS algorithm is that the importance values of all pages are computed off-line and can be directly incorporated into ranking functions of search engines.

Noisy link and topic drifting are two main problems in the classic Web graph mining algorithms. Some links, such as banners, navigation panels, and advertisements, can be viewed as noise with respect to the query topic and do not carry human editorial endorsement. Also, hubs may be mixed, which means that only a portion of the hub content may be relevant to the query. Most link analysis algorithms treat each Web page as an atomic, indivisible unit with no internal structure. This leads to false reinforcements of hub/authority and importance calculation. Cai, He, Wen, and Ma (2004)

used a vision-based page segmentation algorithm to partition each Web page into blocks. By extracting the page-to-block, block-to-page relationships from the link structure and page layout analysis, a semantic graph over the Web can be constructed such that each node exactly represents a single semantic topic. This graph can better describe the semantic structure of the Web. Based on block-level link analysis, they proposed two new algorithms, Block Level PageRank and Block Level HITS, whose performances are shown to exceed the classic PageRank and HITS algorithms.

Community Mining

Many communities, either in an explicit or implicit form, exist in the Web today, and their number is growing at a very fast speed. Discovering communities from a network environment such as the Web has recently become an interesting research problem. The Web can be abstracted into directional or nondirectional graphs with nodes and links. It is usually rather difficult to understand a network's nature directly from its graph structure, particularly when it is a large scale complex graph. Data mining is a method to discover the hidden patterns and knowledge from a huge network. The mined knowledge could provide a higher logical view and more precise insight of the nature of a network and will also dramatically decrease the dimensionality when trying to analyze the structure and evolution of the network.

Quite a lot of work has been done in mining the implicit communities of users, Web pages, or scientific literature from the Web or document citation database using content or link analysis. Several different definitions of community were also raised in the literature. In Gibson et al. (1998), a Web community is a number of representative authority Web pages linked by important hub pages that share a common topic. Kumar, Raghavan, Rajagopalan, and Tomkins (1999) define a Web community as a highly linked bipartite subgraph with at least one core containing complete bipartite subgraph. In Flake, Lawrence, and Lee Giles (2000), a set of Web pages that linked more pages in the community than those outside of the community could be defined as a Web community. Also, a research community could be based on a single-most-cited paper and could contain all papers that cite it (Popescul, Flake, Lawrence, Ungar, & Lee Giles, 2000).

Web Information Extraction

Web IE has the goal of pulling out information from a collection of Web pages and converting it to a homogeneous form that is more readily digested and analyzed for both humans and machines. The results of IE could be used to improve the indexing process, because IE removes irrelevant information in Web pages and facilitates other advanced search functions due to the structured nature of data. The structuralization degrees of Web pages are diverse. Some pages can be just taken as plain text documents. Some pages contain a little loosely structured data, such as a product list in a shopping page or a price table in a hotel page. Some pages are organized with more rigorous structures, such as the home pages of the professors in a university. Other pages have very strict structures, such as the book description pages of Amazon, which are usually generated by a uniform template.

Therefore, basically two kinds of Web IE techniques exist: IE from unstructured pages and IE from semistructured pages. IE tools for unstructured pages are similar to those classical IE tools that typically use natural language processing techniques such as syntactic analysis, semantic analysis, and discourse analysis. IE tools for semistructured pages are different from the classical ones, as IE utilizes available structured information, such as HTML tags and page layouts, to infer the data formats or pages. Such a kind of methods is also called *wrapper induction* (Kushmerick, Weld, & Doorenbos, 1997; Cohen, Hurst, & Jensen, 2002). In contrast to classic IE approaches, wrapper induction operates less dependently of the specific contents of Web pages and mainly focuses on page structure and layout. Existing approaches for Web IE mainly include the manual approach, supervised learning, and unsupervised learning. Although some manually built wrappers exist, supervised learning and unsupervised learning are viewed as more promising ways to learn robust and scalable wrappers, because building IE tools manually is not feasible and scalable for the dynamic, massive and diverse Web contents. Moreover, because supervised learning still relies on manually labeled sample pages and thus also requires substantial human effort, unsupervised learning is the most suitable method for Web IE. There have been several successful fully automatic IE tools using unsupervised learning (Arasu & Garcia-Molina, 2003; Liu, Grossman, & Zhai, 2003).

Deep Web Mining

In the deep Web, it is usually difficult or even impossible to directly obtain the structures (i.e. schemas) of the Web sites' backend databases without cooperation from the sites. Instead, the sites present two other distinguishing structures, interface schema and result schema, to users. The *interface schema* is the schema of the query interface, which exposes attributes that can be queried in the backend database. The *result schema* is the schema of the query results, which exposes attributes that are shown to users.

The interface schema is useful for applications, such as a mediator that queries multiple Web databases, because the mediator needs complete knowledge about the search interface of each database. The result schema is critical for applications, such as data extraction, where instances in the query results are extracted. In addition to the importance of the interface schema and result schema, attribute matching across different schemas is also important. First, matching between different interface schemas and matching between different results schemas (intersite schema matching) are critical for metasearching and data-integration among related Web databases. Second, matching between the interface schema and the result schema of a single Web database (intrasite schema matching) enables automatic data annotation and database content crawling.

Most existing schema-matching approaches for Web databases primarily focus on matching query interfaces (He & Chang, 2003; He, Meng, Yu, & Wu, 2003; Raghavan & Garcia-Molina, 2001). They usually adopt a label-based strategy to identify attribute labels from the descriptive text surrounding interface elements and then find synonymous relationships between the identified labels. The performance of these approaches may be affected when no attribute description can be identified or when the identified description is not informative. In Wang, Wen, Lochovsky, and Ma (2004), an instance-based schema-matching approach was proposed to identify both the interface and result schemas of Web databases. Instance-based approaches depend on the content overlap or statistical properties, such as data ranges and patterns, to determine the similarity of two attributes. Thus, they could effectively deal with the cases where attribute names or labels are missing or not available, which are common for Web databases.

FUTURE TRENDS

It is foreseen that the biggest challenge in the next several decades is how to effectively and efficiently dig out a machine-understandable information and knowledge layer from unorganized and unstructured Web data. However, Web structure mining techniques are still in their youth today. For example, the accuracy of Web information extraction tools, especially those automatically learned tools, is still not satisfactory to meet the requirements of some rigid applications. Also, deep Web mining is a new area, and researchers have many challenges and opportunities to further explore, such as data extraction, data integration, schema learning and matching, and so forth. Moreover, besides Web pages, various other types of structured data exist on the Web, such as e-mail, newsgroup, blog, wiki, and so forth. Applying Web mining techniques to extract structures from these data types is also a very important future research direction.

CONCLUSION

Despite the efforts of XML and semantic Web, which target to bring structures and semantics to the Web, Web structure mining is considered a more promising way to structuralize the Web due to its characteristics of automation, scalability, generality, and robustness. As a result, there has been a rapid growth of technologies for automatically discovering structures from the Web, namely Web graph mining, Web information extraction, and deep Web mining. The mined information and knowledge will greatly improve the effectiveness of current Web search and will enable much more sophisticated Web information retrieval technologies in the future.

Ensemble Data Mining Methods

Nikunj C. Oza
NASA Ames Research Center, USA

INTRODUCTION

Ensemble Data Mining Methods, also known as Committee Methods or Model Combiners, are machine learning methods that leverage the power of multiple models to achieve better prediction accuracy than any of the individual models could on their own. The basic goal when designing an ensemble is the same as when establishing a committee of people: each member of the committee should be as competent as possible, but the members should be complementary to one another. If the members are not complementary, that is, if they always agree, then the committee is unnecessary—any one member is sufficient. If the members are complementary, then when one or a few members make an error, the probability is high that the remaining members can correct this error. Research in ensemble methods has largely revolved around designing ensembles consisting of competent yet complementary models.

BACKGROUND

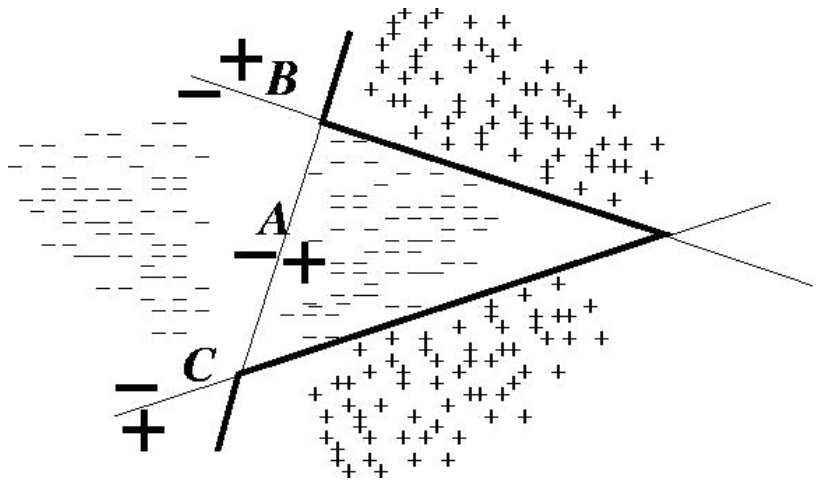
A supervised machine learner constructs a mapping from input data (normally described by several features) to the appropriate outputs. It does this by learning from a training set—N inputs $x_1, x_2, \ldots, x_N$ for which the corresponding true outputs $y_1, y_2, \ldots, y_N$ are known. The model that results is used to map new inputs to the appropriate outputs. In a classification learning task, each output is one or more classes to which the input belongs. The goal of classification learning is to develop a model that separates the data into the different classes, with the aim of classifying new examples in the future. For example, a credit card company may develop a model that separates people who defaulted on their credit cards from those who did not based on other known information such as annual income. A model would be generated based on data from past credit card holders. The model would be used to predict whether a new credit card applicant is likely to default on his credit card and thereby decide whether to approve or deny this applicant a new card. In a regression learning task, each output is a continuous value to be predicted (e.g., the average balance that a credit card holder carries over to the next month).

Many traditional machine learning algorithms generate a single model (e.g., a decision tree or neural network). Ensemble learning methods instead generate multiple models. Given a new example, the ensemble passes it to each of its multiple *base* models, obtains their predictions, and then combines them in some appropriate manner (e.g., averaging or voting). As mentioned earlier, it is important to have base models that are competent but also complementary (Tumer and Ghosh, 1996). To further motivate this point, consider Figure 1. This figure depicts a classification problem in which the goal is to separate the points marked with plus signs from points marked with minus signs. None of the three individual linear classifiers (marked A, B, and C) is able to separate the two classes of points. However, a majority vote over all three linear classifiers yields the piecewise-linear classifier shown as a thick line. This classifier is able to separate the two classes perfectly. For example, the plusses at the top of the figure are correctly classified by A and B, but are misclassified by C. The majority vote over these correctly classifies these points as plusses. This happens because A and B are very different from C. If our ensemble instead consisted of three copies of C, then all three classifiers would misclassify the plusses at the top of the figure, and so would a majority vote over these classifiers.

MAIN THRUST OF THE CHAPTER

We now discuss the key elements of an ensemble learning method and ensemble model and, in the process, discuss several ensemble methods that have been developed.

Figure 1. An ensemble of linear classifiers. Each line—A, B, and C—is a linear classifier. The boldface line is the ensemble that classifies new examples by returning the majority vote of A, B, and C



Ensemble Methods

The example shown in Figure 1 is an artificial example. We cannot normally expect to obtain base models that misclassify examples in completely separate parts of the input space and ensembles that classify all the examples correctly. However, there are many algorithms that attempt to generate a set of base models that make errors that are as different from one another as possible. Methods such as Bagging (Breiman, 1994) and Boosting (Freund and Schapire, 1996) promote diversity by presenting each base model with a different subset of training examples or different weight distributions over the examples. For example, in figure 1, if the plusses in the top part of the figure were temporarily removed from the training set, then a linear classifier learning algorithm trained on the remaining examples would probably yield a classifier similar to C. On the other hand, removing the plusses in the bottom part of the figure would probably yield classifier B or something similar. In this way, running the same learning algorithm on different subsets of training examples can yield very different classifiers which can be combined to yield an effective ensemble. Input Decimation Ensembles (IDE) (Tumer and Oza, 2003) and Stochastic Attribute Selection Committees (SASC) (Zheng and Webb, 1998) instead promote diversity by training each base model with the same training examples but different subsets of the input features. SASC trains each base model with a random subset of input features. IDE selects, for each class, a subset of features that has the highest correlation with the presence or absence of that class. Each feature subset is used to train one base model. However, in both SASC and IDE, all the training patterns are used with equal weight to train all the base models.

So far we have distinguished ensemble methods by the way they train their base models. We can also distinguish methods by the way they combine their base models' predictions. Majority or plurality voting is frequently used for classification problems and is used in Bagging. If the classifiers provide probability values, simple averaging is commonly used and is very effective (Tumer and Ghosh, 1996). Weighted averaging has also been used and different methods for weighting the base models have been examined. Two particularly interesting methods for weighted averaging include Mixtures of Experts (Jordan and Jacobs, 1994) and Merz's use of Principal Components Analysis (PCA) to combine models (Merz, 1999). In Mixtures of Experts, the weights in the weighted average combining are determined by a gating network, which is a model that takes the same inputs that the base models take, and returns a weight for each of the base models. The higher the weight for a base model, the more that base model is trusted to provide the correct answer. These weights are determined during training by how well the base models perform on the training examples. The gating network essentially keeps track of how well each base model performs in each part of the input

space. The hope is that each model learns to specialize in different input regimes and is weighted highly when the input falls into its specialty. Intuitively, we regularly use this notion of giving higher weights to opinions of experts with the most appropriate specialty. Merz's method uses PCA to lower the weights of base models that perform well overall but are redundant and therefore effectively give too much weight to one model. For example, in Figure 1, if there were instead two copies of A and one copy of B in an ensemble of three models, we may prefer to lower the weights of the two copies of A since, essentially, A is being given too much weight. Here, the two copies of A would always outvote B, thereby rendering B useless. Merz's method also increases the weight on base models that do not perform as well overall but perform well in parts of the input space where the other models perform poorly. In this way, a base model's unique contributions are rewarded. Many of the methods described above have been shown to be specific cases of one method: Importance Sampled Learning Ensembles (Friedman and Popescu, 2003).

When designing an ensemble learning method, in addition to choosing the method by which to bring about diversity in the base models and choosing the combining method, one has to choose the type of base model and base model learning algorithm to use. The combining method may restrict the types of base models that can be used. For example, to use average combining in a classification problem, one must have base models that can yield probability estimates. This precludes the use of linear discriminant analysis which is not set up to return probabilities. The vast majority of ensemble methods use only one base model learning algorithm but use the methods described earlier to bring about diversity in the base models. There has been surprisingly little work (e.g., (Merz 1999)) on creating ensembles with many different types of base models.

Two of the most popular ensemble learning algorithms are Bagging and Boosting, which we briefly explain next.

Bagging

*B*ootstrap *Agg*regat*ing* (Bagging) generates multiple bootstrap training sets from the original training set (using sampling with replacement) and uses each of them to generate a classifier for inclusion in the ensemble. The algorithms for bagging and sampling with replacement are given in Figure 2. In these algorithms, $\{(x_1,y_1), (x_2,y_2), \ldots, (x_N,y_N)\}$ is the training set., M is the number of base models to be learned, L_b is the base model learning algorithm, the h_i's are the base models, *random_integer(a,b)* is a function that returns each of the integers from a to b with equal probability, and $I(X)$ is the indicator function that returns 1 if X is true and 0 otherwise.

To create a bootstrap training set from an original training set of size N, we perform N Multinomial trials, where in each trial, we draw one of the N examples. Each example has probability $1/N$ of being drawn in each trial. The second algorithm shown in figure 2 does

Figure 2. Batch bagging algorithm and sampling with replacement

Bagging($\{(x_1, y_1), (x_2, y_2),\ldots,(x_N, y_N)\}$,$M$)
For each m = 1,2,...,M
T_m = Sample_With_Replacement($\{(x_1, y_1), (x_2, y_2),\ldots,(x_N, y_N)\}$,$N$)
$h_m = L_b(T_m)$
Return $h_{fin}(x) = \text{argmax}_{y \in Y} \sum_{m=1}^{M} I(h_m(x) = y)$.

Sample_With_Replacement (T,N)
S = {}
For i = 1,2,...,N
    r = random_integer(1,N)
    Add $T[r]$ to S.
Return S.

exactly this—N times, the algorithm chooses a number r from 1 to N and adds the rth training example to the bootstrap training set S. Clearly, some of the original training examples will not be selected for inclusion in the bootstrap training set and others will be chosen one time or more. In bagging, we create M such bootstrap training sets and then generate classifiers using each of them. Bagging returns a function $h(x)$ that classifies new examples by returning the class y that gets the maximum number of votes from the base models $h_1,h_2,\ldots,h_M$. In bagging, the M bootstrap training sets that are created are likely to have some differences. (Breiman, 1994) demonstrates that bagged ensembles tend to improve upon their base models more if the base model learning algorithms are *unstable*—differences in their training sets tend to induce significant differences in the models. He notes that decision trees are unstable, which explains why bagged decision trees often outperform individual decision trees; however, decision stumps (decision trees with only one variable test) are stable, which explains why bagging with decision stumps tends not to improve upon individual decision stumps.

Boosting

Boosting algorithms are a class of algorithms that have been mathematically proven to improve upon the performance of their base models in certain situations. We now explain the AdaBoost algorithm because it is the most frequently used among all boosting algorithms. AdaBoost generates a sequence of base models with different weight distributions over the training set. The AdaBoost algorithm is shown in Figure 3. Its inputs are a set of N training examples, a base model learning algorithm L_b, and the number M of base models that we wish to combine. AdaBoost was originally designed for two-class classification problems; therefore, for this explanation we will assume that there are two possible classes. However, AdaBoost is regularly used with a larger number of classes. The first step in AdaBoost is to construct an initial distribution of weights D_1 over the training set. This distribution assigns equal weight to all N training examples. We now enter the loop in the algorithm. To construct the first base model, we call L_b with distribution D_1 over the training set. After getting back a model h_1, we calculate its error ε_1 on the training set itself, which is just the sum of the weights of the training examples that h_1 misclassifies. We require that $\varepsilon_1 < 1/2$ (this is the *weak learning* assumption—the error should be less than what we would achieve through randomly guessing the class).[1] If this condition is not satisfied, then we stop and return the ensemble consisting of the previously-generated base models. If this condition is satisfied, then we calculate a new distribution D_2 over the training examples as

Figure 3. AdaBoost algorithm

AdaBoost($\{(x_1, y_1), (x_2, y_2),\ldots,(x_N, y_N)\}$,$L_b$,$M$)

Initialize $D_1(n) = 1/N$ for all $n \in \{1,2,\ldots,N\}$.

For each $m = 1,2,\ldots,M$:

$h_m = L_b(\{(x_1, y_1), (x_2, y_2),\ldots,(x_N, y_N)\},D_m)$

$\varepsilon_m = \sum_{n:h_m(x_n)\neq y_n} D_m(n)$.

If $\varepsilon_m \geq 1/2$ then,

set $M = m - 1$ and abort this loop.

Update distribution D_m:

$$D_{m+1}(n) = D_m(n) \times \begin{cases} \dfrac{1}{2(1-\varepsilon_m)} & \text{if } h_m(x_n) = y_n \\ \dfrac{1}{2\varepsilon_m} & \text{otherwise.} \end{cases}$$

Return $h_{fin}(x) = \text{argmax}_{y\in Y} \sum_{m=1}^{M} I(h_m(x) = y) \log \dfrac{1-\varepsilon_m}{\varepsilon_m}$.

follows. Examples that were correctly classified by h_1 have their weights multiplied by $1/(2(1-\varepsilon_1))$. Examples that were misclassified by h_1 have their weights multiplied by $1/(2\varepsilon_1)$. Note that, because of our condition $\varepsilon_1 < 1/2$, correctly classified examples have their weights reduced and misclassified examples have their weights increased. Specifically, examples that h_1 misclassified have their total weight increased to $1/2$ under D_2 and examples that h_1 correctly classified have their total weight reduced to $1/2$ under D_2. We then go into the next iteration of the loop to construct base model h_2 using the training set and the new distribution D_2. The point is that the next base model will be generated by a weak learner (i.e., the base model will have error less than $1/2$); therefore, at least some of the examples misclassified by the previous base model will have to be correctly classified by the current base model. In this way, boosting forces subsequent base models to correct the mistakes made by earlier models. We construct M base models in this fashion. The ensemble returned by AdaBoost is a function that takes a new example as input and returns the class that gets the maximum weighted vote over the M base models, where each base model's weight is $\log((1-\varepsilon_m)/\varepsilon_m)$, which is proportional to the base model's accuracy on the weighted training set presented to it.

AdaBoost has performed very well in practice and is one of the few theoretically-motivated algorithms that has turned into a practical algorithm. However, AdaBoost can perform poorly when the training data is noisy (Dietterich, 2000), i.e., the inputs or outputs have been randomly contaminated. Noisy examples are normally difficult to learn. Because of this, the weights assigned to noisy examples often become much higher than for the other examples, often causing boosting to focus too much on those noisy examples at the expense of the remaining data. Some work has been done to mitigate the effect of noisy examples on boosting (Oza 2004, Ratsch et. al., 2001).

FUTURE TRENDS

The fields of machine learning and data mining are increasingly moving away from working on small datasets in the form of flat files that are presumed to describe a single process. The fields are changing their focus toward the types of data increasingly being encountered today: very large datasets, possibly distributed among different locations, describing operations with multiple modes, time-series data, online applications (the data is not a time series but nevertheless arrives continually and must be processed as it arrives), partially-labeled data, and documents. Research in ensemble methods is beginning to explore these new types of data. For example, ensemble learning traditionally has required access to the entire dataset at once, i.e., it performs batch learning. However, this is clearly impractical for very large datasets that cannot be loaded into memory all at once. Some recent work (Oza and Russell, 2001; Oza, 2001) applies ensemble learning to such large datasets. In particular, this work develops online versions of bagging and boosting. That is, whereas standard bagging and boosting require at least one scan of the dataset for every base model created, online bagging and online boosting require only one scan of the dataset regardless of the number of base models. Additionally, as new data arrives, the ensembles can be updated without reviewing any past data. However, because of their limited access to the data, these online algorithms do not perform as well as their standard counterparts. Other work has also been done to apply ensemble methods to other types of problems such as remote sensing (Rajan and Ghosh, 2005), person recognition (Chawla and Bowyer, 2005), one vs. all recognition (Cabrera et. al., 2005), and medicine (Pranckeviciene et. al., 2005)—a recent survey of such applications is (Oza and Tumer, 2008). However, most of this work is experimental. Theoretical frameworks that can guide us in the development of new ensemble learning algorithms specifically for modern datasets have yet to be developed.

CONCLUSION

Ensemble Methods began about fifteen years ago as a separate research area within machine learning and were motivated by the idea of wanting to leverage the power of multiple models and not just trust one model built on a small training set. Significant theoretical and experimental developments have occurred over the past fifteen years and have led to several methods, especially bagging and boosting, being used to solve many real problems. However, ensemble methods also appear to be applicable to current and upcoming problems of distributed data mining, online applications, and others. Therefore, practitioners in data mining should stay tuned for further developments in the vibrant area

of ensemble methods. An excellent way to do this is to read a recent textbook on ensembles (Kuncheva, 2004) and follow the series of workshops called the International Workshop on Multiple Classifier Systems (proceedings published by Springer). This series' balance between theory, algorithms, and applications of ensemble methods gives a comprehensive idea of the work being done in the field.

KEY TERMS

Batch Learning: Learning using an algorithm that views the entire dataset at once and can access any part of the dataset at any time and as many times as desired.

Decision Tree: A model consisting of nodes that contain tests on a single attribute and branches representing the different outcomes of the test. A prediction is generated for a new example by performing the test described at the root node and then proceeding along the branch that corresponds to the outcome of the test. If the branch ends in a prediction, then that prediction is returned. If the branch ends in a node, then the test at that node is performed and the appropriate branch selected. This continues until a prediction is found and returned.

Ensemble: A function that returns a combination of the predictions of multiple machine learning models.

Machine Learning: The branch of Artificial Intelligence devoted to enabling computers to learn.

Neural Network: A nonlinear model derived through analogy with the human brain. It consists of a collection of elements that linearly combine their inputs and pass the result through a nonlinear transfer function.

Online Learning: Learning using an algorithm that only examines the dataset once in order. This paradigm is often used in situations when data arrives continually in a stream and predictions must be obtainable at any time.

Principal Components Analysis (PCA): Given a dataset, PCA determines the axes of maximum variance. For example, if the dataset was shaped like an egg, then the long axis of the egg would be the first principal component because the variance is greatest in this direction. All subsequent principal components are found to be orthogonal to all previous components.

ENDNOTE

[1] This requirement is perhaps too strict when there are more than two classes. There is a multi-class version of AdaBoost (Freund and Schapire, 1997) that does not have this requirement. However, the AdaBoost algorithm presented here is often used even when there are more than two classes if the base model learning algorithm is strong enough to satisfy the requirement.

Ensemble Learning for Regression

Niall Rooney

David Patterson
University of Ulster, UK

Chris Nugent
University of Ulster, UK

INTRODUCTION

The concept of ensemble learning has its origins in research from the late 1980s/early 1990s into combining a number of artificial neural networks (ANNs) models for regression tasks. Ensemble learning is now a widely deployed and researched topic within the area of machine learning and data mining. Ensemble learning, as a general definition, refers to the concept of being able to apply more than one learning model to a particular machine learning problem using some method of integration. The desired goal of course is that the ensemble as a unit will outperform any of its individual members for the given learning task. Ensemble learning has been extended to cover other learning tasks such as classification (refer to Kuncheva, 2004 for a detailed overview of this area), online learning (Fern & Givan, 2003) and clustering (Strehl & Ghosh, 2003). The focus of this article is to review ensemble learning with respect to regression, where by regression, we refer to the supervised learning task of creating a model that relates a continuous output variable to a vector of input variables.

BACKGROUND

Ensemble learning consists of two issues that need to be addressed, *ensemble generation*: how does one generate the base models/members of the ensemble and how large should the ensemble size be and *ensemble integration:* how does one integrate the base models' predictions to improve performance? Some ensemble schemes address these issues separately, others such as Bagging (Breiman, 1996a) and Boosting (Freund & Schapire, 1996) do not. The problem of ensemble generation where each base learning model uses the same learning algorithm (*homogeneous learning*) is generally addressed by a number of different techniques: using different samples of the training data or feature subsets for each base model or alternatively, if the learning method has a set of learning parameters, these may be adjusted to have different values for each of the base models. An alternative generation approach is to build the models from a set of different learning algorithms (*heterogeneous learning*). There has been less research in this latter area due to the increased complexity of effectively combining models derived from different algorithms. Ensemble integration can be addressed by either one of two mechanisms: either the predictions of the base models are combined in some fashion during the application phase to give an ensemble prediction (*combination approach*) or the prediction of one base model is selected according to some criteria to form the final prediction (*selection approach*). Both selection and combination can be either *static* in approach, where the learned model does not alter, or *dynamic* in approach, where the prediction strategy is adjusted for each test instance.

Theoretical and empirical work has shown that if an ensemble technique is to be effective, it is important that the base learning models are sufficiently *accurate* and *diverse* in their predictions (Hansen & Salomon, 1990; Sharkey, 1999; Dietterich, 2000). For regression problems, accuracy is usually measured based on the training error of the ensemble members and diversity is measured based on the concept of ambiguity or variance of the ensemble members' predictions (Krogh & Vedelsby, 1995). A well known technique to analyze the nature of supervised learning methods is based on the bias-variance decomposition of the expected error for a given target instance (Geman et al., 1992). In effect, the expected error can be represented by three terms, the

irreducible or random error, the bias (or squared bias) and the variance. The irreducible error is independent of the learning algorithm and places an upper bound on the performance of any regression technique. The bias term is a measure of how closely the learning algorithm's mean prediction over all training sets of fixed size, is near to the target. The variance is a measure of how the learning algorithms predictions for a given target, vary around the mean prediction. The purpose of an ensemble is to try to reduce bias and/or variance in the error. For a linear combination of 1,..,*N* base models where each i^{th} base model's contribution to the ensemble prediction is weighted by a coefficient α_i and $\sum_{i=1..N} \alpha_i = 1$, Krogh & Vedelsby (1995) showed that the generalization error of the ensemble trained on a single data set can also be decomposed into two terms. The first term consists of the weighted error of the individual ensemble members (their *weighted error or average accuracy*) and the second term represents the variability of the ensemble members predictions referred to as the *ambiguity* (or diversity) of the ensemble. They demonstrated that as the ambiguity increases and the first term remains the same, the error of the ensemble decreases. Brown et al. (2005) extended this analysis by looking at the bias-variance decomposition of a similarly composed ensemble and determined that the expected generalization error of the ensemble (if each model was equally weighted) can be decomposed into the expected average individual error and expected ambiguity and showed that these terms are not completely independent. They showed that increasing ambiguity will lead to a reduction in the error variance of the ensemble, but it can also lead to an increase in the level of averaged error in the ensemble members. So, in effect, there is a trade off between the ambiguity/diversity of an ensemble and the accuracy of its members.

MAIN FOCUS

In this section we consider in detail ensemble generation and integration methods.

Ensemble Generation

Ensembles can be generated to increase the level of diversity in homogeneous base models using the following methods:

Vary the learning parameters: If the learning algorithm has learning parameters, set each base model to have different parameter values e.g. in the area of neural networks one can set each base model to have different initial random weights or a different topology (Sharkey, 1999) or in the case of regression trees, each model can be built using a different splitting criteria or pruning strategy. In the technique of random forests (Breiman, 2001), regression trees are grown using a random selection of features for each splitting choice or in addition, randomizing the splitting criteria itself (Geurts et al., 2006).

Vary the data employed: Each base model is built using samples of the data. Resampling methods include cross-validation, boot-strapping, sampling with replacement (employed in Bagging (Breiman, 1996a), and adaptive sampling (employed in Boosting methods). If there are sufficient data, sampling can be replaced by using disjoint training sets for each base model.

Vary the features employed: In this approach, each model is built by a training algorithm, with a variable sub-set of the features in the data. This method was given prominence in the area of classification by Ho (Ho 1998a; Ho 1998b) and consists of building each model using training data consisting of input features in a *r*-dimensional random subspace subset from the original *p*-dimensional feature space. Tsymbal et al. (2003) proposed a variant of this approach to allow variable length feature sub-sets.

Randomised Outputs: In this approach, rather than present different regressors with different samples of input data, each regressor is presented with the same training data, but with output values for each instance perturbed by a randomization process (Breiman, 2000).

Ensemble Integration

The integration of ensembles works by either combining the base models outputs in some fashion or using selection methods to choose the "best" base model. Specific combination/selection methods which learns a meta-model as an integration technique, are described as meta-methods.

Much of the early research involving ensemble learning for regression focused on the combination of ANNs (Sharkey, 1999). However many of these methods can be applied directly to any ensemble of regression models, regardless of the base algorithm

employed. Typically each member of the ensemble was built using the same learning method. Researchers then investigated the effects of having members with different topologies, different initial weights or different training or samples of training data. The outputs from the base models were then combined using a linear function $\sum_{i=1..N} \alpha_i \hat{f}_i(x)$ where N is the size of the ensemble, and α_i is the weighting for model $\hat{f}_i(x)$.

The most simple ensemble method for regression is referred to as the Basic Ensemble Method (BEM) (Perrone & Cooper, 1993). BEM sets the weights α_i:

$$\alpha_i = \frac{1}{N}$$

in other words, the base members are combined using an unweighted averaging mechanism. This method does not take into account the performance of the base models, but as will be seen later with the similar method of Bagging, it can be effective. There exists numerical methods to give more "optimal" weights (values of α) to each base model. The generalised ensemble method (GEM) (Perrone & Cooper, 1993) calculates α based on a symmetric covariance matrix C of the individual models' errors. Another approach to calculate the optimal weights is to use a linear regression (LR) algorithm. However both GEM and LR techniques may suffer from a numerical problem known as the multi-collinear problem. This problem occurs where one or more models can be expressed as a linear combination of one or more of the other models. This can lead to a numerical problem as both techniques require taking the inverse of matrices, causing large rounding errors and as a consequence producing weights that are far from optimal. One approach to ameliorate multi-collinear problems is to used weight regularization, an example of this has been previously mentioned when the weights are constrained to sum to one. Principal components regression (PCR) was developed by Merz & Pazzani (1999) to overcome the multi-collinear problem.

The main idea in PCR is to transform the original learned models to a new set of models using Principal Components Analysis (PCA). The new models are a decomposition of the original models' predictions into N independent components. The most useful initial components are retained and the mapping is reversed to calculate the weights for the original learned models.

Another technique is Mixture of Experts where the weighting coefficients are considered *dynamic*. Such dynamic coefficients are not constants but are functions of the test instance x that is, $\sum_{i=1..N} \alpha_i(x) \hat{f}_i(x)$. This approach requires a simultaneous training step both for the dynamic coefficients and the base members themselves, and as such is a method exclusive to ANN research (Hansen, 1999). Negative-correlation learning is also an intriguing ANN ensemble approach to ensemble combination where the ensemble members are not trained independently of each other, but rather all the individual ensemble networks are trained simultaneously and interact using a combined correlation penalty term in their error functions. As such negative correlation learning tries to create networks which are negatively correlated in their errors (Liu & Yao, 1999; Brown & Wyatt, 2003), i.e. the errors between networks are inversely related. Granitto et al. (2005) use a simulated annealing approach to find the optimal number of training epochs for each ensemble member as determined by calculating the generalization error for a validation set.

Bagging (Bootstrap aggregation) (Breiman 1996a) averages the outputs of each based model where each base model is learned using different training sets generated by sampling with replacement. Breiman showed that this technique is a variance reducing one and is suited for unstable learners that typically have high variance in their error such as regression trees.

Leveraging techniques are based on the principle that the sequential combination of weak regressors based on a simple learning algorithm can be made to produce a strong ensemble of which boosting is a prime example (Duffy & Helmbold, 2002) The main purpose of boosting is to sequentially apply a regression algorithm to repeatedly modified versions of the data, thereby producing a sequence of regressors. The modified versions of the data are based on a sampling process related to the training error of individual instances in the training set. The most well known version of boosting is AdaBoost (adaptive boosting for regression) which combines regressors using the weighted median. Hastie et al. (2001) showed that AdaBoost is equivalent to a forward stage additive model. In a forward stage additive model an unspecified basis function is estimated for each predictor variable and added iteratively to the model. In the case of boosting, the basis functions are the individual ensemble models.

If combination methods rely on the ensemble members being diverse and accurate, global selection methods, where one member of the ensemble is cho-

sen to make all ensemble predictions, clearly do not. The classic simple, static selection method is *Cross Validation* (Schaffer, 1993), which chooses the base model with least estimated error via a cross-validation process. The use of cross-validation ensures that the estimates of error are less biased as they are calculated from different test data to the data on which models are built. The obvious drawback to this approach is that *N* models are built whereas only one is in effect used. To overcome this limitation, researchers (Merz, 1995, Rooney et al., 2004), have focused on localized selection of the base learners, where a base learner is chosen for a query instance based on its performance in the localized region of instance space. This is generally referred to as *a dynamic* ensemble combination technique.

The concept of meta-learning for ensembles is based on the concept of using a learning model (referred to as a meta-model) to combine or select from the base models. Note that this definition of meta-learning only refers to techniques described in this chapter. The most widely studied technique is known as Stacking. The concept of Stacking, (or in terms of regression, Stacked Regression(s)), was originally proposed by Wolpert (1992) and considered by LeBlanc and Tibshirani (1993) to be a bias reducing technique. However, its full range of theoretical properties is still not well understood.

The effectiveness of Stacking is based on its use of cross-validation during the training phase. As it builds the base regression models and estimates the weights using different samples of the training data, so as to reduce bias in the ensemble predictions. Combination is carried out using a learning algorithm or meta-model, rather than a simple linear combination. Originally a meta-model was proposed using a least squares linear regression function to determine the weights, Breiman (1996b) showed that for this to be effective for regression problems, the weights had to be constrained to be non-zero. Of course the meta-model may be any learning algorithm (Hastie et al., 2001). If the meta-model for example is a regression tree, the meta-model is no longer trying to find optimal weights at a global level, but at a piecewise localized level. Rooney & Patterson (2007) combined Stacking with the related technique of Dynamic Integration (Tsymbal et al., 2003), to create a more effective ensemble meta-learner for regression.

FUTURE TRENDS

Notwithstanding the development of new techniques and advances in the theory of ensembles, we identify the following future trends of research

- *Selective combination of ensemble members:* As noted, an effective ensemble requires that each member should be both diverse and accurate. One approach to enabling this is to use hill climbing techniques to selectively adjust the members of the ensemble to combine by calculating metrics based on accuracy or diversity (Opitz & Shavlik, 1996, Carney & Cunningham, 2000) or more simply to selectively reduce the set of ensemble members (Zhou et al., 2002) Potentially this can create a more competent ensemble but also a less complex one. We expect further work in this area particularly in trying to produce small ensembles of transparent and interpretable models such as regression trees.
- *Computationally Efficient methods:* If ensemble techniques are going to be applied to large-scale data mining methods, they need to be computationally efficient. A potential direction of research is the parallelization of ensemble methods – intrinsically such methods as Bagging are easily parallelizable.
- *Heterogeneous ensemble learning:* As discussed most ensemble method use the same learning algorithm to generate base models – there is scope for techniques that effectively combine more than one base learning algorithm.

CONCLUSION

Ensemble learning is an important method of deploying more than one learning model to give improved predictive accuracy for a given learning problem. We have described how regression based ensembles are able to reduce the bias and/or variance of the generalization error and reviewed the main techniques that have been developed for the generation and integration of regression based ensembles.

KEY TERMS

Ensemble: A collection of models.

Ensemble Generation: A method by which an ensemble is generated so that each base model is different. Examples include sampling of data, randomization, different base learning algorithms or different learning algorithm parameterizations.

Ensemble Integration: A technique by which the predictions of base models are combined. Examples include unweighted/weighted averaging.

Ensemble Learning: A learning process involving an ensemble of base models.

Generalization Performance: A measure how well a supervised learning model performs on unseen instances (usually based on an error measure).

Regression/Continuous Prediction: The area of machine learning devoted to developing a predictive model that approximates the hidden function associating a continuous dependent or target or output variable with a set of independent or input variables. There are numerous algorithms with different learning hypothesis spaces for the process of regression.

Regressor: Regression model.

Supervised Learning: The process by which a learning model is produced using training data consisting of instances, each with a vector of inputs and known output values.

Ethics of Data Mining

Jack Cook
Rochester Institute of Technology, USA

INTRODUCTION

Decision makers thirst for answers to questions. As more data is gathered, more questions are posed: Which customers are most likely to respond positively to a marketing campaign, product price change or new product offering? How will the competition react? Which loan applicants are most likely or least likely to default? The ability to raise questions, even those that currently cannot be answered, is a characteristic of a good decision maker. Decision makers no longer have the luxury of making decisions based on gut feeling or intuition. Decisions must be supported by data; otherwise decision makers can expect to be questioned by stockholders, reporters, or attorneys in a court of law. Data mining can support and often direct decision makers in ways that are often counterintuitive. Although data mining can provide considerable insight, there is an "inherent risk that what might be inferred may be private or ethically sensitive" (Fule & Roddick, 2004, p. 159).

Extensively used in telecommunications, financial services, insurance, customer relationship management (CRM), retail, and utilities, data mining more recently has been used by educators, government officials, intelligence agencies, and law enforcement. It helps alleviate data overload by extracting value from volume. However, data analysis is not data mining. Query-driven data analysis, perhaps guided by an idea or hypothesis, that tries to deduce a pattern, verify a hypothesis, or generalize information in order to predict future behavior is not data mining (Edelstein, 2003). It may be a first step, but it is not data mining. Data mining is the process of discovering and interpreting meaningful, previously hidden patterns in the data. It is not a set of descriptive statistics. Description is not prediction. Furthermore, the focus of data mining is on the process, not a particular technique, used to make reasonably accurate predictions. It is iterative in nature and generically can be decomposed into the following steps: (1) data acquisition through translating, cleansing, and transforming data from numerous sources, (2) goal setting or hypotheses construction, (3) data mining, and (4) validating or interpreting results.

The process of generating rules through a mining operation becomes an ethical issue, when the results are used in decision-making processes that affect people or when mining customer data unwittingly compromises the privacy of those customers (Fule & Roddick, 2004). Data miners and decision makers must contemplate ethical issues before encountering one. Otherwise, they risk not identifying when a dilemma exists or making poor choices, since all aspects of the problem have not been identified.

BACKGROUND

Technology has moral properties, just as it has political properties (Brey 2000; Feenberg, 1999; Sclove, 1995; Winner, 1980). Winner (1980) argues that technological artifacts and systems function like laws, serving as frameworks for public order by constraining individuals' behaviors. Sclove (1995) argues that technologies possess the same kinds of structural effects as other elements of society, such as laws, dominant political and economic institutions, and systems of cultural beliefs. Data mining, being a technological artifact, is worthy of study from an ethical perspective due to its increasing importance in decision making, both in the private and public sectors. Computer systems often function less as background technologies and more as active constituents in shaping society (Brey, 2000). Data mining is no exception. Higher integration of data mining capabilities within applications ensures that this particular technological artifact will increasingly shape public and private policies.

Data miners and decision makers obviously are obligated to adhere to the law. But ethics are oftentimes more restrictive than what is called for by law. Ethics are standards of conduct that are agreed upon by cultures and organizations. Supreme Court Justice Potter Stewart defines the difference between ethics and laws as knowing the difference between what you

have a right to do (legally, that is) and what is right to do. Sadly, a number of IS professionals either lack an awareness of what their company actually does with data and data mining results or purposely come to the conclusion that it is not their concern. They are enablers in the sense that they solve management's problems. What management does with that data or results is not their concern.

Most laws do not explicitly address data mining, although court cases are being brought to stop certain data mining practices. A federal court ruled that using data mining tools to search Internet sites for competitive information may be a crime under certain circumstances (Scott, 2002). In *EF Cultural Travel BV vs. Explorica Inc.* (No. 01-2000 1st Cir. Dec. 17, 2001), the First Circuit Court of Appeals in Massachusetts held that Explorica, a tour operator for students, improperly obtained confidential information about how rival EF's Web site worked and used that information to write software that gleaned data about student tour prices from EF's Web site in order to undercut EF's prices (Scott, 2002). In this case, Explorica probably violated the federal Computer Fraud and Abuse Act (18 U.S.C. Sec. 1030). Hence, the source of the data is important when data mining.

Typically, with applied ethics, a morally controversial practice, such as how data mining impacts privacy, "is described and analyzed in descriptive terms, and finally moral principles and judgments are applied to it and moral deliberation takes place, resulting in a moral evaluation, and operationally, a set of policy recommendations" (Brey, 2000, p. 10). Applied ethics is adopted by most of the literature on computer ethics (Brey, 2000). Data mining may appear to be morally neutral, but appearances in this case are deceiving. This paper takes an applied perspective to the ethical dilemmas that arise from the application of data mining in specific circumstances as opposed to examining the technological artifacts (i.e., the specific software and how it generates inferences and predictions) used by data miners.

MAIN THRUST

Computer technology has redefined the boundary between public and private information, making much more information public. Privacy is the freedom granted to individuals to control their exposure to others. A customary distinction is between relational and informational privacy. Relational privacy is the control over one's person and one's personal environment, and concerns the freedom to be left alone without observation or interference by others. Informational privacy is one's control over personal information in the form of text, pictures, recordings, and so forth (Brey, 2000).

Technology cannot be separated from its uses. It is the ethical obligation of any information systems (IS) professional, through whatever means he or she finds out that the data that he or she has been asked to gather or mine is going to be used in an unethical way, to act in a socially and ethically responsible manner. This might mean nothing more than pointing out why such a use is unethical. In other cases, more extreme measures may be warranted. As data mining becomes more commonplace and as companies push for even greater profits and market share, ethical dilemmas will be increasingly encountered. Ten common blunders that a data miner may cause, resulting in potential ethical or possibly legal dilemmas, are (Skalak, 2001):

1. Selecting the wrong problem for data mining.
2. Ignoring what the sponsor thinks data mining is and what it can and cannot do.
3. Leaving insufficient time for data preparation.
4. Looking only at aggregated results, never at individual records.
5. Being nonchalant about keeping track of the mining procedure and results.
6. Ignoring suspicious findings in a haste to move on.
7. Running mining algorithms repeatedly without thinking hard enough about the next stages of the data analysis.
8. Believing everything you are told about the data.
9. Believing everything you are told about your own data mining analyses.
10. Measuring results differently from the way the sponsor will measure them.

These blunders are hidden ethical dilemmas faced by those who perform data mining. In the next subsections, sample ethical dilemmas raised with respect to the application of data mining results in the public sector are examined, followed briefly by those in the private sector.

Ethics of Data Mining in the Public Sector

Many times, the objective of data mining is to build a customer profile based on two types of data—factual (who the customer is) and transactional (what the customer does) (Adomavicius & Tuzhilin, 2001). Often, consumers object to transactional analysis. What follows are two examples; the first (identifying successful students) creates a profile based primarily on factual data, and the second (identifying criminals and terrorists) primarily on transactional.

Identifying Successful Students

Probably the most common and well-developed use of data mining is the attraction and retention of customers. At first, this sounds like an ethically neutral application. Why not apply the concept of students as customers to the academe? When students enter college, the transition from high school for many students is overwhelming, negatively impacting their academic performance. High school is a highly structured Monday-through-Friday schedule. College requires students to study at irregular hours that constantly change from week to week, depending on the workload at that particular point in the course. Course materials are covered at a faster pace; the duration of a single class period is longer; and subjects are often more difficult. Tackling the changes in a student's academic environment and living arrangement as well as developing new interpersonal relationships is daunting for students. Identifying students prone to difficulties and intervening early with support services could significantly improve student success and, ultimately, improve retention and graduation rates.

Consider the following scenario that realistically could arise at many institutions of higher education. Admissions at the institute has been charged with seeking applicants who are more likely to be successful (i.e., graduate from the institute within a five-year period). Someone suggests data mining existing student records to determine the profile of the most likely successful student applicant. With little more than this loose definition of success, a great deal of disparate data is gathered and eventually mined. The results indicate that the most likely successful applicant, based on factual data, is an Asian female whose family's household income is between $75,000 and $125,000 and who graduates in the top 25% of her high school class. Based on this result, admissions chooses to target market such high school students. Is there an ethical dilemma? What about diversity? What percentage of limited marketing funds should be allocated to this customer segment? This scenario highlights the importance of having well-defined goals before beginning the data mining process. The results would have been different if the goal were to find the most diverse student population that achieved a certain graduation rate after five years. In this case, the process was flawed fundamentally and ethically from the beginning.

Identifying Criminals and Terrorists

The key to the prevention, investigation, and prosecution of criminals and terrorists is information, often based on transactional data. Hence, government agencies increasingly desire to collect, analyze, and share information about citizens and aliens. However, according to Rep. Curt Weldon (R-PA), chairman of the House Subcommittee on Military Research and Development, there are 33 classified agency systems in the federal government, but none of them link their raw data together (Verton, 2002). As Steve Cooper, CIO of the Office of Homeland Security, said, "I haven't seen a federal agency yet whose charter includes collaboration with other federal agencies" (Verton, 2002, p. 5). Weldon lambasted the federal government for failing to act on critical data mining and integration proposals that had been authored before the terrorists' attacks on September 11, 2001 (Verton, 2002).

Data to be mined is obtained from a number of sources. Some of these are relatively new and unstructured in nature, such as help desk tickets, customer service complaints, and complex Web searches. In other circumstances, data miners must draw from a large number of sources. For example, the following databases represent some of those used by the U.S. Immigration and Naturalization Service (INS) to capture information on aliens (Verton, 2002).

- Employment Authorization Document System
- Marriage Fraud Amendment System
- Deportable Alien Control System
- Reengineered Naturalization Application Casework System
- Refugees, Asylum, and Parole System
- Integrated Card Production System
- Global Enrollment System

- Arrival Departure Information System
- Enforcement Case Tracking System
- Student and Schools System
- General Counsel Electronic Management System
- Student Exchange Visitor Information System
- Asylum Prescreening System
- Computer-Linked Application Information Management System (two versions)
- Non-Immigrant Information System

There are islands of excellence within the public sector. One such example is the U.S. Army's Land Information Warfare Activity (LIWA), which is credited with "having one of the most effective operations for mining publicly available information in the intelligence community" (Verton, 2002, p. 5).

Businesses have long used data mining. However, recently, governmental agencies have shown growing interest in using "data mining in national security initiatives" (Carlson, 2003, p. 28). Two government data mining projects, the latter renamed by the euphemism "factual data analysis," have been under scrutiny (Carlson, 2003) These projects are the U.S. Transportation Security Administration's (TSA) Computer Assisted Passenger Prescreening System II (CAPPS II) and the Defense Advanced Research Projects Agency's (DARPA) Total Information Awareness (TIA) research project (Gross, 2003). TSA's CAPPS II will analyze the name, address, phone number, and birth date of airline passengers in an effort to detect terrorists (Gross, 2003). James Loy, director of the TSA, stated to Congress that, with CAPPS II, the percentage of airplane travelers going through extra screening is expected to drop significantly from 15% that undergo it today (Carlson, 2003). Decreasing the number of false positive identifications will shorten lines at airports.

TIA, on the other hand, is a set of tools to assist agencies such as the FBI with data mining. It is designed to detect extremely rare patterns. The program will include terrorism scenarios based on previous attacks, intelligence analysis, "war games in which clever people imagine ways to attack the United States and its deployed forces," testified Anthony Tether, director of DARPA, to Congress (Carlson, 2003, p. 22). When asked how DARPA will ensure that personal information caught in TIA's net is correct, Tether stated that "we're not the people who collect the data. We're the people who supply the analytical tools to the people who collect the data" (Gross, 2003, p. 18). "Critics of data mining say that while the technology is guaranteed to invade personal privacy, it is not certain to enhance national security. Terrorists do not operate under discernable patterns, critics say, and therefore the technology will likely be targeted primarily at innocent people" (Carlson, 2003, p. 22). Congress voted to block funding of TIA. But privacy advocates are concerned that the TIA architecture, dubbed "mass dataveillance," may be used as a model for other programs (Carlson, 2003).

Systems such as TIA and CAPPS II raise a number of ethical concerns, as evidenced by the overwhelming opposition to these systems. One system, the Multistate Anti-TeRrorism Information EXchange (MATRIX), represents how data mining has a bad reputation in the public sector. MATRIX is self-defined as "a pilot effort to increase and enhance the exchange of sensitive terrorism and other criminal activity information between local, state, and federal law enforcement agencies" (matrix-at.org, accessed June 27, 2004). Interestingly, MATRIX states explicitly on its Web site that it is not a data-mining application, although the American Civil Liberties Union (ACLU) openly disagrees. At the very least, the perceived opportunity for creating ethical dilemmas and ultimately abuse is something the public is very concerned about, so much so that the project felt that the disclaimer was needed. Due to the extensive writings on data mining in the private sector, the next subsection is brief.

Ethics of Data Mining in the Private Sector

Businesses discriminate constantly. Customers are classified, receiving different services or different cost structures. As long as discrimination is not based on protected characteristics such as age, race, or gender, discriminating is legal. Technological advances make it possible to track in great detail what a person does. Michael Turner, executive director of the Information Services Executive Council, states, "For instance, detailed consumer information lets apparel retailers market their products to consumers with more precision. But if privacy rules impose restrictions and barriers to data collection, those limitations could increase the prices consumers pay when they buy from catalog or online apparel retailers by 3.5% to 11%" (Thibodeau, 2001, p. 36). Obviously, if retailers cannot target their advertising, then their only option is to mass advertise, which drives up costs.

With this profile of personal details comes a substantial ethical obligation to safeguard this data. Ignoring any legal ramifications, the ethical responsibility is placed firmly on IS professionals and businesses, whether they like it or not; otherwise, they risk lawsuits and harming individuals. "The data industry has come under harsh review. There is a raft of federal and local laws under consideration to control the collection, sale, and use of data. American companies have yet to match the tougher privacy regulations already in place in Europe, while personal and class-action litigation against businesses over data privacy issues is increasing" (Wilder & Soat, 2001, p. 38).

FUTURE TRENDS

Data mining traditionally was performed by a trained specialist, using a stand-alone package. This once nascent technique is now being integrated into an increasing number of broader business applications and legacy systems used by those with little formal training, if any, in statistics and other related disciplines. Only recently has privacy and data mining been addressed together, as evidenced by the fact that the first workshop on the subject was held in 2002 (Clifton & Estivill-Castro, 2002). The challenge of ensuring that data mining is used in an ethically and socially responsible manner will increase dramatically.

CONCLUSION

Several lessons should be learned. First, decision makers must understand key strategic issues. The data miner must have an honest and frank dialog with the sponsor concerning objectives. Second, decision makers must not come to rely on data mining to make decisions for them. The best data mining is susceptible to human interpretation. Third, decision makers must be careful not to explain away with intuition data mining results that are counterintuitive. Decision making inherently creates ethical dilemmas, and data mining is but a tool to assist management in key decisions.

KEY TERMS

Applied Ethics: The study of a morally controversial practice, whereby the practice is described and analyzed, and moral principles and judgments are applied, resulting in a set of recommendations.

Ethics: The study of the general nature of morals and values as well as specific moral choices; it also may refer to the rules or standards of conduct that are agreed upon by cultures and organizations that govern personal or professional conduct.

Factual Data: Data that include demographic information such as name, gender, and birth date. It also may contain information derived from transactional data such as someone's favorite beverage.

Factual Data Analysis: Another term for data mining, often used by government agencies. It uses both factual and transactional data.

Informational Privacy: The control over one's personal information in the form of text, pictures, recordings, and such.

Mass Dataveillance: Suspicion-less surveillance of large groups of people.

Relational Privacy: The control over one's person and one's personal environment.

Transactional Data: Data that contains records of purchases over a given period of time, including such information as date, product purchased, and any special requests.

This work was previously published in Encyclopedia of Data Warehousing and Mining, edited by J. Wang, pp. 454-458, copyright 2005 by IGI Publishing, formerly known as Idea Group Publishing (an imprint of IGI Global).

Evaluation of Data Mining Methods

Paolo Giudici
University of Pavia, Italy

INTRODUCTION

Several classes of computational and statistical methods for data mining are available. Each class can be parameterised so that models within the class differ in terms of such parameters (See for instance Giudici, 2003, Hastie et al., 2001, Han and Kamber, 200, Hand et al, 2001 and Witten and Frank, 1999). For example the class of linear regression models, which differ in the number of explanatory variables; the class of bayesian networks, which differ in the number of conditional dependencies (links in the graph); the class of tree models, which differ in the number of leaves and the class multi-layer perceptrons which differ in terms of the number of hidden strata and nodes. Once a class of models has been established the problem is to choose the "best" model from it.

BACKGROUND

A rigorous method to compare models is statistical hypothesis testing. With this in mind one can adopt a sequential procedure that allows a model to be chosen through a sequence of pairwise test comparisons. However, we point out that these procedures are generally not applicable, in particular to computational data mining models, which do not necessarily have an underlying probabilistic model and, therefore, do not allow the application of statistical hypotheses testing theory. Furthermore, it often happens that for a data problem it is possible to use more than one type of model class, with different underlying probabilistic assumptions. For example, for a problem of predictive classification it is possible to use both logistic regression and tree models as well as neural networks.

We also point out that model specification and, therefore, model choice is determined by the type of variables used. These variables can be the result of transformations or of the elimination of observations, following an exploratory analysis. We then need to compare models based on different sets of variables present at the start. For example, how do we compare a linear model with the original explanatory variables with one with a set of transformed explanatory variables?

The previous considerations suggest the need for a systematic study of the methods for comparison and evaluation of data mining models.

MAIN THRUST OF THE CHAPTER

Comparison criteria for data mining models can be classified schematically into: criteria based on statistical tests, based on scoring functions, computational criteria, bayesian criteria and business criteria.

Criteria Based on Statistical Tests

The first are based on the theory of statistical hypothesis testing and, therefore, there is a lot of detailed literature related to this topic. See for example a text about statistical inference, such as Mood, Graybill and Boes (1991) and Bickel and Doksum (1977). A statistical model can be specified by a discrete probability function or by a probability density function, f(x). Such model is usually left unspecified, up to unknown quantities that have to be estimated on the basis of the data at hand. Typically, the observed sample it is not sufficient to reconstruct each detail of f(x), but can indeed be used to approximate f(x) with a certain accuracy. Often a density function is parametric so that it is defined by a vector of parameters $\Theta=(\theta_1,\ldots,\theta_I)$, such that each value θ of Θ corresponds to a particular density function, $p_\theta(x)$. In order to measure the accuracy of a parametric model, one can resort to the notion of distance between a model f, which underlies the data, and an approximating model g (see, for instance, Zucchini,

2000). Notable examples of distance functions are, for categorical variables: the entropic distance, which describes the proportional reduction of the heterogeneity of the dependent variable; the chi-squared distance, based on the distance from the case of independence; the 0-1 distance, which leads to misclassification rates. For quantitative variables, the typical choice is the Euclidean distance, representing the distance between two vectors in a Cartesian space. Another possible choice is the uniform distance, applied when nonparametric models are being used.

Any of the previous distances can be employed to define the notion of discrepancy of an statistical model. The discrepancy of a model, g, can be obtained comparing the unknown probabilistic model, f, and the best parametric statistical model. Since f is unknown, closeness can be measured with respect to a sample estimate of the unknown density f. A common choice of discrepancy function is the Kullback-Leibler divergence, that can be applied to any type of observations. In such context, the best model can be interpreted as that with a minimal loss of information from the true unknown distribution.

It can be shown that the statistical tests used for model comparison are generally based on estimators of the total Kullback-Leibler discrepancy; the most used is the log-likelihood score. Statistical hypothesis testing is based on subsequent pairwise comparisons of log-likelihood scores of alternative models. Hypothesis testing allows to derive a threshold below which the difference between two models is not significant and, therefore, the simpler models can be chosen.

Therefore, with statistical tests it is possible make an accurate choice among the models. The defect of this procedure is that it allows only a partial ordering of models, requiring a comparison between model pairs and, therefore, with a large number of alternatives it is necessary to make heuristic choices regarding the comparison strategy (such as choosing among the forward, backward and stepwise criteria, whose results may diverge). Furthermore, a probabilistic model must be assumed to hold, and this may not always be possible.

Criteria Based on Scoring Functions

A less structured approach has been developed in the field of information theory, giving rise to criteria based on score functions. These criteria give each model a score, which puts them into some kind of complete order. We have seen how the Kullback-Leibler discrepancy can be used to derive statistical tests to compare models. In many cases, however, a formal test cannot be derived. For this reason, it is important to develop scoring functions, that attach a score to each model. The Kullback-Leibler discrepancy estimator is an example of such a scoring function that, for complex models, can be often be approximated asymptotically. A problem with the Kullback-Leibler score is that it depends on the complexity of a model as described, for instance, by the number of parameters. It is thus necessary to employ score functions that penalise model complexity.

The most important of such functions is the AIC (Akaike Information Criterion, Akaike, 1974). From its definition notice that the AIC score essentially penalises the loglikelihood score with a term that increases linearly with model complexity. The AIC criterion is based on the implicit assumption that q remains constant when the size of the sample increases. However this assumption is not always valid and therefore the AIC criterion does not lead to a consistent estimate of the dimension of the unknown model. An alternative, and consistent, scoring function is the BIC criterion (Bayesian Information Criterion), also called SBC, formulated by Schwarz (1978). As can be seen from its definition the BIC differs from the AIC only in the second part which now also depends on the sample size n. Compared to the AIC, when n increases the BIC favours simpler models. As n gets large, the first term (linear in n) will dominate the second term (logarithmic in n). This corresponds to the fact that, for a large n, the variance term in the mean squared error expression tends to be negligible. We also point out that, despite the superficial similarity between the AIC and the BIC, the first is usually justified by resorting to classical asymptotic arguments, while the second by appealing to the Bayesian framework.

To conclude, the scoring function criteria for selecting models are easy to calculate and lead to a total ordering of the models. From most statistical packages we can get the AIC and BIC scores for all the models considered. A further advantage of these criteria is that they can be used also to compare non-nested models and, more generally, models that do not belong to the same class (for instance a probabilistic neural network and a linear regression model).

However, the limit of these criteria is the lack of a threshold, as well the difficult interpretability of their measurement scale. In other words, it is not easy to determine if the difference between two models is significant or not, and how it compares to another difference. These criteria are indeed useful in a preliminary exploratory phase. To examine this criteria and to compare it with the previous ones see, for instance, Zucchini (2000), or Hand, Mannila and Smyth (2001).

Bayesian Criteria

A possible "compromise" between the previous two criteria is the Bayesian criteria which could be developed in a rather coherent way (see e.g. Bernardo and Smith, 1994). It appears to combine the advantages of the two previous approaches: a coherent decision threshold and a complete ordering. One of the problems that may arise is connected to the absence of a general purpose software. For data mining works using Bayesian criteria the reader could see, for instance, Giudici (2001), Giudici and Castelo (2003) and Brooks et al. (2003).

Computational Criteria

The intensive wide spread use of computational methods has led to the development of computationally intensive model comparison criteria. These criteria are usually based on using dataset different than the one being analysed (external validation) and are applicable to all the models considered, even when they belong to different classes (for example in the comparison between logistic regression, decision trees and neural networks, even when the latter two are non probabilistic). A possible problem with these criteria is that they take a long time to be designed and implemented, although general purpose softwares have made this task easier.

The most common of such criterion is based on cross-validation. The idea of the cross-validation method is to divide the sample into two sub-samples, a "training" sample, with n - m observations, and a "validation" sample, with m observations. The first sample is used to fit a model and the second is used to estimate the expected discrepancy or to assess a distance. Using this criterion the choice between two or more models is made by evaluating an appropriate discrepancy function on the validation sample. Notice that the cross-validation idea can be applied to the calculation of any distance function.

One problem regarding the cross-validation criterion is in deciding how to select m, that is, the number of the observations contained in the "validation sample". For example, if we select m = n/2 then only n/2 observations would be available to fit a model. We could reduce m but this would mean having few observations for the validation sampling group and therefore reducing the accuracy with which the choice between models is made. In practice proportions of 75% and 25% are usually used, respectively for the training and the validation samples.

To summarise, these criteria have the advantage of being generally applicable but have the disadvantage of taking a long time to be calculated and of being sensitive to the characteristics of the data being examined. A way to overcome this problem is to consider model combination methods, such as bagging and boosting. For a thorough description of these recent methodologies, see Hastie, Tibshirani and Friedman (2001).

Business Criteria

One last group of criteria seem specifically tailored for the data mining field. These are criteria that compare the performance of the models in terms of their relative losses, connected to the errors of approximation made by fitting data mining models. Criteria based on loss functions have appeared recently, although related ideas are known since longtime in Bayesian decision theory (see for instance Bernardo and Smith, 1984) . They have a great application potential although at present they are mainly concerned with classification problems. For a more detailed examination of these criteria the reader can see for example Hand (1997), Hand, Mannila and Smyth (2001), or the reference manuals on data mining software, such as that of SAS Enterprise Miner (SAS Institute, 2004).

The idea behind these methods is to focus the attention, in the choice among alternative models, to the utility of the obtained results. The best model is the one that leads to the least loss.

Most of the loss function based criteria are based on the confusion matrix. The confusion matrix is used as an indication of the properties of a classification rule. On its main diagonal it contains the number of observations that have been correctly classified for each class. The off-diagonal elements indicate the number of observations that have been incorrectly classified. If it is assumed that each incorrect classification has the

same cost, the proportion of incorrect classifications over the total number of classifications is called rate of error, or misclassification error, and it is the quantity which must be minimised. The assumption of equal costs can be replaced by weighting errors with their relative costs.

The confusion matrix gives rise to a number of graphs that can be used to assess the relative utility of a model, such as the Lift Chart, and the ROC Curve (see Giudici, 2003). The lift chart puts the validation set observations, in increasing or decreasing order, on the basis of their score, which is the probability of the response event (success), as estimated on the basis of the training set. Subsequently, it subdivides such scores in deciles. It then calculates and graphs the observed probability of success for each of the decile classes in the validation set. A model is valid if the observed success probabilities follow the same order (increasing or decreasing) as the estimated ones. Notice that, in order to be better interpreted, the lift chart of a model is usually compared with a baseline curve, for which the probability estimates are drawn in the absence of a model, that is, taking the mean of the observed success probabilities.

The ROC (Receiver Operating Characteristic) curve is a graph that also measures predictive accuracy of a model. It is based on four conditional frequencies that can be derived from a model, and the choice of a cut-off points for its scores: a) the observations predicted as events and effectively such (sensitivity); b) the observations predicted as events and effectively non events; c) the observations predicted as non events and effectively events; d) the observations predicted as non events and effectively such (specificity). The ROC curve is obtained representing, for any fixed cut-off value, a point in the plane having as x-value the false positive value (1-specificity) and as y-value the sensitivity value. Each point in the curve corresponds therefore to a particular cut-off . In terms of model comparison, the best curve is the one that is leftmost, the ideal one coinciding with the y-axis.

To summarise, criteria based on loss functions have the advantage of being easy to understand but, on the other hand, they still need formal improvements and mathematical refinements.

FUTURE TRENDS

It is well known that data mining methods can be classified into exploratory, descriptive (or unsupervised), predictive (or supervised) and local (see e.g. Hand et al, 2001). Exploratory methods are preliminary to others and, therefore, do not need a performance measure. Predictive problems, on the other hand, are the setting where model comparison methods are most needed, mainly because of the abundance of the models available. All presented criteria can be applied to predictive models: this is a rather important aid for model choice.

For descriptive models aimed at summarising variables, such as clustering methods, the evaluation of the results typically proceeds on the basis of the euclidean distance, leading at the R^2 index. We remark that it is important to examine the ratio between the "between" and "total" sums of squares, that leads to R^2 , for each variable in the dataset. This can give a variable-specific measure of the goodness of the cluster representation.

Finally, it is difficult to assess local models, such as association rules, for the bare fact that a global measure of evaluation of such model contradicts with the very notion of a local model. The idea that prevails in the literature is to measure the utility of patterns in terms of how interesting or unexpected they are to the analyst. As measures of interest one can consider, for instance, the support, the confidence and the lift. The former can be used to assess the importance of a rule, in terms of its frequency in the database; the second can be used to investigate possible dependences between variables; finally the lift can be employed to measure the distance from the situation of independence.

CONCLUSION

The evaluation of data mining methods requires a great deal of attention. A valid model evaluation and comparison can improve considerably the efficiency of a data mining process. We have presented several ways to perform model comparison, each has its advantages and disadvantages. Choosing which of them is most suited for a particular application depends on the specific problem and on the resources (e.g. comput-

ing tools and time) available. Furthermore, the choice must also be based upon the kind of usage of the final results. This implies that, for example, in a business setting, comparison criteria based on business quantities are extremely useful.

KEY TERMS

Entropic Distance: The entropic distance of a distribution g from a target distribution f, is:

$$_E d = \sum_i f_i \log \frac{f_i}{g_i}$$

Chi-Squared Distance: The chi-squared distance of a distribution g from a target distribution f is:

$$_{\chi^2} d = \sum_i \frac{(f_i - g_i)^2}{g_i}$$

0-1 Distance: The 0-1 distance between a vector of predicted values, X_g, and a vector of observed values, X_f, is:

$$_{0-1} d = \sum_{r=1}^{n} 1(X_{fr} - X_{gr})$$

where 1(w,z) =1 if w=z and 0 otherwise.

Euclidean Distance: the distance between a a vector of predicted values, X_g, and a vector of observed values, X_f, is expressed by the equation:

$$_2 d(X_f, X_g) = \sqrt{\sum_{r=1}^{n} (X_{fr} - X_{gr})^2}$$

Uniform Distance: The uniform distance betweeen two distribution functions, F and G, with values in [0, 1] is defined by:

$$\sup_{0 \le t \le 1} |F(t) - G(t)|$$

Discrepancy of a Model: Assume that f represents the unknown density of the population, and let g= p_θ be a family of density functions (indexed by a vector of I parameters, θ) that approximates it. Using, to exemplify, the Euclidean distance, the discrepancy of a model g, with respect to a target model f is:

$$\Delta(f, p_\vartheta) = \sum_{i=1}^{n} \left(f(x_i) - p_\vartheta(x_i)\right)^2$$

Kullback-Leibler Divergence: The Kullback-Leibler divergence of a parametric model p_θ with respect to an unknown density f is defined by:

$$\Delta_{K-L}(f, p_\vartheta) = \sum_i f(x_i) \log\left(\frac{f(x_i)}{p_{\hat{\theta}}(x_i)}\right)$$

where the suffix $\hat{\theta}$ indicates the values of the parameters which minimizes the distance with respect to f.

Log-Likelihood Score: The log-likelihood score is defined by

$$-2\sum_{i=1}^{n} \log\left[p_{\hat{\theta}}(x_i)\right]$$

AIC Criterion: The AIC criterion is defined by the following equation:

$$AIC = -2\log L(\hat{\vartheta}; x_1, ..., x_n) + 2q$$

where $\log L(\hat{\vartheta}; x_1, ..., x_n)$ is the logarithm of the likelihood function calculated in the maximum likelihood parameter estimate and q is the number of parameters of the model.

BIC Criterion: The BIC criterion is defined by the following expression:

$$BIC = -2\log L\left(\hat{\vartheta}; x_1, ..., x_n\right) + q\log(n)$$

Evaluation of Decision Rules by Qualities for Decision-Making Systems

Ivan Bruha
McMaster University, Canada

INTRODUCTION

A 'traditional' learning algorithm that can induce a set of decision rules usually represents a robust and comprehensive system that discovers a knowledge from usually large datasets. We call this discipline Data Mining (DM). Any classifier, expert system, or generally a decision-supporting system can then utilize this decision set to derive a decision (prediction) about given problems, observations, diagnostics. DM can be defined as a nontrivial process of identifying valid, novel, and ultimately understandable knowledge in data. It is understood that DM as a multidisciplinary activity points to the overall process of determining a useful knowledge from databases, i.e. extracting high-level knowledge from low-level data in the context of large databases.

A rule-inducing learning algorithm may yield either an ordered or unordered set of *decision rules*. The latter seems to be more understandable by humans and directly applicable in most expert systems or decision-supporting ones. However, classification utilizing the unordered-mode decision rules may be accompanied by some conflict situations, particularly when several rules belonging to different classes match ('fire' for) an input to-be-classified (unseen) object. One of the possible solutions to this conflict is to associate each decision rule induced by a learning algorithm with a numerical factor which is commonly called the *rule quality*.

The chapter first surveys empirical and statistical formulas of the rule quality and compares their characteristics. Statistical tools such as contingency tables, rule consistency, completeness, quality, measures of association, measures of agreement are introduced as suitable vehicles for depicting a behaviour of a decision rule.

After that, a very brief theoretical methodology for defining rule qualities is acquainted. The chapter then concludes by analysis of the formulas for rule qualities, and exhibits a list of future trends in this discipline.

BACKGROUND

Machine Learning (ML) or Data Mining (DM) utilize several paradigms for extracting a knowledge that can be then exploited as a decision scenario (architecture) within an expert system, classification (prediction) one, or any decision-supporting one. One commonly used paradigm in Machine Learning is *divide-and-conquer* that induces decision trees (Quinlan, 1994). Another widely used *covering* paradigm generates sets of decision rules, e.g., the CNx family (Clark & Boswell, 1991; Bruha, 1997), C4.5Rules and Ripper. However, the rule-based classification systems are faced by an important deficiency that is to be solved in order to improve the predictive power of such systems; this issue is discussed in the next section.

Also, it should be mentioned that they are two types of agents in the multistrategy decision-supporting architecture. The simpler one yields a single decision; the more sophisticated one induces a list of several decisions. In both types, each decision should be accompanied by the agent's confidence (belief) into it. These functional measurements are mostly supported by statistical analysis that is based on both the certainty (accuracy, predictability) of the agent itself as well as consistency of its decision. There have been quite a few research enquiries to define formally such statistics; some, however, have yielded in quite complex and hardly enumerable formulas so that they have never been used.

One of the possible solutions to solve the above problems is to associate each decision rule induced by a learning algorithm with a numerical factor: a *rule quality*. The issue fo the rule quality was discussed in many papers; here we introduce just the most essential ones: (Bergadano et al., 1988; Mingers, 1989) were evidently one of the first papers introducing this problematic. (Kononenko, 1992; Bruha, 1997) were the followers; particularly the latter paper presented a methodological insight to this discipline. (An & Cercone,

2001) just extended some of the techniques introduces by (Bruha,1997). (Tkadlec & Bruha, 2003) presents a theoretical methodology and general definitions of the notions of a Designer, Learner, and Classifier in a formal matter, including parameters that are usually attached to these concepts such as rule consistency, completeness, quality, matching rate, etc. That paper also provides the minimum-requirement definitions as necessary conditions for the above concepts. Any designer (decision-system builder) of a new multiple-rule system may start with these minimum requirements.

RULE QUALITY

A rule-inducing algorithm may yield either an ordered or unordered set of decision rules. The latter seems to be more understandable by humans and directly applicable in most decision-supporting systems. However, the classification utilizing an unordered set of decision rules exhibits a significant deficiency, not immediately apparent. Three cases are possible:

1. If an input unseen (to-be-classified) object satisfies (matches, 'fires' for) one or more rules of the same class, then the object is categorized to the class assigned to the rule(s).
2. If the unseen object is not covered by any rule, then either the classifier informs the user about its inability to decide ('I do not know'), or the object is assigned by default to the majority class in the training set, or some similar techniques are invoked.
3. Difficulty arises if the input object satisfies more rules assigned to different classes. Then some schemes have to be applied to assign the unseen input object to the most appropriate class.

One possibility to clarify the conflict situation (case 3) of multiple-rule systems is to associate each rule in the decision-supporting scheme with a numerical factor that can express its properties and characterize a measure of belief in the rule, its power, predictability, reliability, likelihood, and so forth. A collection of these properties is symbolized by a function commonly called the *rule quality*. After choosing a formula for the rule quality, we also have to select a scheme for combining these qualities (*quality combination*).

Quality of rules, its methodology as well as appropriate formulas have been discussed for many years. (Bergadano et al., 1992) is one the first papers that introduces various definitions and formulas for the rule quality; besides rule's power and predictability it measures its size, understandability, and other factors. A survey of the rule combinations can be found, e.g. in (Kohavi & Kunz, 1997). Comprehensive analysis and empirical expertise of formulas of rule qualities and their combining schemes has been published in (Bruha & Tkadlec, 2003), its theoretical methodology in (Tkadlec & Bruha, 2003).

We now discuss the general characteristics of a formula of the rule quality. The first feature required for the rule quality is its *monotony* (or, more precisely, *nondecreasibility*) towards its arguments. Its common arguments are the *consistency* and *completeness* factors of decision rules. Consistency of a decision rule exhibits its 'purity' or reliability, i.e., a rule with high consistency should cover the minimum of the objects that do not belong to the class of the given rule. A rule with high completeness factor, on the other hand, should cover the maximum of objects belonging to the rule's class.

The reason for exploiting the above characteristics is obvious. Any DM algorithm dealing with real-world noisy data is to induce decision rules that cover larger numbers of training examples (objects) even with a few negative ones (not belonging to the class of the rule). In other words, the decision set induced must be not only reliable but also powerful. Its reliability is characterized by a consistency factor and its power by a completeness factor.

Besides the rule quality discussed above there exist other rule measures such as its size (e.g., the size of its condition, usually the number of attribute pairs forming the condition), computational complexity, comprehensibility ('Is the rule telling humans something interesting about the application domain?'), understandability, redundancy (measured within the entire decision set of rules), and similar characteristics (Tan et al., 2002; Srivastava, 2005). However, some of these characteristics are subjective; on contrary, formulas of rule quality are supported by theoretical sources or profound empirical expertise.

Here we just briefly survey the most important characteristics and definitions used by the formulas of rule qualities follow. Let a given task to be classified be characterized by a set of training examples that belong

to two classes, named C and $\bar{C}$ (or, not C). Let R be a decision rule of the class C, i.e.

`R: if Cond then class is C`

Here `R` is the name of the rule, `Cond` represents the condition under which the rule is satisfied (fires), and `C` is the class of the rule, i.e., an unseen object satisfying this condition is classified to the class `C`.

Behaviour of the above decision rule can be formally depicted by the 2×2 *contingency table* (Bishop et al., 1991), which is commonly used in machine learning (Mingers, 1989):

	class C	not class C	
rule R covers	a_{11}	a_{12}	a_{1+}
R does not cover	a_{21}	a_{22}	a_{2+}
	a_{+1}	a_{+2}	a_{++}

where

a_{11} is the number of training examples that are covered by (satisfied by) the rule R and belong to the class C,

a_{12} is the number of examples covered by (satisfied by) the rule R but not belonging to the class C, etc.,

$a_{1+} = a_{11} + a_{12}$ is the number of examples covered by R,

$a_{+1} = a_{11} + a_{21}$ is the number of the training examples of the class C,

$a_{++} = a_{+1} + a_{+2} = a_{1+} + a_{2+}$ is the number of all training examples in the given task.

Using the elements of the contingency table, we may define the *consistency* (*sensitivity*) of a rule R

$$\text{cons}(R) = \frac{a_{11}}{a_{1+}}$$

and its *completeness* (*coverage*) by

$$\text{compl}(R) = \frac{a_{11}}{a_{+1}}$$

Note that other statistics can be easily defined by means of the elements of the above contingency table. The conditional probability $P(C|R)$ of the class C under the condition that the rule R matches an input object is, in fact, equal to cons(R) ; similarly, the probability $P(R|C)$ that the rule R fires under the condition the input object is from the class C is identical to the rule's completeness. The prior probability of the class C is

$$P(C) = \frac{a_{+1}}{a_{++}}$$

Generally we may state that these formulas are functions of any above characteristics, i.e. all nine elements a_{11} to a_{++} of the contingency table, consistency, completeness, and various probabilities above classes and rules. There exist two groups of these formulas: empirical and statistical ones.

1. Empirical Formulas

The way of defining rule quality is an interesting issue in machine learning (Bergadano et al., 1988; Brazdil & Torgo, 1990; Torgo, 1993). However, the majority of these formulas represent an empirical, ad-hoc approach to the definition of rule quality, because they are based on intuitive logic and not necessarily backed by statistical or other theories. The common strategy is to use a weighted sum or multiplication of the consistency and completeness, which is more understandable to humans.

Rule quality as a *weighted sum* of the consistency and completeness has the form:

$$q^{\text{weight}}(R) = w_1 \ \text{cons}(R) + w_2 \ \text{compl}(R)$$

where $w_1, w_2 \in (0,1)$ are user-defined weights, usually $w_1 + w_2 = 1$. This apprehensible formula is nondecreasing towards its arguments. (Torgo, 1993) specifies the above weights by a heuristic formula that emphasizes consistency:

$$w_1 = 0.5 + \tfrac{1}{4}\,\text{cons}(R)$$
$$w_2 = 0.5 \,!\, \tfrac{1}{4}\,\text{cons}(R)$$

Rule quality as a *product* of consistency and completeness has the form:

$$q^{\text{product}}(R) = \text{cons}(R) \,.\, f\,(\text{compl}(R))$$

where f is an increasing function. The completeness works here as a factor that reflects a *confidence* to the consistency of the given rule. After a large number of experiments, (Brazdil & Torgo, 1990) selected an

empiric form of the function f: $f(x) = \exp(x - 1)$

2. Statistical Formulas

The statistical formulas for rule quality are supported by a few theoretical sources. Here we survey two of them.

2A. The theory on ***contingency tables*** seems to be one of these sources, since the performance of any rule can be characterized by them. Generally, there are two groups of measurements (see e.g. (Bishop et al.,1991)): association and agreement.

A measure of *association* (Bishop et al., 1991) indicates a relationship between rows and columns in a 2×2 contingency table so that the *i*-th row may be 'associated' with the *j*-th column. In other words, this measure reflects an 'association' on both diagonals of the contingency table. Two following measures may serve as reasonable rule qualities: the Pearson χ^2 statistic applied to the 2×2 contingency table

$$q^{X^2}(R) = \frac{(a_{11}a_{22} - a_{12}a_{21})^2}{a_{+1}\,a_{+2}\,a_{1+}\,a_{2+}}$$

and the *G2*-likelihood statistic

$$q^{G2}(R) = 2\left(a_{11}\ln\frac{a_{11}a_{++}}{a_{1+}a_{+1}} + a_{12}\ln\frac{a_{12}a_{++}}{a_{1+}a_{+2}}\right).$$

It should be noted that the *J*-measure introduced in (Smyth & Goodman, 1990) and often quoted as one of the most promising measures (Kononenko, 1992), in fact, is equal to the *G2*-likelihood statistic divided by $2a_{++}$.

From the viewpoint of machine learning, the above formulas work properly only if the class *C* is the majority class of examples covered by the rule.

A measure of *agreement* is a special case of association that indicates an 'association' of the elements of a contingency table on its main diagonal only. The simplest measure proposed in (Bishop et al., 1991) is the sum of the main diagonal $a_{11} + a_{22}$.

(Cohen, 1960) suggests comparison of the *actual* agreement

$$Aagree = \frac{1}{a_{++}}\sum_i a_{ii}$$

with the *chance* agreement

$$Cagree = \frac{1}{a_{++}^2}\sum_i a_{i+}a_{+i}$$

which occurs if the row variable is independent of the column variable, i.e., if the rule's coverage does not yield any information about the class *C*. The difference *Aagree* - *Cagree* is then normalized by its maximum possible value. This leads to the measure of agreement that we interpret as a rule quality (named after its author):

$$q^{\text{Cohen}}(R) = \frac{\frac{1}{a_{++}}\sum_i a_{ii} - \frac{1}{a_{++}^2}\sum_i a_{i+}a_{+i}}{1 - \frac{1}{a_{++}^2}\sum_i a_{i+}a_{+i}}$$

Note that here the coefficients $1/a_{++}$ and $1/a_{++}^2$ are used because the a_{ij}'s are *absolute*, not relative frequencies.

Cohen's statistic provides a formula which responds to the agreement on the main diagonal of the contingency table, i.e. when both components a_{11} and a_{22} are reasonably large. On the other hand, Coleman (Bishop, 1991) defines a measure of agreement that indicates an 'association' between the first column and any particular row in the contingency table. For the purpose of the rule quality definition, the agreement between the first column ('example from the class *C* ') and the first row ('rule *R* covers an example') is the proper one. The formula follows Cohen's statistic in principle by normalizing the difference between the 'actual' and 'chance' agreement. Hence, Coleman's formula for the rule quality is

$$q^{\text{Coleman}}(R) = \frac{a_{11} - \frac{1}{a_{++}}a_{1+}a_{+1}}{a_{1+} - \frac{1}{a_{++}}a_{1+}a_{+1}}$$

Coleman's statistic intuitively exhibits necessary properties of a rule quality: agreement between 'rule covers' and 'example from class *C* '. Nevertheless, one can find that Coleman's formula does not properly comprise the completeness of a rule. Therefore, (Bruha & Tkadlec, 2003) have changed slightly the above formula and got two modified ones that exhibit the proper characteristics.

2B. **Information theory** is another source of statistical measurements suitable for defining rule quality.

Following this theory, (Kononenko & Bratko, 1991) define the *information score* for a rule R when classifying an unseen object as $-\log_2 P(C) + \log_2 P(C|R)$. This formula can be also applied to the rule quality:

$$q^{\mathrm{IS}}(R) = -\log_2 \frac{a_{+1}}{a_{++}} + \log_2 \mathrm{cons}(R)$$

More precisely, this formula is valid only if $\mathrm{cons}(R) \geq \frac{a_{+1}}{a_{++}}$ which could be interpreted as a necessary condition for the reliability of a rule. This quality is evidently an increasing function towards its arguments.

The *logical sufficiency* can be also applied for defining a rule quality. Given a rule R and a class C, the logical sufficiency of the rule R with respect to C is defined as

$$q^{\mathrm{LS}}(R) = \frac{P(R \mid C)}{P(R \mid \overline{C})} = \frac{a_{11}a_{+2}}{a_{12}a_{+1}}$$

where $\overline{C}$ represents 'not class C '. A large value of the rule quality $q^{\mathrm{LS}}(R)$ means that the fired rule R supports the class C. Slightly modified formula called *discrimination* can be used for the rule quality, as well:

$$q^{\mathrm{D}}(R) = \frac{P(R \mid C)(1 - P(R \mid \overline{C}))}{P(R \mid \overline{C})(1 - P(R \mid C))} = \frac{a_{11}a_{22}}{a_{12}a_{21}}$$

Its purpose is to find a rule which can discriminate between positive and negative examples of the class C.

This section just discusses, introduces, and analyzes a few empirical and statistical formulas for the rule quality. This direction in DM and ML, however, would need a theoretical support and methodological background. (Tkadlec & Bruha, 2003) expresses just the first step in this direction. Their paper presents a four-tuple of Designer, Learner, Classifier, and Predictor; besides the rule quality, it also introduces the concept of importances (matching ratios) both cumulated (over-all) and class-sensitive. Last but not least, it provides a theoretical methodology for the designer (domain expert, decision-system builder) how to build up a multiple-rule system.

FUTURE TRENDS

Here are some directions the research of the evaluation of decision-supporting systems can continue.

- When we choose a formula for the rule quality, we also have to select a *scheme for combining* these qualities. It may happen that an unseen (to-be-classified) object matches (satisfies) more rules that belong to different classes; to solve this conflict case, the qualities of fired rules of the same class have to be combined using a certain scheme (formula). Consequently, the rule-quality combination with the maximum value will determine the class of the unseen object. There exist just preliminary studies of the combination schemes, e.g., (Kononenko, 1992). One direction in the future research should thus invent a few powerful and robust combination schemes, incl. the corresponding methodology and theory.
- Also, the research is to continue in formulating more sophisticated methodology and theory above the problematic of designing new formulas for rule qualities. (Tkadlec & Bruha, 2003) is just the first step; the paper, in fact, does not exhibit any profound theorem, just methodology, definitions, and a couple of lemmas.
- The methodology and theoretical formalism for single decision rules can be extended to the entire decision set of rules (knowledge base, model). A *model quality* thus represents the predictive power of the entire model (decision set of rules). It can be consequently utilized in a multi-level decision-supporting system which consists of two levels: the base level (consisting of 'base' models) and the second one (a 'super-model', meta-model). This second level then combines the decisions of the base models (utilizing their model qualities) in order to make up the final decision. (We can view a base model as a 'physician' who has to find a diagnosis of a patient, and the second level as a 'council' of physicians that combines the decisions of all the members according to physicians' qualities, and makes up the final verdict of the patient's diagnosis.)
- In most decision-supporting systems, the rule qualities are static, constant, calculated a priori, before the actual classification or prediction. Their

predictability can be improved by a dynamic change of their values during the classification process. One possible scheme implants a feedback loop from the classifier to the learner (Bruha, 2000); it refines (modifies) the rule qualities according to the correct/false predictions made by the classifier by changing the qualities of the rules that were involved in the current classification.

CONCLUSION

This chapter deals with the conceptuality of rule quality, and solves some conflicts in multiple-rule systems. Many experimental comparisons of various formulas of rule quality has been carried out in several papers, e.g., (Bruha & Tkadlec, 2003; An & Cercone, 2001).

By analyzing those experiments, one can find that the weighted sum - particularly with the weights proposed by (Torgo, 1993) - and the two modifications of Coleman's quality exhibit the best performance. The second successful group (as for the classification accuracy) are q^{product}, q^{LS}, and the *J*-measure. The worst rule qualities are the formulas q^{IS} and q^{χ^2}.

The weighted-sum quality exhibits quite interesting characteristic. By selecting the weights w_1 and w_2 a user may choose between inducing only reliable rules (when supporting consistency of rules) and only robust rules (when supporting completeness). However, our experiments undoubtedly revealed that a larger support of completeness deteriorates the classification accuracy.

Generally speaking, the statistical formulas introduced above exhibit the *independence* property: they yield the value zero if and only if the rule does not have any expressive capability, i.e., if its distribution is equal to the distribution of the entire training set. The name is derived from the fact that the columns and rows in the contingency table are independent in this case. The independence property can be also expressed by the consistency or completeness; it arises if

$$\text{cons}(R) = \text{compl}(R) = \frac{a_{+1}}{a_{++}}$$

One may observe that majority of the quality formulas introduced here are applicable. Although the empirical formulas are not backed by any statistical theory, they work quite well. Also, the classification accuracy of the statistical formulas has negligible difference in comparison to the empirical ones. On the other hand, statistical formulas have been derived from statistical theories and exhibit the independence property which has the advantage that the threshold of meaningful rules is clearly expressed. To be more precise, even the statistical formulas are applied mostly in an ad-hoc, empirical fashion, since most algorithms do not check the conditions or assumptions of their applicability. Unlike the empirical formulas, however, we are aware of the error we have made when the conditions of applicability are not checked. If needed, a checking condition could in principle be embedded into the algorithm.

KEY TERMS

Classifier: A decision-supporting system that given an unseen input object yields a prediction, for instance, it classifies the given object to a certain class.

Completeness of a Rule: It exhibits the rule's power, i.e. a rule with high completeness factor covers the maximum of objects belonging to the rule's class.

Consistency of a Rule: It exhibits the rule's 'purity' or reliability, i.e., a rule with high consistency should cover the minimum of the objects that do not belong to the class of the given rule.

Contingency Table: A matrix of size $M*N$ whose elements represent the relation between two variables, say X and Y, the first having M discrete values X_1,..., X_M, the latter N values Y_1,..., Y_N; the (m,n)-th element of the table thus exhibits the relation between the values X_m and Y_n.

Decision Rule: An element (piece) of knowledge, usually in the form of 'if-then statement':

```
if Condition then Action/Class
```

If its `Condition` is satisfied (i.e., matches a fact in the corresponding database of a given problem, or an input object), then its `Action` (e.g., decision making) is performed, usually an input unseen (to-be-classified) object is assigned to the `Class`.

Decision Set: Ordered or unordered set of decision rules; a common knowledge representation tool (utilized e.g. in most expert systems).

Model (Knowledge Base): Formally described concept of a certain problem; usually represented by a set of production rules, decision rules, semantic nets, frames.

Model Quality: Similar to rule quality, but it characterizes the decision power, predictability, and reliability of the entire model (decision set of rules, knowledge base) as a unit.

Rule Quality: A numerical factor that characterizes a measure of belief in the given decision rule, its power, predictability, reliability, likelihood.

The Evolution of SDI Geospatial Data Clearinghouses

INTRODUCTION

Geospatial data and the technologies that drive them have altered the landscape of our understanding of the world around us. The data, software and services related to geospatial information have given us the opportunity to visualize existing phenomena, to understand connections, and to address problems from environmental management to emergency response. From the ever-present Google Earth images we are shown in our televised weather reports to the 3D flyovers of war zones on the news, geospatial information is everywhere. In the decade or so since U.S. President William Clinton set the stage by announcing the establishment of the National Spatial Data Infrastructure (NSDI), the concept of the geospatial data clearinghouse has shifted dramatically to fulfill the increasing need to streamline government processes, increase collaboration, and to meet the demands of data users and data developers (Clinton, 1994). The announcement of the NSDI gave birth to a Global Spatial Data Infrastructure (GSDI) movement that would be supported by a network of SDIs or geospatial data clearinghouses from local, state, and national levels.

From this point on, the evolution of the geospatial data clearinghouse has been rapid and punctuated with challenges to both the developer and the user. From the earliest incarnations of these now pervasive resources as simple FTP data transfer sites to the latest developments in Internet Map Services and real time data services, geospatial data clearinghouses have provided the backbone for the exponential growth of Geographic Information Systems (GIS). In this section, the authors will examine the background of the geospatial data clearinghouse movement, address the basic phases of clearinghouse development, and review the trends that have taken the world's clearinghouses from FTP to Internet Map Services and beyond.

THE SPATIAL DATA INFRASTRUCTURE MOVEMENT

No discussion of SDIs and geospatial data clearinghouses would be complete without a brief introduction to the history of the movement.

The growth of geospatial data clearinghouse movement can trace its origins to the spatial data infrastructure initiatives of the 1990s when spatial data sharing began in earnest. In the United States an effort to organize spatial data and develop standards for sharing data began as the NSDI. First envisioned in 1993, the concept of the coordinated data model set forth the ideas and goals of widespread sharing of data and resources (National Research Council, 1993). By 1995, the United States had developed a plan for data sharing and established a gateway by which participants could register their metadata holdings through a centralized source (FGDC95). Sharing data through this gateway required developing metadata to an accepted standard and utilized the Z39.50 protocol—both of which will be described in the next section.

The spatial data infrastructure concept as it has evolved has, at its core, the premise that sharing data eliminates redundancy, enhances opportunities for cooperative efforts, and facilitates collaboration. In addition, the SDI movement also has two additional advantages. First, it allows a more effective and efficient interaction with geospatial data and, second, it helps to stimulate the market for the geospatial industry

(Bernard, 2002). The general approach to developing an SDI is to first understand how and where geospatial data is created. Most SDIs or geospatial clearinghouses base their first level data collection efforts on framework data (FGDC95). Framework data is created by government agencies—local, state, federal, or regional for the purpose of conducting their business such as development and maintenance of roads, levying taxes, monitoring streams, or creating land use ordinances. These business practices translate themselves, in the geopspatial data world, into transportation network data, parcel or cadastral data, water quality data, aerial photographs, or interpreted satellite imagery. Other organizations can then build upon this framework data to create watershed assessments, economic development plans, or biodiversity and habitat maps. This pyramid of data sharing—from local to national—has been the cornerstone of the original concept of the SDI and considered a fundamental key to building an SDI (Rajabifard & Williamson, 2001).

The SDI movement now encompasses countries and regions all over the world and is now considered a global movement and potential global resource. Many countries maintain now clearinghouses participating in regional efforts. One effort along these lines is the GSDI (Nebert, 2004). The GSDI, which resulted from meetings held in 1995, is a non-profit organization working to further the goals of data sharing and to bring attention to the value of the SDI movement with a particular emphasis on developing nations (Stevens et al., 2004). Other projects including the Geographic Information Network in Europe (GINIE) project are working toward collaboration and cooperation in sharing geospatial data (Craglia, 2003). As of 2006, there were approximately 500 geospatial data clearinghouses throughout the world. The activities of the clearinghouses range from coordinating data acquisition and developing data standards to developing applications and services for public use with an average operating cost of approximately € 1,500,000 per year (approximately $ 1,875,000) (Crompvoets et al., 2006).

EVOLUTION OF SERVICES AND ACCESS IN THE GEOSPATIAL DATA CLEARINGHOUSE

There are several developmental phases that geospatial data clearinghouses engage in to become fully operational and integrated into a larger SDI, e.g., data acquisition and documentation, data access and retrieval capabilities, storage architecture development, and application development. These phases can be sequential or can be performed simultaneously but all must be addressed. It is important to note that technology, both internal and external to the clearinghouse, changes rapidly and therefore any clearinghouse must be developed to be dynamic to meet the changing nature of the technology and the changing needs of its users. Each geospatial data clearinghouse also must address the particulars of their organization such as available software, hardware, database environment, technical capabilities of staff, and the requirements of their primary clients or users. In some cases, clearinghouses have undertaken an effort to develop user requirements and assess needs prior to implementation of new services or architectures. The user needs and requirements assessment addresses all phases of the clearinghouse from both internal and external perspectives and provides the framework with which to build services and organizational capability (Kelly & Stauffer, 2000). Within the requirements phase, examination of resources available to the clearinghouse must be determined and if inadequate, acquired. There is little doubt that the key to success relies heavily on the resources of the geospatial data clearinghouse and its ability to store and provide access to large datasets and thousands of data files (Kelly & Stauffer, 2000). Another equally significant component of building an SDI is identifying how the resource will support activities in the region. The clearinghouse can bring together disparate data sets, store data for those organizations that are unable to store or provide access to their own information, and can offer access to data that crosses boundaries or regions to enable efforts that are outside traditional jurisdictions of agencies or organizations (Rajabifard & Williamson, 2001).

Metadata

The key component to any geospatial data clearinghouse is geospatial metadata. The metadata forms the core of all other operations and should be addressed in the initial phase of clearinghouse development. The Federal Geographic Data Committee (FGDC) developed its initial standards for geospatial metadata in the mid 1990's. This standard, which is used as the basis for metadata in geospatial data clearinghouses today is re-

ferred to as the Content Standard for Digital Geospatial Metadata (CSDGM) (FGDC98). The impact of CSDGM cannot be overstated. The early metadata standard has grown over the years and been adapted and accepted internationally by the International Organization for Standardization (ISO). The metadata not only serves as a mechanism to document the data but also serves as the standard basis for distributed sharing across clearinghouses through centralized gateways or national SDI (Figure 1). The standards used to query remote catalogs have their origins in the development of the ANSI Z39.50 standard (now known as the ISO 23950 Search and Retrieval Protocol) which was originally designed for libraries to search and retrieve records from remote library catalogs (Nebert, 2004). In addition to addressing the metadata standard, a secondary yet equally important issue is format. Initially metadata was either HTML or text format and then parsed using a metadata parser into the standard fields. One of the first clearinghouses to implement XML (Extensible Markup Language) based metadata was Pennsylvania Spatial Data Access (PASDA). PASDA, which was first developed in 1996, utilized XML metadata in an effort to better manage data and to make updates and alterations to metadata more efficient (Kelly & Stauffer, 2000).

Data Acquisition

One of the most significant challenges for any geospatial data clearinghouse is the acquisition of data. Each country, state, and region face their own internal issues related to data sharing such as legal liability questions and right to know laws, therefore the data and services for each clearinghouse differ. The ideal concept for sharing would be from local government, since it can be the most detailed and up-to-date, to state and federal government clearinghouses—the hierarchy of data sharing (Figure 2). However, it can be difficult to acquire local government data unless partnerships are developed to encourage and enable sharing of local data (McDougall et al., 2005).

There are some success stories that do demonstrate the benefits of partnerships and some even with major metropolitan areas. The City of Philadelphia, which maintains one of the most advanced geospatial enter-

Figure 1. User access to remote data stores via SDI gateway

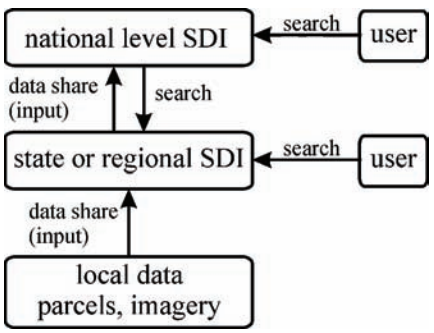

Figure 3. Internet Map Service approach to sharing data

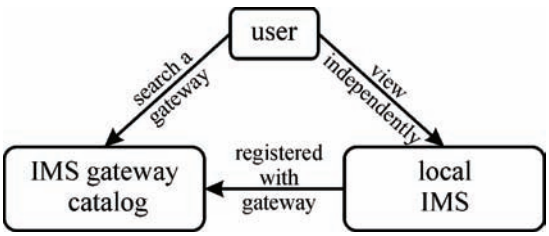

Figure 4. Common architecture of a current geospatial data clearinghouse

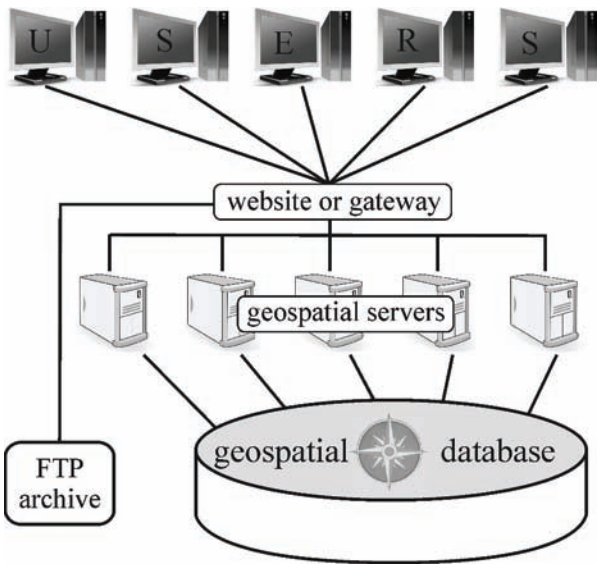

prise architectures in the US, shares its data through the state geospatial data clearinghouse PASDA.

However, in general the partnership approach has lead to spotty participation by local and regional organizations therefore many geospatial clearinghouses base their initial efforts on acquiring data which is freely available and which has no distribution restrictions. In the United States, this data tends to be from the Federal government. The initial data sets are comprised of elevation, scanned geo-referenced topographic maps, and aerial photographs. If the geospatial data clearinghouse is state-related, additional more detailed information such as roads, streams, boundary files, parks and recreational data are added to the data collection.

However, changes in technology have altered the concept of how data is shared. The increase in web-based GIS applications or Internet Map Services (IMS) has allowed local governments, as well as others, to share their data via IMS catalogs by registering their "service" versus sharing their data files. In this approach, access is still provided to the data, although with limited download capabilities, and local control and hosting is maintained (Figure 3).

Architecture

Geospatial data have traditionally been accessed via the Internet through file transfer protocol (FTP) or more recently viewed through web based interfaces or IMS. The earliest geospatial data clearinghouses required an FTP server, metadata that could be in HTML (Hypertext Markup Language), later XML, and simple search mechanisms driven by keywords or descriptors in the metadata. In cases such as these the onus was on the user or client to access and manipulate the data into their own environment. However, recent developments in database management and software, and advances in the overall technologies related to the Internet are

driving the rapid changes in geospatial clearinghouses. Users who are requiring more web-based services, customizing capabilities, and faster performance times combined with the exponential growth in available data has increased the requirements for clearinghouses (Kelly & Stauffer, 2000). Within the past six years, user needs have moved clearinghouse operations from simple FTP sites to complex organizations supporting large relational database management systems (RDBMS) composed of vast vector and raster data stores, specialized customization engines—reprojectors and data clipping utilities, access to temporal data, analysis tools and multiple IMS applications while still maintaining archival copies and direct FTP download capabilities (Figure 4).

EMERGING TRENDS IN GEOSPATIAL DATA CLEARINGHOSUE DEVELOPMENT

The dramatic shift from serving data and metadata through a simple web based interface to storing and providing access to thousands of unique data sets through multiple applications has placed the clearinghouse movement on the cutting edge of geospatial technologies. These cutting technologies stem from advancements in managing data in a Relational Database Management system (RDBMS) with the accompanying increase in performance of IMS and temporal data integration techniques.

RDBMS and Its Impact on Data Management

The current movement in geospatial data clearinghouses is to support and manage data within an RDBMS. In essence this approach has altered not only how the data is managed but has also improved the performance and utility of the data by enabling application developers to create IMS and other services that mirror desktop capabilities. Advancements in database technology and software such as ESRI Spatial Database Engine (SDE), in combination with databases such as Oracle or DB2, can support the management of large quantities of vector and raster data. The data is stored within the database in table spaces that are referenced, within the DB2 architecture, by configuration keywords that point to attribute table spaces and coordinate table spaces. For vector data, a spatial index grid is created which allows features to be indexed by one or more grids and stored in the database based on spatial index keys that correspond to the index grid. In general, raster data, which are in essence multidimensional grids can be stored as binary large objects or BLOBs within the table spaces. Interfacing with the database is a broker such as SDE which enables both input and retrieval of the raster BLOBs. In addition, techniques, such as the use of pyramids that render the image at a reduced resolution, increase the performance of the database for the end user. In addition, a clearinghouse that uses a RDBMS architecture is more readily able to manage temporal or dynamic data and automate processes for updating applications and services (Kelly et al, 2007). These advances in managing and retrieving data within the RDBMS/SDE environment have substantially increased performance and speed even more so in an IMS environment (Chaowei, et al, 2005). Another impact of this trend is that as relational database management become mainstreamed with the more user friendly and affordable databases such as MySQL, an open source RDBMS that uses Structured Query Language (SQL), the ability for smaller organizations to develop higher functioning IMS is within the realm of possibility.

Internet Map Services

In the past few years, IMS, which encompass everything from stand alone applications dedicated to a specific theme or dataset (i.e., "My Watershed Mapper"), have grown to represent the single most important trend in the geospatial data clearinghouse movement. The early period of IMS development included applications comprised of a set of data, predefined by the developer, which users could view via an interactive map interface within an HTML page. However, there were few if any customization capabilities and limited download capabilities. The user was simply viewing the data and turning data layers on and off. Another component of early IMS development was the use of a Web GIS interface or map as part of a search engine to access data and metadata from data clearinghouses or spatial data distribution websites (Kraak, 2004). Building on the advances of RDBMS and software, IMS developers have been able to set aside the historical constraints that hindered development in the 1990s. Initially, data used for IMS were stored in a flat

file structure, such as ESRI shapefiles with which the Internet mapping server interacted directly. While this was somewhat effective for small files in the kilobyte or single megabyte range, it became more cumbersome and inefficient for the increasing amount and size of detailed vector and raster data, such as high-resolution aerial photography. But as the use of RDBMS became the backbone of many geospatial data clearinghouse architectures, IMS developers began to take advantage of the data retrieval performance and efficiency of relational databases.

Changes in IMS have emerged over the past few years that herald a change in how users interact with geospatial data clearinghouses. The development of Web Feature Services (WFS) and Web Map Services (WMS) are pushing the envelope of an open GIS environment and enabling interoperability across platforms. There are several types of emerging IMS. These include the feature service and image service. The image service allows the user to view a snapshot of the data. This type of service is particularly meaningful for those utilizing raster data, aerial photography, or other static data sets. The feature service is the more intelligent of the two as it brings with it the spatial features and geometry of the data and allows the user to determine the functionality and components such as the symbology of the data. WFS is particularly applicable for use with real-time data streaming (Zhang & Li, 2005).

Changes in technology have allowed geospatial data clearinghouses to deploy applications and services containing terabytes of spatial data within acceptable time frames and with improved performance. IMS has moved the geospatial data clearinghouse from a provider of data to download to interactive, user centered resources that allow users to virtually bring terabytes of data to their desktop without downloading a single file.

Temporal Data

As geospatial data clearinghouses have crossed over into the IMS environment, the issue of integrating temporal data has become an emerging challenge (Kelly et al, 2007). The expectations for clearinghouses are moving toward not only providing terabytes of data but also toward providing data that is dynamic. Temporal data, unlike traditional spatial data in which the attributes remain constant, has constantly changing attributes and numerous data formats and types with which to contend (Van der Wel, et al., 2004). Temporal data by nature presents numerous challenges to the geospatial data clearinghouse because it carries with it the added dimension of time. An prime example of the complexity of temporal data integration is weather data. The development of services based on temporal information such as weather data must be undertaken with the understanding that this data is unique in format and that the frequency of updates require that any service be refreshed "on the fly" so the information will always be up to date. The number of surface points and types of data such as data taken from satellite or radar can overwhelm even a sophisticated server architecture (Liknes, 2000). However, the significance of these data to users from emergency management communities to health and welfare agencies cannot be underestimated. Therefore, it is imperative that geospatial data clearinghouses play a role in providing access to this vital data.

CONCLUSION

The changes in geospatial data clearinghouse structure and services in less than a decade have been dramatic and have had a significant impact on the financial and technical requirements for supporting an SDI geospatial data clearinghouse. As stated earlier in this section, the average cost of maintaining and expanding a clearinghouse is clear since most of the costs are assessed on personnel, hardware, software, and other apparent expenses; it is more difficult to assess the financial benefit (Gillespie, 2000). In addition, despite many changes in technology and the increasing amount of accessible data, some challenges remain. Local data is still underrepresented in the clearinghouse environment and the ever-changing technology landscape requires that geospatial data clearinghouse operations be dynamic and flexible. As trends such as IMS, the use of temporal data, and the enhancement of relational database architectures continue, geospatial data clearinghouses will be faced with providing growing amounts of data to ever more savvy and knowledgeable users.

KEY TERMS

BLOB: Binary Large Object is a collection of binary data stored as a single entity in a database management system

Feature Service: The OpenGIS Web Feature Service Interface Standard (WFS) is an interface allowing requests for geographical features across the web using platform-independent calls. The XML-based GML is the default payload encoding for transporting the geographic features.

ISO 23950 and Z39.50: International standard specifying a client/server based protocol for information retrieval from remote networks or databases.

Metadata: Metadata (Greek meta "after" and Latin data "information") are data that describe other data. Generally, a set of metadata describes a single set of data, called a resource. Metadata is machine understandable information for the web.

Open GIS: Open GIS is the full integration of geospatial data into mainstream information technology. What this means is that GIS users would be able to freely exchange data over a range of GIS software systems and networks without having to worry about format conversion or proprietary data types.

SDE: SDE (Spatial Data Engine) is a software product from Environmental Systems Research Institute (ESRI) that stores GIS data in a relational database, such as Oracle or Informix. SDE manages the data inside of tables in the database, and handles data input and retrieval.

Web Mapping Services (WMS): A Web Map Service (WMS) produces maps of geo-referenced data and images (e.g. GIF, JPG) of geospatial data.

XML : Extensible Markup Language (XML) was created by W3C to describe data, specify document structure (similar to HTML), and to assist in transfer of data.

Evolutionary Approach to Dimensionality Reduction

INTRODUCTION

Excess of data due to different voluminous storage and online devices has become a bottleneck to seek meaningful information therein and we are information wise rich but knowledge wise poor. One of the major problems in extracting knowledge from large databases is the size of dimension i.e. number of features, of databases. More often than not, it is observed that some features do not affect the performance of a classifier. There could be features that are derogatory in nature and degrade the performance of classifiers used subsequently for dimensionality reduction (DR). Thus one can have redundant features, bad features and highly correlated features. Removing such features not only improves the performance of the system but also makes the learning task much simpler. Data mining as a multidisciplinary joint effort from databases, machine learning, and statistics, is championing in turning mountains of data into nuggets (Mitra, Murthy, & Pal, 2002)

Feature Analysis

DR is achieved through feature analysis which includes feature selection (FS) and feature extraction (FE). The term FS refers to selecting the best subset of the input feature set whereas creating new features based on transformation or combination of the original feature set is called FE. FS and FE can be achieved using supervised and unsupervised approaches. In a supervised approach, class label of each data pattern is given and the process of selection will use this knowledge for determining the accuracy of classification whereas in unsupervised FS, class level is not given and process will apply natural clustering of the data sets.

BACKGROUND

Feature Selection (FS)

The main task of FS is to select the most discriminatory features from original feature set to lower the dimension of pattern space in terms of internal information of feature samples. Ho (Ho, 1998) combined and constructed multiple classifiers using randomly selected features which can achieve better performance in classification than using the complete set of features. The only way to guarantee the selection of an optimal feature vector is an exhaustive search of all possible subset of features (Zhang, Verma, & Kumar, 2005).

Feature Selection Methods

In the FS procedures, four basic stages are distinguished:

1 **Generation procedure:** In this stage a possible subset of features to represent the problem is determined. This procedure is carried according to one of the standard methods used for this purpose.
2. **Evaluation function:** In this stage the subset of features selected in the previous stage is evaluated according to some fitness function.
3. **Stopping criterion:** It is verified if the evaluation of the selected subset satisfies the stopping criterion defined for the searching procedure.

4. **Validation procedure:** It will be used to test the quality of the selected subset of features.

FS methods can be divided into two categories: the wrapper method and the filter one. In the wrapper methods, the classification accuracy is employed to evaluate feature subsets, whereas in the filter methods, various measurements may be used as FS criteria. The wrapper methods may perform better, but huge computational effort is required (Chow, & Huang, 2005). Thus, it is difficult to deal with large feature sets, such as the gene (feature) set of a cDNA data. A hybrid method suggested by Liu (Liu, & Yu 2005) attempts to take advantage of both the methods by exploiting their different evaluation criteria in different search stages. The FS criteria in the filter methods fall into two categories: the classifier-parameter-based criterion and the classifier-free one.

An unsupervised algorithm (Mitra, Murthy, & Pal, 2002) uses feature dependency/similarity for redundancy reduction. The method involves partitioning of the original feature set into some distinct subsets or clusters so that the features within a cluster are highly similar while those in different clusters are dissimilar. A single feature from each such cluster is then selected to constitute the resulting reduced subset.

Use of soft computing methods like GA, fuzzy logic and Neural Networks for FS and Feature ranking is suggested in (Pal, 1999). FS method can be categorized (Muni, Pal & Das, 2006) into five groups based on the evaluation function, distance, information, dependence, consistency (all filter types) and classifier error rate (wrapper type). It is stated in (Setiono, & Liu, 1997) that the process of FS works opposite to ID3 (Quinlan,1993). Instead of selecting one attribute at a time, it starts with taking whole set of attributes and removes irrelevant attribute one by one using a three layer feed forward neural network. In (Basak, Pal, 2000) neuro-fuzzy approach was used for unsupervised FS and comparison is done with other supervised approaches. Recently developed Best Incremental Ranked Subset (BIRS) based algorithm (Roberto Ruiza, José C. Riquelmea, Jesús S. Aguilar-Ruizb, 2006) presents a fast search through the attribute space and any classifier can be embedded into it as evaluator. BIRS chooses a small subset of genes from the original set (0.0018% on average) with similar predictive performance to others. For very high dimensional datasets, wrapper-based methods might be computationally unfeasible, so BIRS turns out a fast technique that provides good performance in prediction accuracy.

Feature Extraction (FE)

In a supervised approach, FE is performed by a technique called discriminant analysis (Steve De Backer, 2002). Another supervised criterion for non-Gaussian class-conditional densities is based on the Patrick-Fisher distance using Parzen density estimates .The best known unsupervised feature extractor is the principal component analysis (PCA) or Karhunen-Lo`eve expansion, that computes the $\boldsymbol{d}$ largest eigenvectors from $\mathbf{D} \times \mathbf{D}$ covariance matrix of the $\boldsymbol{n}$, **D**-dimensional patterns. Since PCA uses the most expressive features (eigenvectors with largest eigenvalues), it effectively approximates the data by a linear subspace using the mean squared error criterion.

MAIN FOCUS

Evolutionary Approach for DR

Most of the researchers prefer to apply evolutionary approach to select features. There are evolutionary programming (EP) approaches like particle swarm optimization (PSO), ant colony optimization (PSO), genetic algorithms (GA); however GA is the most widely used approach whereas ACO and PSO are the emerging area in DR. Before describing GA approaches for DR, we outline PSO and ACO.

Particle Swarm Optimization (PSO)

Particle swarm optimizers are population-based optimization algorithms modeled after the simulation of social behavior of bird flocks (Kennedy, Eberhart, 2001). A swarm of individuals, called particles, fly through the search space. Each particle represents a candidate solution to the optimization problem. The position of a particle is influenced by the best position visited by itself (i.e. its own experience) and the position of the best particle in its neighborhood (i.e. the experience of neighboring particles called *gbest*/*lbest*) (Engelbrecht, 2002).

Ant Colony Optimization (ACO)

Dorigo (Dorigo, & Stützle, 2004) introduces the behavior of ants. It is a probabilistic technique to solve computational problems. When ants walk randomly in search of food, after finding food, they lay down a substance called pheromone in their trails. Other ants follow this trail laying down more and more pheromone to strengthen the path.

Genetic Algorithms (GA) Based FS

The GA is biologically inspired and has many mechanisms mimicking natural evolution (Oh, Lee , & Moon 2004). GA is naturally applicable to FS since the problem has an exponential search space. The pioneering work by Siedlecki (Siedlecki, Sklansky, 1989) demonstrated evidence for the superiority of the GA compared to representative classical algorithms.

Genetic algorithm (GA) (Goldberg, 1989) is one of the powerful evolutionary algorithms used for simultaneous FS. In a typical GA, each chromosome represents a prospective solution of the problem. The set of all chromosomes is usually called a population. The chromosome can either be represented as a binary string or in real code depending on the nature of a problem. The problem is associated with a fitness function. The population goes through a repeated set of iterations with crossover and mutation operation to find a better solution (better fitness value) after each iteration. At a certain fitness level or after a certain number of iterations, the procedure is stopped and the chromosome giving the best fitness value is preserved as the best solution of the problem.

Fitness function for DR

Each chromosome in the population is first made to represent all features of the pattern in a binary manner.

Sammon's Error used as the fitness function is given as follows.

Let $\boldsymbol{X = \{x_k \mid x_k = (x_{k1}, x_{k2}, \ldots, x_{kp})^T,\ k=1,2,\ldots,n\}}$ be the set of $\boldsymbol{n}$ input vectors and let $\boldsymbol{Y = \{y_k \mid y_k = (y_{k1}, y_{k2}, \ldots, y_{kq})^T,\ k=1,2,\ldots,n\}}$ be the unknown vectors to be found. Let $\mathbf{d^*_{ij} = d(x_i, x_j)}$, $\mathbf{x_i, x_j} \in \boldsymbol{X}$ and $\boldsymbol{d_{ij} = d(y_i, y_j)}$, $\mathbf{y_i, y_j} \in \boldsymbol{Y}$, where $\boldsymbol{d(x_i, x_j)}$ be the Euclidean distance between $\boldsymbol{x_i}$ and $\boldsymbol{x_j}$. Sammon Error $\boldsymbol{E}$ is given by,

$$E = \frac{1}{\sum_{i<j} d^*_{ij}} \sum_{i<j} \frac{(d^*_{ij} - d_{ij})^2}{d^*_{ij}} \qquad (1)$$

Procedure

The entire procedure is outlined below.

A. Initialize the population

Let p be the length of each chromosome which is equal to the number of features present in the original data set. Let N_p be the size of the population matrix having N number of chromosomes. Initialize each chromosome of the population by randomly assigning 0 and 1 to its different positions.

B. Measure of fitness

If the i^{th} bit of the chromosome is a 1, then i^{th} feature of the original data set is allowed to participate while computing Sammon Error. Compute d^*_{ij} and d_{ij} for the data set for reduced and entire data set respectively. Calculate the fitness of each chromosome by computing the Sammon Error E given by Eq.(1).

C. Selection, crossover and mutation

Using roulette wheel selection method, (or any other selection criterion like uniform random) different pairs of chromosomes are selected for cross over process. The selected pairs are allowed to undergo a crossover (here also one can apply a single point or a two point crossover) operation to generate new offspring. These offspring are again selected randomly for mutation. In this manner a new population is constructed.

D. Termination of GA

Compute the fitness of each chromosome of new population and compare the fitness of each chromosome of new population with that in the initial one. Retain the chromosome for which Sammon Error is lesser in the initial population than that in the new population otherwise replace the chromosome of new population with that in the initial population. Stop the GA after a sufficiently large number of iterations. Note the number of the features and their locations in the final chromosome having least Sammon Error.

E. Validation

Apply k-means clustering (for unsupervised classification) and k-NN classifier (k-Nearest Neighbor, for supervised classification) techniques to compute and compare the accuracies of the reduced and entire data sets.

After, a reduced data set is obtained, it will be appropriate to ensure that the topology *i.e.* the structure of the original data set is preserved in the reduced set. For this purpose, we compute the proximity matrices of the original and reduced data sets and compute correlation coefficients of the two matrices. High values of correlation coefficients confirm that the structure of the data set is preserved in reduced data set (Saxena, Kothari, 2007). A fuzzy approach is used before for DR with structure preserving (Pal, Mandal, 2002) but GA based approaches have not been reported so far.

GAs have been used to search for feature subsets in conjunction with several classification methods (Cantú-Paz, 2004) such as neural networks, decision trees, k-nearest neighbors rules and Naive Bayes.

The GA for FS can be applied with some penalty (Oh, Lee, & Moon, 2004). In order to force a feature subset to satisfy the given subset size requirement, the size value, *d* is taken as a constraint and a penalty is imposed on chromosomes breaking this constraint. A novel hybrid GA (HGA) is proposed to solve the FS problem. Local search operations parameterized with ripple factors were devised and embedded in the HGAs. Using standard data sets, experiments justified the proposed method.

The GA Feature Extractor

Here, the objective function consists of the classification performance obtained by a k-NN classifier, using the value of features provided by the GA (Raymer, 2000). In order to prevent any initial bias due to the natural ranges of values for the original features, input feature values are normalized over the range [1.0, 10.0]. Prior to each GA experiment, the k-NN classifier is trained with a set of patterns with an equal number of samples of each class. A second set of patterns, disjoint to the training set, is set aside to serve as a tuning set. To evaluate a particular set of weights, the GA scales the training and tuning set feature values according to the weight set, and classified the tuning set with the weighted k-NN classifier. The performance of the weight set is determined according to the classification accuracy on the tuning set, the balance in accuracy among classes, the number of correct votes cast during k-NN classification, and the parsimony of the weight set (the number of features eliminated from classification by masking). Since the particular GA engine used minimizes the objective function, the following error function is used to evaluate each weight w^*

$$\text{error}(w^*) = C_{pred}(\text{ no. of incorrect predictions}) + C_{rmask}(\textit{ no. of unmasked features}) + C_{votes}(\textit{ no. of incorrect votes}) + C_{diff}(\textit{ difference in accuracy between classes})$$

where C_{pred}, C_{rmask}, C_{votes}, C_{diff} are anti-fitness function coefficients.

In most cases, GAs, combine different optimization objectives into a single objective function. The main drawback of this kind of strategy lies in the difficulty of exploring different possibilities of trade-offs among objectives. Morita (Morita, Sabourin, Bortolozzi, & Suen 2003) proposed a methodology for FS in unsupervised learning for handwritten month word recognition. It makes use of the Nondominated Sorting genetic algorithm (NSGA) proposed by Srinivas (Srinivas, Deb, 1995) which deals with multi-objective optimization. The objective is to find a set of nondominant solutions which contain the more discriminant features and the more pertinent number of clusters. Two criteria are used to guide the search: minimization of the number of features and minimization of a validity index that measures the quality of clusters. A standard K-means algorithm is applied to form the given number of clusters based on the selected features.

In another approach, using a new method called ReliefF (Zhang, Wang, Zhao, & Yang, 2003), the key idea is to estimate the quality of attributes according to how well their values distinguish between the instances that are near to each other. For that purpose, given a randomly selected instance *R*, ReliefF searches for k-NN from the same class, called nearHits, and also k-NN from each of the different classes, called nearMisses. The quality estimation w [A] for each A is updated depending on *R*, nearHits and nearMisses. In the update formula, the contribution of all the hits and misses are averaged. The process is repeated for m times to R retum weights of all features, where m is a user-defined parameter. ReliefF is fast, not lim-

ited by data types, fairly attribute noise-tolerant, and unaffected by feature interaction, but it does not deal well with redundant features. GA-Wrapper and ReliefF-GA-Wrapper methods are proposed and shown experimentally that ReliefF-GA-Wrapper gets better accuracy than GA-Wrapper.

An online FS algorithm using genetic programming (GP), named as GPmfts (multitree genetic programming based FS), is presented in (Muni, Pal, & Das, 2006). For a *c*–class problem, a population of classifiers, each having c trees is constructed using a randomly chosen feature subset. The size of the feature subset is determined probabilistically by assigning higher probabilities to smaller sizes. The classifiers which are more accurate using a small number of features are given higher probability to pass through the GP evolutionary operations. The method automatically selects the required features while designing classifiers for a multi-category classification problem.

FUTURE TRENDS

DR is an important component of data mining. Besides GA, there are several EP based DR techniques like PSO, ACO which are still unexplored and it will be interesting to apply these techniques. In addition, other techniques like wavelet, PCA , decision trees, rough sets can also be applied for DR. A good hybridization of existing techniques can also be modeled to take merits of inherent individual techniques.

CONCLUSION

This article presents various DR techniques using EP approaches in general and GA in particular. It can be observed that every technique has its own merits and limitations depending on the size and nature of the data sets. A Data set for which FS and FE require exhaustive search, evolutionary/GA methods is a natural selection as in the case of handwritten digit string recognition (Oliveira, & Sabourin, 2003) because GA makes efforts to simultaneous allocation of search in many regions of the search space, this is also known as implicit parallelism. It can be noted from various results presented by researchers that GA with variations in crossover, selection, mutation, and even in fitness function can be made more effective in finding an optimal subset of features.

KEY TERMS

Classification: It refers to labeling a class to a pattern in a data set. It can be supervised, when label is given and unsupervised when no labeling is given in advance. The accuracy of classification is a major criterion to achieve DR as removing features should not affect the classification accuracy of the data set.

Dimensionality Reduction (DR): The attributes in a data set are called features. The number of features in a data set is called its dimensionality. Eliminating redundant or harmful features from a data set is called DR.

Feature Analysis: It includes feature selection (FS) and feature extraction (FE). FS selects subset of features from the data set where as FE combines subsets of features to generate a new feature.

Genetic Algorithms (GA): These are randomized search and optimization methods based on principles of evolution and natural genetics. The algorithms apply crossover, selection, mutation and elitism operations to seek better solution with every execution.

Evolutionary Computation and Genetic Algorithms

William H. Hsu
Kansas State University, USA

INTRODUCTION

A **genetic algorithm** (**GA**) is a method used to find approximate solutions to difficult search, optimization, and machine learning problems (Goldberg, 1989) by applying principles of evolutionary biology to computer science. Genetic algorithms use biologically-derived techniques such as inheritance, mutation, natural selection, and recombination. They are a particular class of evolutionary algorithms.

Genetic algorithms are typically implemented as a computer simulation in which a population of abstract representations (called *chromosomes*) of candidate solutions (called *individuals*) to an optimization problem evolves toward better solutions. Traditionally, solutions are represented in binary as strings of 0s and 1s, but different encodings are also possible. The evolution starts from a population of completely random individuals and happens in generations. In each generation, multiple individuals are stochastically selected from the current population, modified (mutated or recombined) to form a new population, which becomes current in the next iteration of the algorithm.

BACKGROUND

Operation of a GA

The problem to be solved is represented by a list of parameters, referred to as *chromosomes* or genomes by analogy with genome biology. These parameters are used to drive an evaluation procedure. Chromosomes are typically represented as simple strings of data and instructions, in a manner not unlike instructions for a von Neumann machine. A wide variety of other data structures for storing chromosomes have also been tested, with varying degrees of success in different problem domains.

Initially several such parameter lists or chromosomes are generated. This may be totally random, or the programmer may seed the gene pool with "hints" to form an initial pool of possible solutions. This is called the *first generation pool*.

During each successive generation, each organism is evaluated, and a measure of quality or *fitness* is returned by a fitness function. The pool is sorted, with those having better fitness (representing better solutions to the problem) ranked at the top. "Better" in this context is relative, as initial solutions are all likely to be rather poor.

The next step is to generate a second generation pool of organisms, which is done using any or all of the genetic operators: selection, crossover (or recombination), and mutation. A pair of organisms is selected for breeding. Selection is biased towards elements of the initial generation which have better fitness, though it is usually not so biased that poorer elements have no chance to participate, in order to prevent the solution set from converging too early to a sub-optimal or local solution. There are several well-defined organism selection methods; roulette wheel selection and tournament selection are popular methods.

Following selection, the *crossover* (or *recombination*) operation is performed upon the selected chromosomes. Most genetic algorithms will have a single tweakable *probability of crossover* (P_c), typically between 0.6 and 1.0, which encodes the probability that two selected organisms will actually breed. A random number between 0 and 1 is generated, and if it falls under the crossover threshold, the organisms are mated; otherwise, they are propagated into the next generation unchanged. Crossover results in two new child chromosomes, which are added to the second generation pool. The chromosomes of the parents are mixed in some way during crossover, typically by simply swapping a portion of the underlying data structure (although other, more complex merging mechanisms have proved useful for certain types of problems.) This process is repeated with different parent organisms until there are an appropriate number of candidate solutions in the second generation pool.

The next step is to mutate the newly created offspring. Typical genetic algorithms have a fixed, very small *probability of mutation (P_m)* of perhaps 0.01 or less. A random number between 0 and 1 is generated; if it falls within the P_m range, the new child organism's chromosome is randomly mutated in some way, typically by simply randomly altering bits in the chromosome data structure.

These processes ultimately result in a second generation pool of chromosomes that is different from the initial generation. Generally the average degree of fitness will have increased by this procedure for the second generation pool, since only the best organisms from the first generation are selected for breeding. The entire process is repeated for this second generation: each organism in the second generation pool is then evaluated, the fitness value for each organism is obtained, pairs are selected for breeding, a third generation pool is generated, etc. The process is repeated until an organism is produced which gives a solution that is "good enough".

A slight variant of this method of pool generation is to allow some of the better organisms from the first generation to carry over to the second, unaltered. This form of genetic algorithm is known as an *elite selection strategy*.

MAIN THRUST OF THE CHAPTER

Observations

There are several general observations about the generation of solutions via a genetic algorithm:

- GAs may have a tendency to converge towards local solutions rather than global solutions to the problem to be solved.
- Operating on dynamic data sets is difficult, as genomes begin to converge early on towards solutions which may no longer be valid for later data. Several methods have been proposed to remedy this by increasing genetic diversity somehow and preventing early convergence, either by increasing the probability of mutation when the solution quality drops (called *triggered hypermutation*), or by occasionally introducing entirely new, randomly generated elements into the gene pool (called *random immigrants*).
- As time goes on, each generation will tend to have multiple copies of successful parameter lists, which require evaluation, and this can slow down processing.
- Selection is clearly an important genetic operator, but opinion is divided over the importance of crossover verses mutation. Some argue that crossover is the most important, while mutation is only necessary to ensure that potential solutions are not lost. Others argue that crossover in a largely uniform population only serves to propagate innovations originally found by mutation, and in a non-uniform population crossover is nearly always equivalent to a very large mutation (which is likely to be catastrophic).
- Though GAs can be used for global optimization in known intractable domains, GAs are not always good at finding optimal solutions. Their strength tends to be in rapidly locating *good* solutions, even for difficult search spaces.

Variants

The simplest algorithm represents each chromosome as a bit string. Typically, numeric parameters can be represented by integers, though it is possible to use floating point representations. The basic algorithm performs crossover and mutation at the bit level.

Other variants treat the chromosome as a list of numbers which are indexes into an instruction table, nodes in a linked list, hashes, objects, or any other imaginable data structure. Crossover and mutation are performed so as to respect data element boundaries. For most data types, specific variation operators can be designed. Different chromosomal data types seem to work better or worse for different specific problem domains.

Efficiency

Genetic algorithms are known to produce good results for some problems. Their major disadvantage is that they are relatively slow, being very computationally intensive compared to other methods, such as random optimization.

Recent speed improvements have focused on speciation, where crossover can only occur if individuals are closely-enough related.

Genetic algorithms are extremely easy to adapt to parallel computing and clustering environments. One method simply treats each node as a parallel population. Organisms are then migrated from one pool to another according to various propagation techniques.

Another method, the Farmer/worker architecture, designates one node the *farmer*, responsible for organism selection and fitness assignment, and the other nodes as *workers*, responsible for recombination, mutation, and function evaluation.

GA Approaches to Data Mining: Feature Selection, Variable Ordering, Clustering

A genetic program is ideal for implementing wrappers where parameters are naturally encoded as chromosomes such as bit strings or permutations. This is precisely the case with variable (feature subset) selection, where a bit string can denote membership in the subset. Both feature selection (also called *variable elimination*) and variable ordering are methods for inductive bias control where the input representation is changed from the default: the original set of variables in a predetermined or random order.

- **Wrappers for feature selection:** Yang and Honavar (1998) describe how to develop a basic GA for feature selection. With a genetic wrapper, we seek to evolve parameter values using the performance criterion of the overall learning system as fitness. The term *wrapper* refers to the inclusion of an inductive learning module, or inducer, that produces a trained model such as a decision tree; the GA "wraps" around this module by taking the output of each inducer applied to a projection of the data that is specified by an individual chromosome, and measuring the fitness of this output. That is, it validates the model on holdout or cross-validation data. The performance of the overall system depends on the quality of the validation data, the fitness criterion, and also the "wrapped" inducer. For example, Minaei-Bidgoli and Punch (2003) report good results for a classification problem in the domain of education (predicting student performance) using a GA in tandem with principal components analysis (PCA) for front-end feature extraction and *k*-nearest neighbor as the wrapped inducer.
- **Wrappers for variable ordering:** To encode a variable ordering problem using a GA, a chromosome must represent a permutation α that describes the order in which variables are considered. In Bayesian network structure learning, for example, the permutation dictates an ordering of candidate nodes (variables) in a graphical model whose structure is unknown.
- **Clustering:** In some designs, a GA is used to perform feature extraction as well. This can be a single integrated GA for feature selection and extraction or one specially designed to perform clustering as Maulika and Bandyopadhyay (2000) developed.

Many authors of GA-based wrappers have independently derived criteria that resemble *minimum description length* (*MDL*) estimators – that is, they seek to minimize model size and the sample complexity of input as well as maximize generalization accuracy.

An additional benefit of genetic algorithm-based wrappers is that it can automatically calibrate "empirically determined" constants such as the coefficients *a*, *b*, and *c* introduced in the previous section. As we noted, this can be done using individual training data sets rather than assuming that a single optimum exists for a large set of machine learning problems. This is preferable to empirically calibrating parameters as if a single "best mixture" existed. Even if a very large and representative corpus of data sets were used for this purpose, there is no reason to believe that there is a single *a posteriori* optimum for genetic parameters such as weight allocation to inferential loss, model complexity, and sample complexity of data in the variable selection wrapper.

Finally, genetic wrappers can "tune themselves" – for example, the GA-based inductive learning system of De Jong and Spears (1991) learns propositional rules from data and adjusts constraint parameters that control how these rules can be generalized. Mitchell notes (1997) that this is a method for evolving the learning strategy itself. Many classifier systems also implement performance-tuning wrappers in this way. Finally, population size and other constants for controlling elitism, niching, sharing, and scaling can be controlled using automatically tuned, or "parameterless", GAs.

GA Approaches to Data Warehousing and Data Modeling

Cheng, Lee, and Wong (2002) apply a genetic algorithm to perform vertical partitioning of a relational database via clustering. The objective is to minimize the number of page accesses (block transfers and seeks) while grouping some attributes of the original relations into frequently-used vertical class fragments. By treating the table of transactions versus attributes as a map to be divided into contiguous clusters, (Cheng, et al., 2002). are able to reformulate the vertical partitioning problem as a Traveling Salesman Problem, a classical *NP*-complete optimization problem where genetic algorithms have successfully been applied (Goldberg, 1989). Zhang, et al. (2001) use a query cost-driven genetic algorithm to optimize single composite queries, multiple queries with reusable relational expressions, and precomputed materialized views for data warehousing. The latter is treated as a feature selection problem represented using a simple GA with single-point crossover. Osinski (2005) uses a similar approach to select subcubes and construct indices as a step in query optimization. The goal for all of the above researchers was a database that responds efficiently to data warehousing and online analytical processing operations.

GA-Based Inducers

De Jong and Spears (1991) pioneered the use of GAs in rule induction, but work on integrating the various criteria for rule quality, including various interestingness measures, continues. Ghosh and Nath (2004) have recently explored the intrinsically multi-objective fitness of rules, which trade novelty against generality and applicability (coverage) and accuracy. Shenoy *et al.* (2005) show how GAs provide a viable adaptive method for dealing with rule induction from dynamic data sets — those that reflect frequent changes in consumer habits and buying patterns.

Problem domains

Problems which appear to be particularly appropriate for solution by genetic algorithms include timetabling and scheduling problems, and many scheduling software packages are based on GAs. GAs have also been applied to engineering and are often applied as an approach to solve global optimization problems. Because of their ability to deal with hard problems, particularly by exploring combinatorially large and complex search spaces rapidly, GAs have been seen by researchers such as Flockhart and Radcliffe (1996) as a potential guiding mechanism for knowledge discovery in databases, that can tune parameters such as interestingness measures, and "steer" a data mining system away from wasteful patterns and rules.

History

John Holland was the pioneering founder of much of today's work in genetic algorithms, which has moved on from a purely theoretical subject (though based on computer modelling) to provide methods which can be used to actually solve some difficult problems today.

Pseudo-code Algorithm

Choose initial population
Evaluate each individual's fitness
Repeat
    Select best-ranking individuals to reproduce
    Mate pairs at random
    Apply crossover operator
    Apply mutation operator
    Evaluate each individual's fitness
Until terminating condition (see below)

Terminating conditions often include:

- Fixed number of generations reached
- Budgeting: Allocated computation time/money used up
- An individual is found that satisfies minimum criteria
- The highest ranking individual's fitness is reaching or has reached a plateau such that successive iterations are not producing better results anymore.
- Manual inspection: May require start-and-stop ability
- Combinations of the above

FUTURE TRENDS

Related techniques

Genetic programming is a related technique developed by John Koza, in which computer programs, rather than

function parameters, are optimised. Genetic programming often uses tree-based internal data structures to represent the computer programs for adaptation instead of the list, or array, structures typical of genetic algorithms. Genetic programming algorithms typically require running time that is orders of magnitude greater than that for genetic algorithms, but they may be suitable for problems that are intractable with genetic algorithms.

CONCLUSION

Genetic algorithms provide a parallelizable and flexible mechanism for search and optimization that can be applied to several crucial problems in data warehousing and mining. These include feature selection, partitioning, and extraction (especially by clustering). However, as Goldberg (2002) notes, the science of genetic algorithms is still emerging, with new analytical methods ranging from schema theory to Markov chain analysis providing different ways to design working GA-based systems. The complex dynamics of genetic algorithms makes some engineers and scientists reluctant to use them for applications where convergence must be precisely guaranteed or predictable; however, genetic algorithms remain a very important general-purpose methodology that sometimes provides solutions where deterministic and classical stochastic methods fail. In data mining and warehousing, as in other domains where machine learning and optimization problems abound, genetic algorithms are useful because their fitness-driven design formulation makes them easy to automate and experiment with.

KEY TERMS

Chromosome: In genetic and evolutionary computation, a representation of the degrees of freedom of the system; analogous to a (stylized) biological chromosome, the threadlike structure which carries genes, the functional units of heredity.

Crossover: The sexual reproduction operator in genetic algorithms, typically producing one or two offspring from a selected pair of parents.

Evolutionary Computation: Solution approach guided by biological evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a model that best represents the data.

Mutation: One of two random search operators in genetic algorithms, or the sole one in selecto-mutative evolutionary algorithms, changing chromosomes at a randomly selected point.

Rule Induction: Process of learning, from cases or instances, if-then rule relationships consisting of an antecedent (if-part, defining the preconditions or coverage of the rule) and a consequent (then-part, stating a classification, prediction, or other expression of a property that holds for cases defined in the antecedent).

Selection: The means by which the fittest individuals are chosen and propagate from generation to generation in a GA.

Evolutionary Data Mining for Genomics

INTRODUCTION

Knowledge discovery from genomic data has become an important research area for biologists. Nowadays, a lot of data is available on the web, but the corresponding knowledge is not necessarly also available. For example, the first draft of the human genome, which contains 3×10^9 letters, has been achieved in June 2000, but up to now only a small part of the hidden knowledge has been discovered. The aim of bioinformatics is to bring together biology, computer science, mathematics, statistics and information theory to analyze biological data for interpretation and prediction. Hence many problems encountered while studying genomic data may be modeled as data mining tasks, such as feature selection, classification, clustering, and association rule discovery.

An important characteristic of genomic applications is the large amount of data to analyze and it is, most of the time, not possible to enumerate all the possibilities. Therefore, we propose to model these knowledge discovery tasks as combinatorial optimization tasks, in order to apply efficient optimization algorithms to extract knowledge from large datasets. To design an efficient optimization algorithm, several aspects have to be considered. The main one is the choice of the type of resolution method according to the characteristics of the problem. Is it an easy problem, for which a polynomial algorithm may be found? If yes, let us design such an algorithm. Unfortunately, most of the time the response to the question is 'NO' and only heuristics, that may find good but not necessarily optimal solutions, can be used. In our approach we focus on evolutionary computation, which has already shown an interesting ability to solve highly complex combinatorial problems.

In this chapter, we will show the efficiency of such an approach while describing the main steps required to solve data mining problems from genomics with evolutionary algorithms. We will illustrate these steps with a real problem.

BACKGROUND

Evolutionary data mining for genomics groups three important fields: Evolutionary computation, knowledge discovery and genomics.

It is now well known that evolutionary algorithms are well suited for some data mining tasks and the reader may refer, for example, to (Freitas, 2008).

Here we want to show the interest of dealing with genomic data using evolutionary approaches. A first proof of this interest may be the book of Gary Fogel and David Corne on « Evolutionary Computation in Bioinformatics » which groups several applications of evolutionary computation to problems in the biological sciences, and in particular in bioinformatics (Corne, Pan, Fogel, 2008). In this book, several data mining tasks are addressed, such as feature selection or clustering, and solved thanks to evolutionary approaches.

Another proof of the interest of such approaches is the number of sessions around "Evolutionary computation in bioinformatics" in congresses on Evolutionary Computation. Man can take as an example, EvoBio, European Workshop on Evolutionary Computation and Machine Learning in Bioinformatics, or the special sessions on "Evolutionary computation in bioinformatics and computational biology" that have been organized during the last Congresses on Evolutionary Computation (CEC'06, CEC'07).

The aim of genomic studies is to understand the function of genes, to determine which genes are involved

in a given process and how genes are related. Hence experiments are conducted, for example, to localize coding regions in DNA sequences and/or to evaluate the expression level of genes in certain conditions. Resulting from this, data available for the bioinformatics researcher may not only deal with DNA sequence information but also with other types of data like for example in multi-factorial diseases the Body Mass Index, the sex, and the age. The example used to illustrate this chapter may be classified in this category.

Another type of data deals with the recent technology, called microarray, which allows the simultaneous measurement of the expression level of thousand of genes under different conditions (various time points of a process, absorption of different drugs…). This type of data requires specific data mining tasks as the number of genes to study is very large and the number of conditions may be limited. This kind of technology has now been extended to protein microarrays and generates also large amount of data. Classical questions are the classification or the clustering of genes based on their expression pattern, and commonly used approaches may vary from statistical approaches (Yeung & Ruzzo, 2001) to evolutionary approaches (Merz, 2002) and may use additional biological information such as the Gene Ontology - GO - (Speer, Spieth & Zell, 2004). A bi-clustering approach that allows the grouping of instances having similar characteristic for a subset of attributes (here, genes having the same expression patterns for a subset of conditions), has been applied to deal with this type of data and evolutionary approaches proposed (Bleuler, Prelié & Ziztler, 2004). Some authors are also working on the proposition of highly specialized crossover and mutation operators (Hernandez, Duval & Hao, 2007). In this context of microarray data analysis, data mining approaches have been proposed. Hence, for example, association rule discovery has been realized using evolutionary algorithms (Khabzaoui, Dhaenens & Talbi, 2004), as well as feature selection and classification (Jirapech-Umpai & Aitken, 2005).

MAIN THRUST OF THE CHAPTER

In order to extract knowledge from genomic data using evolutionary algorithms, several steps have to be considered:

1. Identification of the knowledge discovery task from the biological problem under study,
2. Design of this task as an optimization problem,
3. Resolution using an evolutionary approach.

In this part, we will focus on each of these steps. First we will present the genomic application we will use to illustrate the rest of the chapter and indicate the knowledge discovery tasks that have been extracted. Then we will show the challenges and some proposed solutions for the two other steps.

Genomics Application

The genomic problem under study is to formulate hypothesis on predisposition factors of different multifactorial diseases such as diabetes and obesity. In such diseases, one of the difficulties is that healthy people can become affected during their life so only the affected status is relevant. This work has been done in collaboration with the Biology Institute of Lille (IBL).

One approach aims to discover the contribution of environmental factors and genetic factors in the pathogenesis of the disease under study by discovering complex interactions such as [(gene A and gene B) or (gene C and environmental factor D)] in one or more population. The rest of the paper will take this problem as an illustration.

To deal with such a genomic application, the first thing is to formulate the underlying problem into a classical data mining task. This work must be done through discussions and cooperations with biologists in order to agree on the aim of the study. For example, in data of the problem under study, identifying groups of people can be modeled as a clustering task as we can not take into account non-affected people. Moreover a lot of attributes (features) have to be studied (a choice of 3652 points of comparison on the 23 chromosomes and two environmental factors) and classical clustering algorithms are not able to cope with so many features. So we decide to firstly execute a feature selection in order to reduce the number of loci into consideration and to extract the most influential features which will be used for the clustering. Hence, the model of this problem is decomposed into two phases: feature selection and clustering. The clustering is used to group individuals of same characteristics.

From a Data Mining Task to an Optimization Problem

One of the main difficulty in turning a data mining task into an optimization problem is to define the criterion to optimize. The choice of the optimization criterion which measures the quality of candidate knowledge to be extracted is very important and the quality of the results of the approach depends on it. Indeed, developing a very efficient method that does not use the right criterion will lead to obtain "the right answer to the wrong question"!! The optimization criterion can be either specific to the data mining task or dependent on the biological application, and different choices exist. For example, considering the gene clustering, the optimization criterion can be the minimization of the minimum sum-of-squares (MSS) (Merz, 2002) while for the determination of the members of a predictive gene group, the criterion can be the maximization of the classification success using a maximum likelihood (MLHD) classification method (Ooi & Tan, 2003).

Once the optimization criterion is defined, the second step of the design of the data mining task into an optimization problem is to define the encoding of a solution which may be independent of the resolution method. For example, for clustering problems in gene expression mining with evolutionary algorithm, Faulkenauer and Marchand (2001) used the specific CGA encoding that is dedicated to grouping problems and is well suited to clustering.

Regarding the genomic application used to illustrate the chapter, two phases are isolated. For the feature selection, an optimization approach is adopted, using an evolutionary algorithm (see next paragraph) whereas a classical approach (k-means) is chosen for the clustering phase (MacQueen, 1967). Determining the optimization criterion for the feature selection was not an easy task as it is difficult not to favor small sets of features. A corrective factor is introduced (Jourdan et al., 2002).

Solving with Evolutionary Algorithms

Once the formalization of the data mining task into an optimization problem is done, resolution methods can be either, exact methods, specific heuristics or metaheuristics. As the space of the potential knowledge is exponential in genomics problems (Zaki & Ho, 2000), exact methods are almost always discarded. The drawbacks of heuristic approaches are that it is difficult to cope with multiple solutions and not easy to integrate specific knowledge in a general approach. The advantages of metaheuristics are that you can define a general framework to solve the problem while specializing some agents in order to suit to a specific problem. Genetic Algorithms (GAs), which represent a class of evolutionary methods, have given good results on hard combinatorial problems (Michalewicz, 1996).

In order to develop a genetic algorithm for knowledge discovery, we have to focus on:

- Operators,
- Diversification mechanisms,
- Intensification mechanisms.

Operators allow GAs to explore the search space and must be adapted to the problem. There are commonly two classes of operators: mutation and crossover. The mutation allows diversity. For the feature selection task under study, the mutation flips *n* bits (Jourdan, Dhaenens & Talbi, 2001). The crossover produces one, two or more children solutions by recombining two or more parents. The objective of this mechanism is to keep useful information of the parents in order to ameliorate the solutions. In the considered problem, the subset-oriented common feature crossover operator (SSOCF) has been used. Its objective is to produce offsprings that have a distribution similar to their parents. This operator is well adapted for feature selection (Emmanouilidis, Hunter & MacIntyre, 2000). Another advantage of evolutionary algorithms is that you can easily use other data mining algorithms as an operator; for example a kmeans iteration may be used as an operator in a clustering problem (Krishma & Murty, 1999).

Working on knowledge discovery on a particular domain with optimization methods leads to the definition and the use of several operators, where some may use domain knowledge and some other may be specific to the model and/or the encoding. To take advantage of all the operators, the idea is to use adaptive mechanisms (Hong, Wang & Chen, 2000) that help to adapt application probabilities of these operators according to the progress they produce. Hence, operators that are less efficient are less used and this may change during the search if they become more efficient.

Diversification mechanisms are designed to avoid premature convergence. There exist several mecha-

nisms. The more classical are the sharing and the random immigrant. The sharing boosts the selection of individuals that lie in less crowded areas of the search space. To apply such a mechanism, a distance between solutions has to be defined. In the feature selection for the genomic association discovery, a distance has been defined by integrating knowledge of the application domain. The distance is correlated to a Hamming distance which integrates biological notions (chromosomal cut, inheritance notion…).

A further approach to the diversification of the population, is 'the random immigrant' that introduces new individuals. An idea is to generate new individuals by recording statistics on previous selections.

Assessing the efficiency of such algorithms applied to genomic data is not easy as most of the time, biologists have no exact idea about what must be found. Hence, one step in this analysis is to develop simulated data for which optimal results are known. In this manner it is possible to measure the efficiency of the proposed method. For example, for the problem under study, predetermined genomic associations were constructed to form simulated data. Then the algorithm has been tested on these data and was able to find these associations.

FUTURE TRENDS

There is much works on evolutionary data mining for genomics. In order to be more and more efficient and to propose more interesting solutions to biologists, the researchers are investigating multicriteria design of the data mining tasks. Indeed, we exposed that one of the critical phases was the determination of the optimization criterion, and it may be difficult to select a single one. As a response to this problem, the multicriteria design allows us to take into account some criteria dedicated to a specific data mining task and some criteria coming from the application domain. Evolutionary algorithms that work on a population of solutions, are well adapted to multicriteria problems as they can exploit Pareto approaches and propose several good solutions (solutions of best compromise).

For data mining in genomics, association rule discovery has not been very well applied, and should be studied carefully as this is a very general model. Moreover, an interesting multicriteria model has been proposed for this task and starts to give some interesting results by using multicriteria genetic algorithms (Jourdan et al., 2004).

CONCLUSION

Genomic is a real challenge for researchers in data mining as most of the problems encountered are difficult to address for several reasons: 1/ the objectives are not always very clear, neither for the data mining specialist, nor for the biologist and a real dialog has to exist between the two; 2/ data may be uncertain and noisy; 3/ the number of experiments may be not enough in comparison with the number of elements that have to be studied.

In this chapter we present the different phases required to deal with data mining problems arriving in genomics thanks to optimization approaches. The objective was to give, for each phase, the main challenges and to illustrate through an example some responses. We saw that the definition of the optimization criterion is a central point of this approach and the multicriteria optimization may be used as a response to this difficulty.

KEY TERMS

Association Rule Discovery: Implication of the form X → Y where X and Y are sets of items, that indicates that if the condition X is verified, the prediction may be Y valid according to quality criteria (support, confidence, surprise, …).

Bioinformatics: Field of science in which biology, computer science, and information technology merge into a single discipline.

Clustering: Data mining task in which the system has to group a set of objects without any information on the characteristics of the classes.

Crossover (in Genetic algorithm): Genetic operator used to vary the genotype of a chromosome or chromosomes from one generation to the next. It is analogous to reproduction and biological crossover, upon which genetic algorithms are based.

Feature (or Attribute): Quantity or quality describing an instance.

Feature Selection: Task of identifying and selecting a useful subset of features from a large set of redundant, perhaps irrelevant, features.

Genetic Algorithm: Evolutionary algorithm using a population and based on the Darwinian principle: the "survive of the fittests".

Multifactorial Disease: Disease caused by several factors. Often, multifactorial diseases are due to two kinds of causality which interact: one is genetic (and often polygenetic) and the other is environmental.

Mutation (in Genetic algorithm): Genetic operator used to maintain genetic diversity from one generation of a population of chromosomes to the next. It is analogous to biological mutation and it modifies a small part of the genotype.

Optimization Criterion: Measure that evaluates the quality of a solution of an optimization problem.

INTRODUCTION

Artificial Neural Networks (ANNs) are learning systems from the Artificial Intelligence (AI) world that have been used for solving complex problems related to different aspects as classification, clustering, or regression (Haykin, 1999), although they have been specially used in Data Mining. These systems are, due to their interesting characteristics, powerful techniques used by the researchers in different environments (Rabuñal, 2005).

Nevertheless, the use of ANNs implies certain problems, mainly related to their development processes. The development of ANNs can be divided into two parts: architecture development and training and validation. The architecture development determines not only the number of neurons of the ANN, but also the type of the connections among those neurons. The training will determine the connection weights for such architecture.

Traditionally, and given that the architecture of the network depends on the problem to be solved, the architecture design process is usually performed by the use of a manual process, meaning that the expert has to test different architectures to find the one able to achieve the best results. Therefore, the expert must perform various tests for training different architectures in order to determine which one of these architectures is the best one. This is a slow process due to the fact that architecture determination is a manual process, although techniques for relatively automatic creation of ANNs have been recently developed.

This work presents various techniques for the development of ANNs, so that there would be needed much less human participation for such development.

BACKGROUND

The development of ANNs has been widely treated with very different techniques in AI. The world of evolutionary algorithms is not an exception, and proof of it is the large amount of works that have been published is this aspect using several techniques (Nolfi, 2002; Cantú-Paz, 2005). These techniques follow the general strategy of an evolutionary algorithm: an initial population with different types of genotypes encoding also different parameters – commonly, the connection weights and/or the architecture of the network and/or the learning rules – is randomly created. Such population is evaluated for determining the fitness of every individual. Subsequently, the population is repeatedly induced to evolve by means of different genetic operators (replication, crossover, mutation) until a certain termination parameter has been fulfilled (for instance, the achievement of an individual good enough or the accomplishment of a predetermined number of generations).

As a general rule, the field of ANNs generation using evolutionary algorithms is divided into three

main groups: evolution of weights, architectures and learning rules.

The evolution of weight starts from an ANN with an already determined topology. In this case, the problem to be solved is the training of the connection weights, attempting to minimise the network failure. Most of training algorithms, as backpropagation (BP) algorithm (Rumelhart, 1986), are based on gradient minimisation, which presents several inconveniences (Sutton, 1986). The main of these disadvantages is that, quite frequently, the algorithm gets stuck into a local minimum of the fitness function and it is unable to reach a global minimum. One of the options for overcoming this situation is the use of an evolutionary algorithm, so the training process is done by means of the evolution of the connection weights within the environment defined by both, the network architecture, and the task to be solved. In such cases, the weights can be represented either as the concatenation of binary values or of real numbers on a genetic algorithm (GA) (Greenwood, 1997). The main disadvantage of this type of encoding is the permutation problem. This problem means that the order in which weights are taken at the vector might cause that equivalent networks might correspond to completely different chromosomes, making the crossover operator inefficient.

The evolution of architectures includes the generation of the topological structure. This means establishing the connectivity and the transfer function of each neuron. The network architecture is highly important for the successful application of the ANN, since the architecture has a very significant impact on the processing ability of the network. Therefore, the network design, traditionally performed by a human expert using trial and error techniques on a group of different architectures, is crucial. In order to develop ANN architectures by means of an evolutionary algorithm it is needed to choose how to encode the genotype of a given network for it to be used by the genetic operators.

At the first option, direct encoding, there is a one-to-one correspondence between every one of the genes and their subsequent phenotypes (Miller, 1989). The most typical encoding method consists of a matrix that represents an architecture where every element reveals the presence or absence of connection between two nodes (Alba, 1993). These types of encoding are generally quite simple and easy to implement. However, they also have a large amount of inconveniences as scalability (Kitano, 1990), the incapability of encoding repeated structures, or permutation (Yao, 1998).

In comparison with direct encoding, there are some indirect encoding methods. In these methods, only some characteristics of the architecture are encoded in the chromosome and. These methods have several types of representation.

Firstly, the parametric representations represent the network as a group of parameters such as number of hidden layers, number of nodes for each layer, number of connections between two layers, etc (Harp, 1989). Although the parametric representation can reduce the length of the chromosome, the evolutionary algorithm performs the search within a restricted area in the search space representing all the possible architectures. Another non direct representation type is based on a representation system that uses the grammatical rules (Kitano, 1990). In this system, the network is represented by a group of rules, shaped as production rules that make a matrix that represents the network, which has several restrictions.

The growing methods represent another type of encoding. In this case, the genotype does not encode a network directly, but it contains a group of instructions for building up the phenotype. The genotype decoding will consist on the execution of those instructions (Nolfi, 2002), which can include neuronal migrations, neuronal duplication or transformation, and neuronal differentiation.

Another important non-direct codification is based on the use of fractal subsets of a map. According to Merrill (1991), the fractal representation of the architectures is biologically more plausible than a representation with the shape of rules. Three parameters are used which take real values to specify each node in an architecture: a border code, an entry coefficient and an exit code.

One important characteristic to bear in mind is that all those methods evolve architectures, either alone (most commonly) or together with the weights. The transfer function for every node of the architecture is supposed to have been previously fixed by a human expert and is the same for all the nodes of the network –or at least, all the nodes of the same layer–, despite of the fact that such function has proved to have a significant impact on network performance (DasGupta, 1992). Only few methods that also induce the evolution of the transfer function have been developed (Hwang, 1997).

With regards to the evolution of the learning rule, there are several approaches (Turney, 1996), although

most of them are only based on how learning can modify or guide the evolution and also on the relationship among the architecture and the connection weights. There are only few works focused on the evolution of the learning rule itself.

ANN DEVELOPMENT WITH GENETIC PROGRAMMING

This section very briefly shows an example of how to develop ANNs using an AI tool, Genetic Programming (GP), which performs an evolutionary algorithm, and how it can be applied to Data Mining tasks.

Genetic Programming

GP (Koza, 92) is based on the evolution of a given population. Its working is similar to a GA. In this population, every individual represents a solution for a problem that is intended to be solved. The evolution is achieved by means of the selection of the best individuals – although the worst ones have also a little chance of being selected – and their mutual combination for creating new solutions. This process is developed using selection, crossover and mutation operators. After several generations, the population is expected to contain some good solutions for the problem.

The GP encoding for the solutions is tree-shaped, so the user must specify which are the terminals (leaves of the tree) and the functions (nodes capable of having descendants) for being used by the evolutionary algorithm in order to build complex expressions. These can be mathematical (including, for instance, arithmetical or trigonometric operators), logical (with Boolean or relational operators, among others) or other type of even more complex expressions.

The wide application of GP to various environments and its consequent success are due to its capability for being adapted to numerous different problems. Although the main and more direct application is the generation of mathematical expressions (Rivero, 2005), GP has been also used in others fields such as filter design (Rabuñal, 2003), knowledge extraction (Rabuñal, 2004), image processing (Rivero, 2004), etc.

Model Overview

The GP-development of ANNs is performed by means of the GP typing property (Montana, 1995). This property provides the ability of developing structures that follow a specific grammar with certain restrictions. In order to be able to use GP to develop any kind of system, it is necessary to specify the set of operators that will be in the tree. With them, the evolutionary system must be able to build correct trees that represent ANNs. An overview of the operators used here can be seen on Table 1.

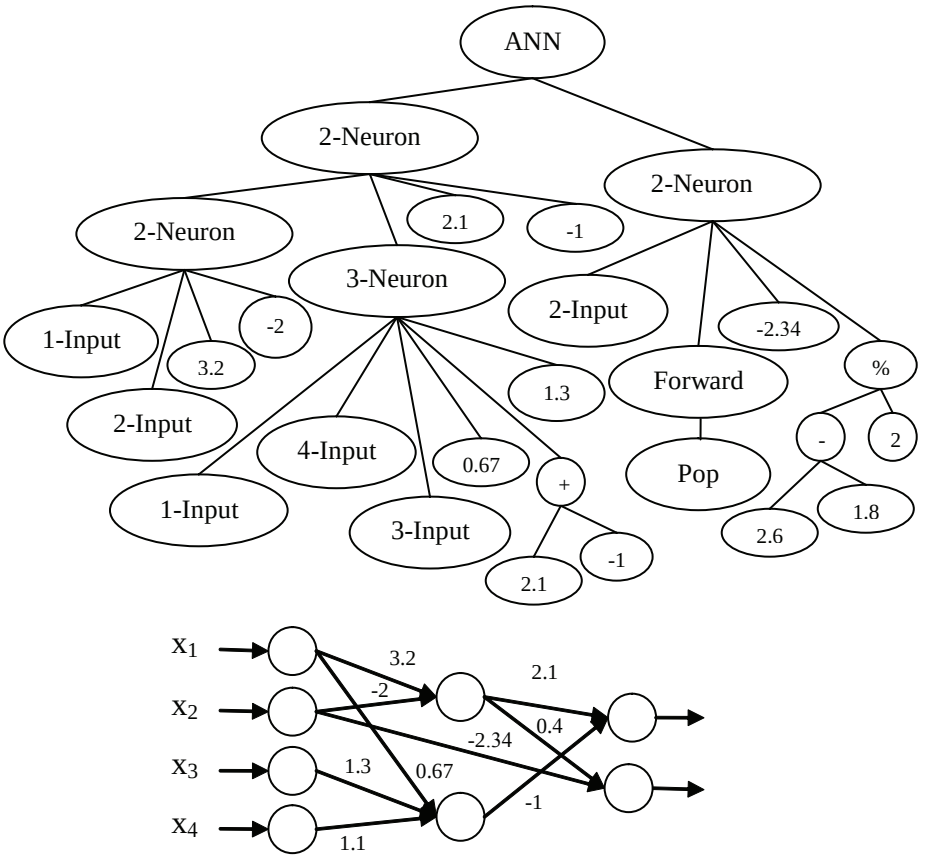
This table shows a summary of the operators that can be used in the tree. This set of terminals and functions are used to build a tree that represents an ANN. Although these sets are not explained in the text, in Fig. 1 can be seen an example of how they can be used to represent an ANN.

These operators are used to build GP trees. These trees have to be evaluated, and, once the tree has been evaluated, the genotype turns into phenotype. In other words, it is converted into an ANN with its weights

Table 1. Summary of the operators to be used in the tree

Node	Type	Num. Children	Children type
ANN	ANN	Num. outputs	NEURON
n-Neuron	NEURON	2*n	n NEURON n REAL (weights)
n-Input	NEURON	0	-
+,-,*,%	REAL	2	REAL
[-4.4]	REAL	0	-
Forward	NEURON	1	NEURON
Pop	NEURON	0	-

Figure. 1. GP tree and its resulting network



already set (thus it does not need to be trained) and therefore can be evaluated. The evolutionary process demands the assignation of a fitness value to every genotype. Such value is the result of the evaluation of the network with the pattern set that represents the problem. This result is the Mean Square Error (MSE) of the difference between the network outputs and the desired outputs. Nevertheless, this value has been modified in order to induce the system to generate simple networks. The modification has been made by adding a penalization value multiplied by the number of neurons of the network. In such way, and given that the evolutionary system has been designed in order to minimise an error value, when adding a fitness value, a larger network would have a worse fitness value. Therefore, the existence of simple networks would be preferred as the penalization value that is added is proportional to the number of neurons at the ANN. The calculus of the final fitness will be as follows:

$$fitness = MSE + N * P$$

Where N is the number of neurons of the network and P is the penalization value for such number.

Example of Applications

This technique has been used for solving problems of different complexity taken from the UCI (Mertz, 2002). All these problems are knowledge-extraction problems from databases where, taking certain features as a basis, it is intended to perform a prediction about another attribute of the database. A small summary of the problems to be solved can be seen at Table 2.

All these databases have been normalised between 0 and 1 and divided into two parts, taking the 70% of the data base for training and using the remaining 30% for performing tests.

Preliminary Results

Several experiments have been performed in order to evaluate the system performance with regards to data mining. The values taken for the parameters at these experiments were the following:

- Crossover rate: 95%.
- Mutation probabillity: 4%.
- Selection algorithm: 2-individual tournament.
- Creation algorithm: Ramped Half&Half.
- Tree maximum height: 6.
- Maximum inputs for each neuron: 12.

Table 3 shows a comparison of the results obtained for different penalization values. The values range from very high (0.1) to very small (0.00001,0). High values only enables the creation of very small networks with a subsequent high error which enables the creation of large networks, and low values lead to overfitting problem. This overfitting can be noticed at the table in the training error decrease together with a test error increase.

The number of neurons as well as of connections that were obtained at the resulting networks is also shown in table 3. Logically, such number is higher as the penalization increases. The results correspond to the MSE obtained after both, the training and the test of every problem. As it can be observed, the results clearly prove that the problems have been satisfactorily solved and, as far as penalization parameter is concerned, intermediate values are preferred for the creation of

Table 2. Summary of the problems to be solved

	Number of inputs	Number of instances	Number of outputs
Breast Cancer	9	699	1
Iris Flower	4	150	3
Ionosphere	34	351	1

Table 3. Results with different penalization values

		Penalization					
		0.1	0.01	0.001	0.0001	0.00001	0

	Connections	6.1	11.95	48.3	128.15	197.4	261.8
	Training	0.09836	0.06253	0.03097	0.02114	0.02264	0.01781
	test	0.10941	0.09127	**0.06854**	0.07269	0.07393	0.07123

networks. These intermediate values in the parameter will allow the creation of networks large enough for solving the problem, avoiding over-fitting, although it should be changed for every problem.

FUTURE TRENDS

The future line of works in this area would be the study of the rest of system parameters in order to evaluate their impact on the results from different problems.

Another interesting line consists on the modification of the GP algorithm for its operation with graphs instead of trees. In such way, the neurons connectivity will be reflected more directly in the genotype, with no need of special operators, therefore positively affecting to the system efficiency.

CONCLUSION

This work presents an overview of techniques in which EC tools are used to develop ANNs. It also presents a new method for ANN creation by means of PG. It is described how the GP algorithm can be configured for the development of simpler networks.

The results presented here are preliminary, since it is needed the performance of more experiments in order to study the effect of the different parameters attending to the complexity of the problem to be solved. In any case, despite using the same parameter values for all the problems during the experiments described here, the results have been quite good.

KEY TERMS

Area of the Search Space: Set of specific ranges or values of the input variables that constitute a subset of the search space.

Artificial Neural Networks: A network of many simple processors ("units" or "neurons") that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Back-Propagation Algorithm: Learning algorithm of ANNs, based on minimising the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns, relationships or obtaining systems that perform useful tasks such as classification, prediction, estimation, or affinity grouping.

Evolutionary Computation: Solution approach guided by biological evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a model that best represents the data.

Genetic Programming: Machine learning technique that uses an evolutionary algorithm in order to optimise the population of computer programs according to a fitness function which determines the capability of a program for performing a given task.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

Genotype: The representation of an individual on an entire collection of genes which the crossover and mutation operators are applied to.

Phenotype: Expression of the properties coded by the individual's genotype.

Population: Pool of individuals exhibiting equal or similar genome structures, which allows the application of genetic operators.

Evolutionary Mining of Rule Ensembles

Jorge Muruzábal
University Rey Juan Carlos, Spain

INTRODUCTION

Ensemble rule based classification methods have been popular for a while in the machine-learning literature (Hand, 1997). Given the advent of low-cost, high-computing power, we are curious to see how far can we go by repeating some basic learning process, obtaining a variety of possible inferences, and finally basing the global classification decision on some sort of ensemble summary. Some general benefits to this idea have been observed indeed, and we are gaining wider and deeper insights on exactly why this is the case in many fronts of interest.

There are many ways to approach the ensemble-building task. Instead of locating ensemble members independently, as in Bagging (Breiman, 1996), or with little feedback from the joint behavior of the forming ensemble, as in Boosting (see, e.g., Schapire & Singer, 1998), members can be created at random and then made subject to an evolutionary process guided by some fitness measure. Evolutionary algorithms mimic the process of natural evolution and thus involve populations of individuals (rather than a single solution iteratively improved by hill climbing or otherwise). Hence, they are naturally linked to ensemble-learning methods. Based on the long-term processing of the data and the application of suitable evolutionary operators, fitness landscapes can be designed in intuitive ways to prime the ensemble's desired properties. Most notably, beyond the intrinsic fitness measures typically used in pure optimization processes, fitness can also be endogenous, that is, it can prime the context of each individual as well.

BACKGROUND

A number of evolutionary mining algorithms are available nowadays. These algorithms may differ in the nature of the evolutionary process or in the basic models considered for the data or in other ways. For example, approaches based on the genetic programming (GP), evolutionary programming (EP), and classifier system (CS) paradigms have been considered, while predictive rules, trees, graphs, and other structures been have evolved. See Eiben and Smith (2003) for an introduction to the general GP, EP, and CS frameworks and Koza, Keane, Streeter, Mydlowec, Yu, and Lanza (2003) for an idea of performance by GP algorithms at the patent level. Here I focus on ensemble –rule based methods for classification tasks or supervised learning (Hand, 1997).

The CS architecture is naturally suitable for this sort of rule assembly problems, for its basic representation unit is the rule, or classifier (Holland, Holyoak, Nisbett, & Thagard, 1986). Interestingly, tentative ensembles in CS algorithms are constantly tested for successful cooperation (leading to correct predictions). The fitness measure seeks to reinforce those classifiers leading to success in each case. However interesting, the CS approach in no way exhausts the scope of evolutionary computation ideas for ensemble-based learning; see, for example, Kuncheva and Jain (2000), Liu, Yao, and Higuchi (2000), and Folino, Pizzuti, and Spezzano (2003).

Ensembles of trees or rules are the natural reference for evolutionary mining approaches. Smaller trees, made by rules (leaves) with just a few tests, are of particular interest. Stumps place a single test and constitute an extreme case (which is nevertheless used often). These rules are more general and hence tend to make more mistakes, yet they are also easier to grasp and explain. A related notion is that of support, the estimated probability that new data satisfy a given rule's conditions. A great deal of effort has been done in the contemporary CS literature to discern the idea of adequate generality, a recurrent topic in the machine-learning arena.

MAIN THRUST

Evolutionary and Tree-Based Rule Ensembles

In this section, I review various methods for ensemble formation. As noted earlier, in this article, I use the ensemble to build averages of rules. Instead of averaging, one could also select the most suitable classifier in each case and make the decision on the basis of that rule alone (Hand, Adams, & Kelly, 2001). This alternative idea may provide additional insights of interest, but I do not analyze it further here.

It is conjectured that maximizing the degree of interaction amongst the rules already available is critical for efficient learning (Kuncheva & Jain, 2000; Hand et al., 2001). A fundamental issue concerns then the extent to which tentative rules work together and are capable of influencing the learning of new rules. Conventional methods like Bagging and Boosting show at most moderate amounts of interaction in this sense. While Bagging and Boosting are useful, well-known data-mining tools, it is appropriate to explore other ensemble-learning ideas as well. In this article, I focus mainly on the CS algorithm. CS approaches provide interesting architectures and introduce complex nonlinear processes to model prediction and reinforcement. I discuss a specific CS algorithm and show how it opens interesting pathways for emergent cooperative behaviour.

Conventional Rule Assembly

In Bagging methods, different training samples are created by bootstraping, and the same basic learning procedure is applied on each bootstrapped sample. In Bagging trees, predictions are decided by majority voting or by averaging the various opinions available in each case. This idea is known to reduce the basic instability of trees (Breiman, 1996).

A distinctive feature of the Boosting approach is the iterative calling to a basic weak learner (WL) algorithm (Schapire & Singer, 1998). Each time the WL is invoked, it takes as input the training set — together with a dynamic (probability) weight distribution over the data — and returns a single tree. The output of the algorithm is a weighted sum itself, where the weights are proportional to individual performance error. The WL learning algorithm needs only to produce moderately successful models. Thus, trees and simplified trees (stumps) constitute a popular choice. Several weight updating schemes have been proposed. Schapire and Singer update weights according to the success of the last model incorporated, whereas in their LogitBoost algorithm, Friedman, Hastie, and Tibshirani (2000) let the weights depend on overall probabilistic estimates. This latter idea better reflects the joint work of all classifiers available so far and hence should provide a more effective guide for the WL in general.

The notion of abstention brings a connection with the CS approach that will be apparent as I discuss the match set idea in the followins sections. In standard boosting trees, each tree contributes a leaf to the overall prediction for any new x input data vector, so the number of expressing rules is the number of boosting rounds independently of x. In the system proposed by Cohen and Singer (1999), the WL essentially produces rules or single leaves C (rather than whole trees). Their classifiers are then maps taking only two values, a real number for those x verifying the leaf and 0 elsewhere. The final boosting aggregation for x is thus unaffected by all abstaining rules (with $x \notin C$), so the number of expressing rules may be a small fraction of the total number of rules.

The General CS-Based Evolutionary Approach

The general classifier system (CS) architecture invented by John Holland constitutes perhaps one of the most sophisticated classes of evolutionary computation algorithms (Hollandet et al., 1986). Originally conceived as a model for cognitive tasks, it has been considered in many (simplified) forms to address a number of learning problems. The nowadays standard stimulus-response (or single-step) CS architecture provides a fascinating approach to the representation issue. Straightforward rules (classifiers) constitute the CS building blocks. CS algorithms maintain a population of such predictive rules whose conditions are hyperplanes involving the wild-card character #. If we generalize the idea of hyperplane to mean "conjunctions of conditions on predictors where each condition involves a single predictor," We see that these rules are also used by many other learning algorithms. Undoubtedly, hyperplane interpretability is a major factor behind this popularity.

Critical subsystems in CS algorithms are the performance, credit-apportionment, and rule discovery modules (Eiben & Smith, 2003). As regards credit-apportionment, the question has been recently raised about the suitability of endogenous reward schemes, where *endogenous* refers to the overall context in which classifiers act, versus other schemes based on intrinsic value measures (Booker, 2000). A well-known family of algorithms is XCS (and descendants), some of which have been previously advocated as data-mining tools (see, e.g., Wilson, 2001). The complexity of the CS dynamics has been analyzed in detail in Westerdale (2001).

The match set $M=M(x)$ is the subset of matched (concurrently activated) rules, that is, the collection of all classifiers whose condition is verified by the input data vector x. The (point) prediction for a new x will be based exclusively on the information contained in this ensemble M.

A System Based on Support and Predictive Scoring

Support is a familiar notion in various data-mining scenarios. There is a general trade-off between support and predictive accuracy: the larger the support, the lower the accuracy. The importance of explicitly bounding support (or deliberately seeking high support) has been recognized often in the literature (Greene & Smith, 1994; Friedman & Fisher, 1999; Muselli & Liberati, 2002). Because the world of generality intended by using only high-support rules introduces increased levels of uncertainty and error, statistical tools would seem indispensable for its proper modeling. To this end, classifiers in the BYPASS algorithm (Muruzábal, 2001) differ from other CS alternatives in that they enjoy (support-minded) probabilistic predictions (thus extending the more common single-label predictions). Support plays an outstanding role: A minimum support level b is input by the analyst at the outset, and consideration is restricted to rules with (estimated) support above b. The underlying predictive distributions, R, are easily constructed and coherently updated following a standard Bayesian Multinomial-Dirichlet process, whereas their toll on the system is minimal memory-wise. Actual predictions are built by first averaging the matched predictive distributions and then picking the maximum a posteriori label of the result. Hence, by promoting mixtures of probability distributions, the BYPASS algorithm connects readily with mainstream ensemble-learning methods.

We can find sometimes perfect regularities, that is, subsets C for which the conditional distribution of the response Y (given $X \in C$) equals 1 for some output class: $P(Y=j \mid X \in C)=1$ for some j and 0 elsewhere. In the well-known multiplexer environment, for example, there exists a set of such classifiers such that 100% performance can be achieved. But in real situations, it will be difficult to locate strictly neat C unless its support is quite small. Moreover, putting too much emphasis on error-free behavior may increase the risk of overfitting; that is, we may infer rules that do not apply (or generalize poorly) over a test sample. When restricting the search to high-support rules, probability distributions are well equipped to represent high-uncertainty patterns. When the largest $P(Y=j \mid X \in C)$ is small, it may be especially important to estimate $P(Y=j \mid X \in C)$ for all j.

Furthermore, the use of probabilistic predictions $R(j)$ for $j=1, ..., k$, where k is the number of output classes, makes possible a natural ranking of the $M=M(x)$ assigned probabilities $R_i(y)$ for the true class y related to the current x. Rules i with large $R_i(y)$ (scoring high) are generally preferred in each niche. In fact, only a few rules are rewarded at each step, so rules compete with each other for the limited amount of resources. Persistent lack of reward means extinction — to survive, classifiers must get reward from time to time. Note that newly discovered, more effective rules with even better scores may cut dramatically the reward given previously to other rules in certain niches. The fitness landscape is thus highly dynamic, and lower scores $p_i(y)$ may get reward and survive provided they are the best so far at some niche. An intrinsic measure of fitness for a classifier $C \rightarrow R$ (such as the lifetime average score -log $R(Y)$, where Y is conditioned by $X \in C$) could hardly play the same role.

It is worth noting that BYPASS integrates three learning modes in its classifiers: Bayesian at the data-processing level, reinforcement at the survival (competition) level, and genetic at the rule-discovery (exploration) level. Standard genetic algorithms (GAs) are triggered by system failure and act always circumscribed to M. Because the Bayesian updating guarantees that in the long run, predictive distributions R reflect the true conditional probabilities $P(Y=j \mid X \in C)$, scores

Table 1. The skeleton BYPASS algorithm

Input parameters (h: reward intensity) (u: minimum utility)
Initialize classifier population, say P
Iterate for a fixed number of cycles:
- Sample training item (x,y) from file
- Build match set M=M(x) including all rules with x ? C
- Build point prediction y*
- Check for success y* = y
  - If successful, reward the h ≥2 highest scores $R_i(y)$ in M
  - If unsuccessful, add a new rule to P via a GA or otherwise
- Update predictive distributions R (in M)
- Update utility counters (in P)
- Check for low utility via threshold u and possibly delete some rules

become highly reliable to form the basis of learning engines such as reward or crossover selection. The BYPASS algorithm is sketched in Table 1. Note that utility reflects accumulated reward (Muruzábal, 2001). Because only matched rules get reward, high support is a necessary (but not sufficient) condition to have high utility. Conversely, low-uncertainty regularities need to comply with the (induced) bound on support. The background generalization rate $P_{\#}$ (controlling the number of #s in the random *C* built along the run) is omitted for clarity, although some tuning of $P_{\#}$ with regard to threshold *u* is often required in practice.

BYPASS has been tested on various tasks under demanding *b* (and not very large *h*), and the results have been satisfactory in general. Comparative smaller populations are used, and low uncertainty but high support rules are uncovered. Very high values for $P_{\#}$ (as high as 0.975) have been tested successfully in some cases (Muruzábal, 2001). In the juxtaposed (or concatenated) multiplexer environment, BYPASS is shown to maintain a compact population of relatively high uncertainty rules that solves the problem by bringing about appropriate match sets (nearly) all the time. Recent work by Butz, Goldberg, and Tharakunnel (2003) shows that XCS also solves this problem, although working at a lower level of support (generality).

To summarize, BYPASS does not relay on rule plurality for knowledge encoding because it uses compact probabilistic predictions (bounded by support). It requires no intrinsic value for rules and no added tailor-made heuristics. Besides, it tends to keep population size under control (with increased processing speed and memory savings). The ensembles (match sets) derived from evolution in BYPASS have shown good promise of cooperation.

FUTURE TRENDS

Quick interactive data-mining algorithms and protocols are nice when human judgment is available. When not, computer-intensive, autonomous algorithms capable of thoroughly squeezing the data are also nice for preliminary exploration and other purposes. In a sense, we should tend to rely on the latter to mitigate the nearly ubiquitous data overflow problem. Representation schemes and learning engines are crucial to the success of these unmanned agents and need, of course, further investigation. Ensemble methods have lots of appealing features and will be subject to further analysis and testing. Evolutionary algorithms will continue to uprise and succeed in yet some other application areas. Additional commercial spin-offs will keep coming. Although great progress has been made in identifying many key insights in the CS framework, some central points still need further discussion. Specifically, the idea of rules that perform its prediction following some kind of more elaborate computation is appealing, and indeed more functional representations of classifiers (such as multilayer perceptrons) have been proposed in the CS literature (see, e.g., Bull, 2002). On the theoretical side, a formal framework for more rigorous analysis in high-support learning is much needed. The task is not easy, however, because the target is somewhat more vague, and individual as well as collective interests should be brought to terms when evaluating the generality and uncertainty associated to rules. Also, further research should be conducted to clearly delineate the strengths of the various CS approaches against current alternative methods for rule ensemble formation and data mining.

CONCLUSION

Evolutionary rule mining is a successful, promising research area. Evolutionary algorithms constitute by now a very useful and wide class of stochastic optimization methods. The evolutionary CS approach is likely to provide interesting insights and cross-fertilization of ideas with other data-mining methods. The BYPASS algorithm discussed in this article has been shown to tolerate the high support constraint well, leading to pleasant and unexpected results in some problems. These results stress the latent predictive power of the ensembles formed by high uncertainty rules.

KEY TERMS

Classification: The central problem in (supervised) data mining. Given a training data set, classification algorithms provide predictions for new data based on predictive rules and other types of models.

Classifier System: A rich class of evolutionary computation algorithms building on the idea of evolving a population of predictive (or behavioral) rules under the enforcement of certain competition and cooperation processes. Note that classifier systems can also be understood as systems capable of performing classification. Not all CSs in the sense meant here qualify as classifier systems in the broader sense, but a variety of CS algorithms concerned with classification do.

Ensemble-Based Methods: A general technique that seeks to profit from the fact that multiple rule generation followed by prediction averaging reduces test error.

Evolutionary Computation: The solution approach guided by artificial evolution, which begins with random populations (of solution models), then iteratively applies algorithms of various kinds to find the best or fittest models.

Fitness Landscape: Optimization space due to the characteristics of the fitness measure used to define the evolutionary computation process.

Predictive Rules: Standard *if-then* rules with the consequent expressing some form of prediction about the output variable.

Rule Mining: A computer-intensive task whereby data sets are extensively probed for useful predictive rules.

Test Error: Learning systems should be evaluated with regard to their true error rate, which in practice is approximated by the error rate on test data, or test error.

On Explanation-Oriented Data Mining

Yiyu Yao
University of Regina, Canada

Yan Zhao
University of Regina, Canada

INTRODUCTION

The objective of data mining is to discover new and useful knowledge, in order to gain a better understanding of nature. This in fact is the goal of scientists when carrying out scientific research, independent in their various disciplines. This goal-oriented view enables us to re-examine data mining in a wider context of scientific research. The consequence after the immediate comparison between scientific research and data mining is that, an explanation discovery and evaluation task is added to the existing data mining framework. In this chapter, we elaborate the basic concerns and methods of explanation discovery and evaluation. Explanation-oriented association mining is employed as a concrete example to show the whole framework.

BACKGROUND

Scientific research and data mining have much in common in terms of their goals, tasks, processes and methodologies. As a recently emerged multi-disciplinary study, data mining and knowledge discovery can benefit from the long established studies of scientific research and investigation (Martella *et al*., 1999). By viewing data mining in a wider context of scientific research, we can obtain insights into the necessities and benefits of explanation discovery. The model of explanation-oriented data mining is a recent result from such an investigation (Yao *et al*., 2003). The basic idea of explanation-oriented data mining has drawn attentions from many researchers (Lin & Chalupsky, 2004; Yao, 2003) ever since the introduction of it.

Common Goals of Scientific Research and Data Mining

Scientific research is affected by the perceptions and the purposes of science. Martella *et al*. (1999) summarized the main purposes of science, namely, to describe and predict, to improve or manipulate the world around us, and to explain our world. The results of the scientific research process provide a description of an event or a phenomenon. The knowledge obtained from research helps us to make predictions about what will happen in the future. Research findings are useful for us to make an improvement in the subject matter. Research findings can be used to determine the best or the most effective interventions that will bring about desirable changes. Finally, scientists develop models and theories to explain why a phenomenon occurs.

Goals similar to those of scientific research have been discussed by many researchers in data mining. For example, Fayyad *et al*. (1996) identified two high-level goals of data mining as prediction and description. Prediction involves the use of some variables to predict the values of some other variables, and description focuses on patterns that describe the data. Ling *et al*. (2002) studied the issue of manipulation and action based on the discovered knowledge. Yao *et al*. (2003) introduced the notion of explanation-oriented data mining, which focuses on constructing models for the explanation of data mining results.

Common Processes of Scientific Research and Data Mining

The process of scientific research includes idea generation, problem definition, procedure design and planning, observation and experimentation, data analysis, result interpretation, and communication. It is possible to combine several phases into one, or to divide one phase into more detailed steps. The division between phases is not a clear cut. The research process does not follow a rigid sequencing of the phases. Iteration of different phrases may be necessary (Graziano & Raulin, 2000, Martella *et al*., 1999).

Many researchers have proposed and studied models of data mining processes (Fayyad *et al*.,

1996; Mannila, 1997; Yao *et al*., 2003; Zhong *et al*., 2001). The model that adds the explanation facility to the commonly used models is recently proposed by Yao *et al*. The process thus is composed by: date preprocessing, data transformation, pattern discovery and evaluation, explanation discovery and evaluation, and pattern representation. Like the research process, the process of data mining also is an iterative process and there is no clear cut between different phases. In fact, Zhong, *et al*. (2001) argued that it should be a dynamically organized process. The whole framework is illustrated in Figure 1.

There is a parallel correspondence between the processes of scientific research and data mining. The main difference lies in the subjects that perform the tasks. Research is carried out by scientists, and data mining is done by computer systems. In particular, data mining may be viewed as a study of domain-independent research methods with emphasis on data analysis. The higher and more abstract level of comparisons of, and connections between, scientific research and data mining may be further studied in levels that are more concrete. There are bi-directional benefits. The experiences and results from the studies of research methods can be applied to data mining problems; the data mining algorithms can be used to support scientific research.

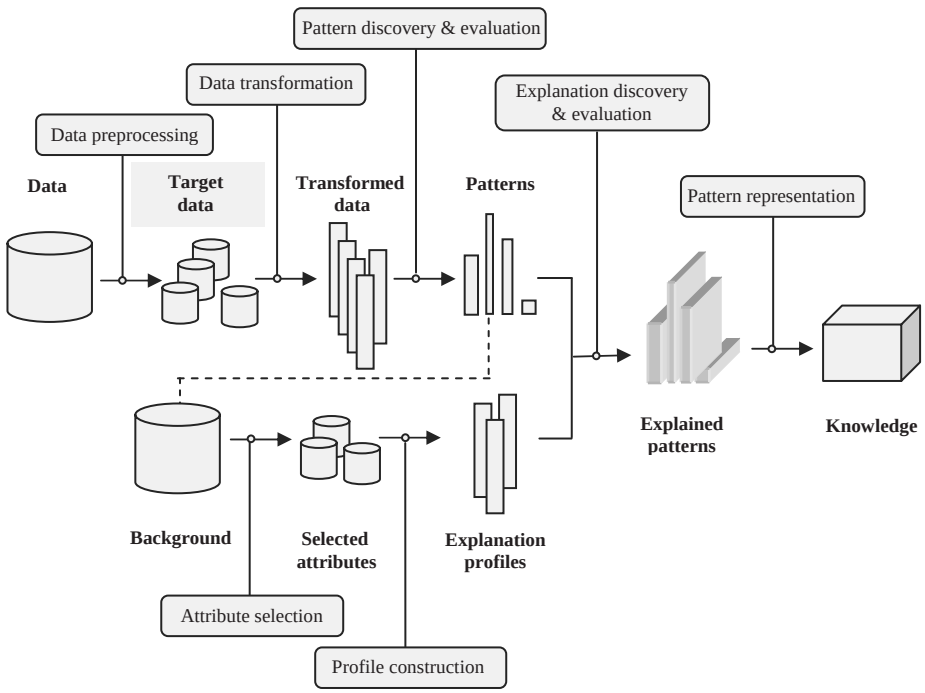
MAIN THRUST OF THE CHAPTER

Explanations of data mining address several important questions. What needs to be explained? How to explain the discovered knowledge? Moreover, is an explanation correct and complete? By answering these questions, one can better understand explanation-oriented data mining. In this section, the ideas and processes of explanation profile construction, explanation discovery and explanation evaluation are demonstrated by explanation-oriented association mining.

Basic Issues

- Explanation-oriented data mining explains and interprets the knowledge discovered from data. Knowledge can be discovered by unsupervised learning methods. Unsupervised learning studies how systems can learn to represent, summarize, and organize the data in a way that reflects the internal structure (namely, a pattern) of the

Figure 1. A framework of explanation-oriented data mining



overall collection. This process does not explain the patterns, but describes them. The primary unsupervised techniques include clustering mining, belief (usually Bayesian) networks learning, and association mining. The criteria for choosing the pattern to be explained are directly related to pattern evaluation step of data mining.

- Explanation-oriented data mining needs the background knowledge to infer features that can possibly explain a discovered pattern.
  The theory of explanation can be deeply impacted by considerations from many branches of inquiry: physics, chemistry, meteorology, human culture, logic, psychology, and the methodology of science above all. In data mining, explanation can be made at a shallow, syntactic level based on statistical information, or at a deep, semantic level based on domain knowledge. The required information and knowledge for explanation may not necessarily be inside the original dataset. A user needs to collect additional information for explanation discovery according to his/her background knowledge. It is argued that the power of explanations involves the power of insight and anticipation. One collects certain features based on the underlying hypothesis that they may provide explanations of the discovered pattern. That something is unexplainable may simply be an expression of the inability to discover an explanation of a desired sort. The process of selecting the relevant and explanatory features may be subjective, and trial-and-error. In general, the better our background knowledge, the more accurate the inferred explanations are likely to be.
- Explanation-oriented data mining explains inductively. That is, it draws an inference from a set of acquired training instances, and justifies or predicts the instances one might observe in the future.
  Supervised learning methods can be applied for the explanation discovery. The goal of supervised learning is to find a model that will correctly associate the input patterns with the classes. In real world applications, supervised learning models are extremely useful analytic techniques. The widely used supervised learning methods include decision tree learning, rule-based learning, and decision graph learning. The learned results are represented as either a tree, or a set of if-then rules.
- The constructed explanations give some evidence of under what conditions (within the background knowledge) the discovered pattern is most likely to happen, or how the background knowledge is related to the pattern.
  The role of explanation in data mining is positioned among proper description, relation and causality. Comprehensibility is the key factor in explanations. The accuracy of the constructed explanations relies on the amount of training examples. Explanation-oriented data mining performs poorly with insufficient data or poor presuppositions. Different background knowledge may infer different explanations. There is no reason to believe that only one unique explanation exists. One can use statistical measures and domain knowledge to evaluate different explanations.

A Concrete Example: Explanation-Oriented Association Mining

Explanations, also expressed as conditions, can provide additional semantics to a standard association. For example, by adding time, place, and/or customer profiles as conditions, one can identify when, where, and/or to whom an association occurs.

Explanation Profile Construction

The approach of explanation-oriented association mining combines unsupervised and supervised learning methods. It is to discover an association first, and then to explain the association. Conceptually, this method consists of two data tables. One table is used to learn associated patterns. An unsupervised learning algorithm, like the Apriori algorithm (Agrawal *et al*., 1993), can be applied to discover frequent associations. To discover other types of associations, different algorithms can be applied. By picking one interested associated pattern, we can assign objects as positive instances if they satisfy the desired associated pattern, and negative instances, otherwise. In the other table, a set of explanation profiles, with respect to the interested associated pattern, are collected according to the user's background knowledge and inferences. This table is used to search for explanations of the selected associated pattern. We can construct an explanation

table by combining the decisions label and explanation profiles as the schema that describes all the objects in the first table.

Explanation Discovery

Conditions that explain the associated pattern are searched by using a supervised learning algorithm in the constructed explanation table. A classical supervised learning algorithm such as ID3 (Quinlan, 1983), C4.5 (Quinlan, 1993), PRISM (Cendrowska, 1987), and many more (Brodie & Dejong, 2001; Han & Kamber, 2000; Mitchell, 1999) may be used to discover explanations. The Apriori-ID3 algorithm, which can be regarded as an example of explanation-oriented association mining method, is described below.

Explanation Evaluation

Once explanations are generated, it is necessary to evaluate them. For explanation-oriented association mining, we want to compare a conditional association (explained association) with its unconditional counterpart, as well as to compare different conditions.

Let T be a transaction table. Suppose for a desired pattern ϕ generated by an unsupervised learning algorithm from T, E is a constructed explanation profile table associated with ϕ. Suppose there is a set K of conditions (explanations) discovered by a supervised learning algorithm from E, and $\lambda \in K$ is one explanation. Two points are noted: first, the set K of explanations can be different according to various explanation profile tables, or various supervised learning algorithms. Second, not all explanations in K are equally interesting. Different conditions may have different degrees of interestingness.

Suppose ε is a quantitative measure used to evaluate plausible explanations, which can be the support measure for an undirected association, the confidence or coverage measure for a one-way association, or the similarity measure for a two-way association (refer to Yao & Zhong, 1999). A condition $\lambda \in K$ provides an explanation of a discovered pattern ϕ if $\varepsilon(\phi \mid \lambda) > \varepsilon(\phi)$. One can further evaluate explanations quantitatively based on several measures, such as absolute difference (*AD*), relative difference (*RD*) and ratio of change (*RC*):

$$AD(\phi \mid \lambda) = \varepsilon(\phi \mid \lambda) - \varepsilon(\phi),$$

$$RD(\phi \mid \lambda) = \frac{\varepsilon(\phi \mid \lambda) - \varepsilon(\phi)}{\varepsilon(\phi)},$$

$$RC(\phi \mid \lambda) = \frac{\varepsilon(\phi \mid \lambda) - \varepsilon(\phi)}{1 - \varepsilon(\phi)}.$$

The absolute difference represents the disparity between the pattern and the pattern under the condition. For a positive value, one may say that the condition supports ϕ, for a negative value, one may say that the condition rejects ϕ. The relative difference is the ratio of absolute difference to the value of the unconditional pattern. The ratio of change compares the actual change and the maximum potential change. Normally, a user is not interested in a pattern that cannot be explained. However, this situation might stimulate him/her to infer a different set of explanation profiles in order to construct a new set of explanations of the pattern.

Generality is the measure to quantify the size of a condition with respect to the whole data. When the generality of conditions is essential, a compound measure should be applied. For example, one may be interested

The Apriori-ID3 algorithm
Input: A transaction table and a related explanation profile table.
Output: Associations and explained associations.

1. Use the Apriori algorithm to generate a set of frequent associations in the transaction table. For each association $\phi \wedge \varphi$ in the set, *support*($\phi \wedge \varphi$) ≥ *minsup*, and *confidence*($\phi \Rightarrow \varphi$) ≥ *minconf*.
2. If the association $\phi \wedge \varphi$ is considered interesting (with respect to the user feedback or interestingness measures), then
   a. Introduce a binary attribute named *Decision*. Given a transaction, its value on *Decision* is "+" if it satisfies $\phi \wedge \varphi$ in the original transaction table, otherwise its value is "-".
   b. Construct an information table by using the attribute *Decision* and explanation profiles. The new table is called an *explanation table*.
   c. By treating *Decision* as the target class, apply the ID3 algorithm to derive classification rules of the form $\lambda \Rightarrow$ (*Decision* = "+"). The condition λ is a formula discovered in the explanation table, which states that under λ the association $\phi \wedge \varphi$ occurs.
   d. Evaluate the constructed explanation(s).

in discovering an accurate explanation with a high ratio of change and a high generality. However, it often happens that an explanation has a high generality but a low *RC* value, while another explanation has a low generality but a high *RC* value. A trade-off between these two explanations does not necessarily exist.

A good explanation system must be able to rank the discovered explanations and to reject bad explanations. It should be realized that evaluation is a difficult process because so many different kinds of knowledge can come into play. In many cases, one must rely on domain experts to reject uninteresting explanations.

Applications of Explanation-Oriented Data Mining

The idea of explanation-oriented association mining can be illustrated by a project called *WebAnalysis*, which attempts to explain Web browsing behaviour based on users' features (Zhao, 2003).

We use Active Server Pages (ASP) to create a set of Web pages. Ten popular categories of Web sites ranked by *PC Magazine* in 2001 are included. The association rule mining in the log file shows that many people who are interested in finance also are interested in business. We want to explain this frequent association by answering a more general question: "do users' profiles affect their browsing behaviours?" We thus recall users' personal information such as age, gender and occupation, which have been collected and stored in another log file, originally for security purposes. By combining the user profiles with the decisions on the association, we obtain some plausible explanations like: business-related readers in the age group of 30-39 most likely have this browsing habit; business-related female readers also are interested in these two categories.

Suppose we are not interested in users' demographics information, instead, we collect some other information such as users' access time and duration, operating system, browser and region. We may have different plausible explanations based on this different expectation.

An ontology-based clustering project, called ONTOCLUST, can be borrowed to embody the explanation-oriented clustering analysis (Wang & Hamilton, 2005). The project demonstrates the usage of spatial ontology for explaining the population distribution and clustering. The experiment shows that the resulting Canadian population clusters are matched with the locations of major cities and geographical area in the ontology, and then we can explain the clustering results.

FUTURE TRENDS

Considerable research remains to be done for explanation discovery and evaluation. In this chapter, rule-based explanation is discovered by inductive supervised learning algorithms. Alternatively, case-based explanations need to be addressed too. Based on the case-based explanation, a pattern is explained if an actual prior case is presented to provide compelling support. One of the perceived benefits of case-based explanation is that the rule generation effort is saved. Instead, some similarity functions need to be studied to score the distance between the descriptions of the newly discovered pattern and an existing one, and retrieve the most similar case as an explanation.

The discovered explanations of the selected pattern provide conclusive evidence for the new instances. In other words, the new instances can be explained and implied by the explanations. This is normally true when the explanations are sound and complete. However, sometimes, the discovered explanations cannot guarantee that a certain instance perfectly fit it. Even worse, a new dataset as a whole may show a change or a confliction with the learned explanations. This is because the explanations may be context-dependent on certain spatial and/or temporal interval. To consolidate the explanations we have discovered, a spatial-temporal reasoning model needs to be introduced to show the trend and evolution of the pattern to be explained.

CONCLUSION

Explanation-oriented data mining offers a new point of view. It closely relates scientific research and data mining, which have bi-directional benefits. The idea of explanation-oriented mining may have a significant impact on the understanding of data mining and effective applications of data mining results.

KEY TERMS

Absolute Difference: A measure that represents the difference between an association and a conditional association based on a given measure. The condition provides a plausible explanation.

Explanation-Oriented Data Mining: A general framework includes data pre-processing, data transformation, pattern discovery and evaluation, explanation discovery and evaluation, and pattern presentation. This framework is consistent with the general model of scientific research processes.

Generality: A measure that quantifies the coverage of an explanation in the whole dataset.

Goals of Scientific Research: The purposes of science are to describe and predict, to improve or manipulate the world around us, and to explain our world. One goal of scientific research is to discover

new and useful knowledge for the purpose of science. As a specific research field, data mining shares this common goal, and may be considered as a research support system.

Method of Explanation-Oriented Data Mining: The method consists of two main steps and uses two data tables. One table is used to learn a pattern. The other table, an explanation profile table, is constructed and used for explaining one desired pattern. In the first step, an unsupervised learning algorithm is used to discover a pattern of interest. In the second step, by treating objects satisfying the pattern as positive instances, and treating the rest as negative instances, one can search for conditions that explain the pattern by a supervised learning algorithm.

Ratio of Change: A ratio of actual change (absolute difference) to the maximum potential change.

Relative Difference: A measure that represents the difference between an association and a conditional association relative to the association based on a given measure.

Scientific Research Processes: A general model consists of the following phases: idea generation, problem definition, procedure design/planning, observation/experimentation, data analysis, results interpretation, and communication. It is possible to combine several phases, or to divide one phase into more detailed steps. The division between phases is not a clear cut. Iteration of different phrases may be necessary.

Extending a Conceptual Multidimensional Model for Representing Spatial Data

INTRODUCTION

Data warehouses keep large amounts of historical data in order to help users at different management levels to make more effective decisions. Conventional data warehouses are designed based on a multidimensional view of data. They are usually represented as *star* or *snowflake schemas* that contain relational tables called fact and dimension tables. A *fact table* expresses the focus of analysis (e.g., analysis of sales) and contains numeric data called *measures* (e.g., quantity). Measures can be analyzed according to different analysis criteria or *dimensions* (e.g., by product). Dimensions include attributes that can form *hierarchies* (e.g., product-category). Data in a data warehouse can be dynamically manipulated using on-line analysis processing (OLAP) systems. In particular, these systems allow automatic measure aggregations while traversing hierarchies. For example, the roll-up operation transforms detailed measures into aggregated data (e.g., daily into monthly sales) while the drill-down operation does the contrary.

Data warehouses typically include a location dimension, e.g., store or client address. This dimension is usually represented in an alphanumeric format. However, the advantages of using spatial data in the analysis process are well known since visualizing data in space allows users to reveal patterns that are difficult to discover otherwise. Spatial databases have been used for several decades for storing and managing spatial data. This kind of data typically represents geographical objects, i.e., objects located on the Earth's surface (such as mountains, cities) or geographic phenomena (such as temperature, altitude). Due to technological advances, the amount of available spatial data is growing considerably, e.g., satellite images, and location data from remote sensing systems, such as Global Positioning Systems (GPS). Spatial databases are typically used for daily business manipulations, e.g., to find a specific place from the current position given by a GPS. However, spatial databases are not well suited for supporting the decision-making process (Bédard, Rivest, & Proulx, 2007), e.g., to find the best location for a new store. Therefore, the field of spatial data warehouses emerged as a response to the necessity of analyzing high volumes of spatial data.

Since applications including spatial data are usually complex, they should be modeled at a conceptual level taking into account users' requirements and leaving out complex implementation details. The advantages of using conceptual models for database design are well known. In conventional data warehouses, a multidimensional model is commonly used for expressing users' requirements and for facilitating the subsequent implementation; however, in spatial data warehouses this model is seldom used. Further, existing conceptual models for spatial databases are not adequate for multidimensional modeling since they do not include the concepts of dimensions, hierarchies, and measures.

BACKGROUND

Only a few conceptual models for spatial data warehouse applications have been proposed in the literature (Jensen, Klygis, Pedersen, & Timko, 2004; Timko & Pedersen, 2004; Pestana, Mira da Silva, & Bédard, 2005; Ahmed & Miquel, 2005; Bimonte, Tchounikine, & Miquel, 2005). Some of these models include the concepts presented in Malinowski and Zimányi (2004) and Malinowski and Zimányi (2005), to which we will refer in the next section; other models extend non-spatial multidimensional models with different aspects, such as imprecision (Jensen *et al.*, 2004), location-based data (Timko & Pedersen, 2004), or continuous phenomena such as temperature or elevation (Ahmed & Miquel, 2005).

Other authors consider spatial dimensions and spatial measures (Stefanovic, Han, & Koperski, 2000; Rivest, Bédard, & Marchand, 2001; Fidalgo, Times, Silva, & Souza, 2004); however, their models are mainly based on the star and snowflake representations and have some restrictions, as we will see in the next section.

We advocate that it is necessary to have a conceptual multidimensional model that provides organized spatial data warehouse representation (Bédard, Merrett, & Han, 2001) facilitating spatial on-line analytical processing (Shekhar & Chalwa, 2003; Bédard *et al.*, 2007), spatial data mining (Miller & Han, 2001), and spatial statistical analysis. This model should be able to represent multidimensional elements, i.e., dimensions, hierarchies, facts, and measures, but also provide spatial support.

Spatial objects correspond to real-world entities for which the application needs to keep their spatial characteristics. Spatial objects consist of a *thematic* (or descriptive) component and a *spatial* component. The thematic component is represented using traditional DBMS data types, such as integer, string, and date. The spatial component includes its geometry, which can be of type point, line, surface, or a collection of these types. Spatial objects relate to each other with topological relationships. Different topological relationships have been defined (Egenhofer, 1993). They allow, e.g., determining whether two counties touches (i.e., share a common border), whether a highway crosses a county, or whether a city is inside a county.

Pictograms are typically used for representing spatial objects and topological relationships in conceptual models. For example, the conceptual spatio-temporal model MADS (Parent *et al.* 2006) uses the pictograms shown in Figure 1.

The inclusion of spatial support in a conceptual multidimensional model should consider different aspects not present in conventional multidimensional models, such as the topological relationships existing between the different elements of the multidimensional model or aggregations of spatial measures, among others. While some of these aspects are briefly mentioned in the literature, e.g., spatial aggregations (Pedersen & Tryfona, 2001), others are neglected, e.g., the influence on aggregation procedures of the topological relationships between spatial objects forming hierarchies.

Figure 1. Pictograms for a) spatial data types and b) topological relationships

(b)

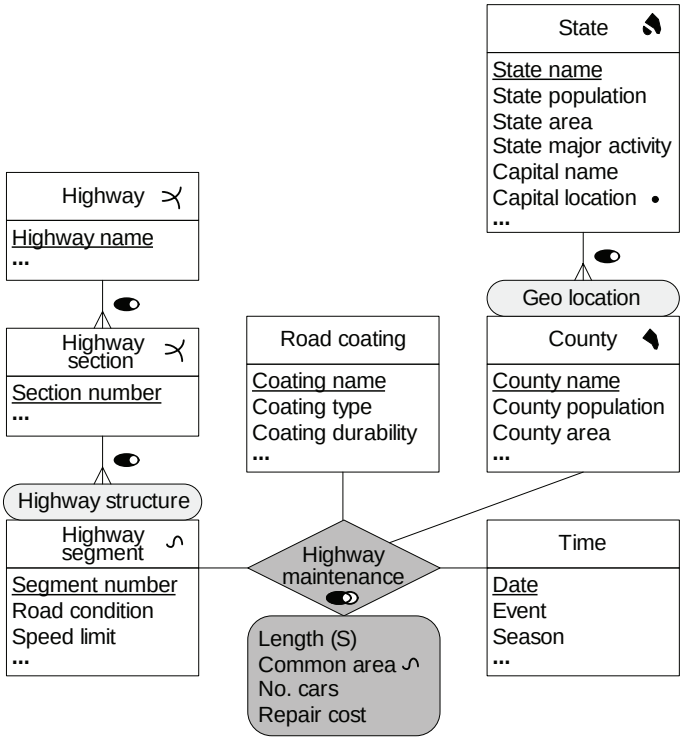
MAIN FOCUS

The MultiDim model (Malinowski & Zimányi, 2008a, 2008b) is a conceptual multidimensional model that allows designers to represent fact relationships, measures, dimensions, and hierarchies. It was extended by the inclusion of spatial support in the different elements of the model (Malinowski & Zimányi, 2004; Malinowski & Zimányi, 2005). We briefly present next our model.

A Conceptual Multidimensional Model for Spatial Data Warehouses

To describe the MultiDim model, we use an example concerning the analysis of highway maintenance costs. Highways are divided into highways sections, which at their turn are divided into highway segments. For each segment, the information about the number of cars and repairing cost during different periods of time is available. Since the maintenance of highway segments is the responsibility of counties through which the highway passes, the analysis should consider the administrative division of the territory, i.e., county and state. The analysis should also help to reveal how the different

Figure 2. An example of a multidimensional schema with spatial elements



types of road coating influence the maintenance costs. The multidimensional schema that represents these requirements is shown in Figure 2. To understand the constructs of the MutiDim model, we ignore for the moment the spatial support, i.e., the symbols for the geometries and the topological relationships.

A *dimension* is an abstract concept for grouping data that shares a common semantic meaning within the domain being modeled. It represents either a level or one or more hierarchies. *Levels* correspond to entity types in the entity-relationship model; they represent a set of instances, called *members*, having common characteristics. For example, Road Coating in Figure 2 is a one-level dimension.

Hierarchies are required for establishing meaningful paths for the roll-up and drill-down operations. A hierarchy contains several related levels, such as the County and State levels in Figure 2. They can express different structures according to an *analysis criterion*, e.g., geographical location. We use the criterion name to differentiate them, such as Geo location, or Highway structure in Figure 2.

Given two related levels of a hierarchy, one of them is called *child* and the other *parent* depending on whether they include more detailed or more general data, respectively. In Figure 2, Highway segment is a child level while Highway section is a parent level. A level of a hierarchy that does not have a child level is called *leaf* (e.g., Highway segment); the level that does not have a parent level is called *root* (e.g., Highway).

The relationships between child and parent levels are characterized by *cardinalities*. They indicate the minimum and the maximum numbers of members in one level that can be related to a member in another level. In Figure 2, the cardinality between the County and State levels is many-to-one indicating that a county can belong to only one state and a state can include many counties. Different cardinalities may exist between levels leading to different types of hierarchies (Malinowski & Zimányi, 2008a, 2008b).

Levels contain one or several *key attributes* (underlined in Figure 2) and may also have other *descriptive* attributes. Key attributes indicate how child members are grouped into parent members for the roll-up operation. For example, in Figure 2 since State name is the

key of the State level, counties will be grouped according to the state name to which they belong.

A *fact relationship* (e.g., Highway maintenance in Figure 2) represents an n-ary relationship between leaf levels. It expresses the focus of analysis and may contain attributes commonly called *measures* (e.g., Repair cost in the figure). They are used to perform quantitative analysis, such as to analyze the repairing cost during different periods of time.

Spatial Elements

The MultiDim model allows including spatial support for levels, attributes, fact relationships, and measures (Malinowski & Zimányi, 2004; Malinowski & Zimányi, 2005).

Spatial levels are levels for which the application needs to keep their spatial characteristics. This is captured by its geometry, which is represented using the pictograms shown in Figure 1 a). The schema in Figure 2 has five spatial levels: County, State, Highway segment, Highway section, and Highway. A level may have spatial attributes independently of the fact that it is spatial or not, e.g., in Figure 2 the spatial level State contains a spatial attribute Capital.

A *spatial dimension* (respectively, *spatial hierarchy*) is a dimension (respectively, a hierarchy) that includes at least one spatial level. Two linked spatial levels in a hierarchy are related through a topological relationship. These are represented using the pictograms of Figure 1 b). By default we suppose the *coveredBy* topological relationship, which indicates that the geometry of a child member is covered by the geometry of a parent member. For example, in Figure 2, the geometry of each county must be covered by the geometry of the corresponding state. However, in real-world situations different topological relationships can exist between spatial levels. It is important to consider these different topological relationships because they determine the complexity of the procedures for measure aggregation in roll-up operations (Malinowski & Zimányi, 2005).

A *spatial fact relationship* relates two or more spatial levels, e.g., in Figure 2 Highway maintenance relates the Highway segment and the County spatial levels. It may require the inclusion of a spatial predicate for spatial join operations. For example, in the figure an intersection topological relationship indicates that users focus their analysis on those highway segments that intersect counties. If this topological relationship is not included, users are interested in any topological relationships that may exist between them.

A (spatial) fact relationship may include measures, which may be spatial or thematic. *Thematic measures* are usual numeric measures as in conventional data warehouses, while *spatial measures* are represented by a geometry. Notice that thematic measures may be calculated using spatial operators, such as distance, area, etc. To indicate that a measure is calculated using spatial operators, we use the symbol (S). The schema in Figure 2 contains two measures. Length is a thematic measure (a number) calculated using spatial operators; it represents the length of the part of a highway segment that belongs to a county. Common area is a spatial measure representing the geometry of the common part. Measures require the specification of the function used for aggregations along the hierarchies. By default we use *sum* for numerical measures and *spatial union* for spatial measures.

Different Approaches for Spatial Data Warehouses

The MultiDim model extends current conceptual models for spatial data warehouses in several ways. It allows representing spatial and non-spatial elements in an orthogonal way; therefore users can choose the representation that better fits their analysis requirements. In particular we allow a non-spatial level (e.g., address represented by an alphanumeric data type) to roll-up to a spatial level (e.g., city represented by a surface). Further, we allow a dimension to be spatial even if it has only one spatial level, e.g., a State dimension that is spatial without any other geographical division. We also classify different kinds of spatial hierarchies existing in real-world situations (Malinowski & Zimányi, 2005) that are currently ignored in research related to spatial data warehouses. With respect to spatial measures, we based our approach on Stefanovic *et al.* (2000) and Rivest *et al.* (2001); however, we clearly separate the conceptual and the implementation aspects. Further, in our model a spatial measure can be related to non-spatial dimensions as can be seen in Figure 3.

For the schema in Figure 3 the user is interested in analyzing locations of accidents taking into account the different insurance categories (full coverage, partial coverage, etc.) and particular client data. The model includes a spatial measure representing the location of an accident. As already said above, a spatial function is

Figure 3. Schema for analysis of accidents with a spatial measure location

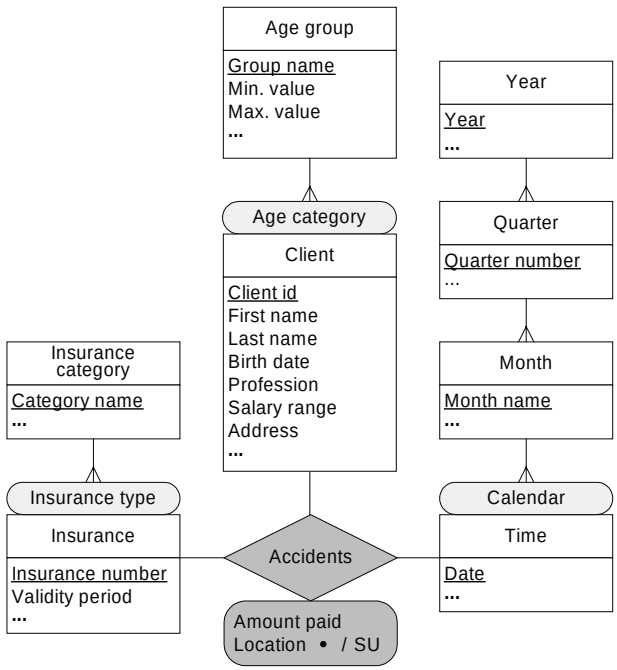


Figure 4. Spatial dimension: another variant of a schema for analysis of accidents

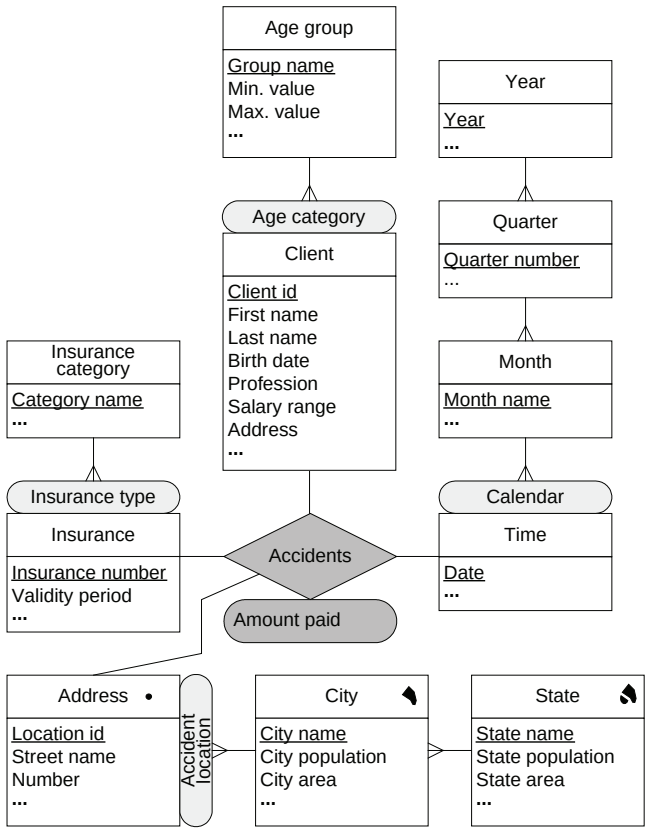

needed to aggregate spatial measures through hierarchies. By default the spatial union is used: when a user rolls-up to the Insurance category level, the locations corresponding to different categories will be aggregated and represented as a set of points. Other spatial operators can be also used, e.g., center of n points.

Other models (e.g., Fidalgo *et al.*, 2004) do not allow spatial measures and convert them into spatial dimensions. However, the resulting model corresponds to different analysis criteria and answers to different queries. For example, Figure 4 shows an alternative schema for the analysis of accidents that results from transforming the spatial measure Location of the Figure 3 into a spatial dimension Address.

For the schema in Figure 4 the focus of analysis has been changed to the amount of insurance paid according to different geographical locations. Therefore, using this schema, users can compare the amount of insurance paid in different geographic zones; however, they cannot aggregate locations (e.g., using spatial union) of accidents as can be done for the schema in Figure 3. As can be seen, although these models are similar, different analyses can be made when a location is handled as a spatial measure or as a spatial hierarchy. It is the designer's decision to determine which of these models better represents users' needs.

To show the feasibility of implementing our spatial multidimensional model, we present in Malinowski and Zimányi, (2007, 2008b) their mappings to the object-relational model and give examples of their implementation in Oracle 10g.

FUTURE TRENDS

Bédard *et al.*, (2007) developed a spatial OLAP tool that includes the roll-up and drill-down operations. However, it is necessary to extend these operations for different types of spatial hierarchies (Malinowski & Zimányi, 2005).

Another interesting research problem is the inclusion of spatial data represented as continuous fields, such as temperature, altitude, or soil cover. Although some solutions already exist (Ahmed & Miquel, 2005), additional research is required in different issues, e.g., spatial hierarchies composed by levels representing field data or spatial measures representing continuous phenomena and their aggregations.

Another issue is to cope with multiple representations of spatial data, i.e., allowing the same real-world object to have different geometries. Multiple representations are common in spatial databases. It is also an important aspect in the context of data warehouses since spatial data may be integrated from different source systems that use different geometries for the same spatial object. An additional difficulty arises when the levels composing a hierarchy can have multiple representations and one of them must be chosen during roll-up and drill-down operations.

CONCLUSION

In this paper, we referred to spatial data warehouses as a combination of conventional data warehouses and spatial databases. We presented different elements of a spatial multidimensional model, such as spatial levels, spatial hierarchies, spatial fact relationships, and spatial measures.

The spatial extension of the conceptual multidimensional model aims at improving the data analysis and design for spatial data warehouse and spatial OLAP applications by integrating spatial components in a multidimensional model. Being platform independent, it helps to establish a communication bridge between users and designers. It reduces the difficulties of modeling spatial applications, since decision-making users do not usually possess the expertise required by the software used for managing spatial data. Further, spatial OLAP tools developers can have a common vision of the different features that comprise a spatial multidimensional model and of the different roles that each element of this model plays. This can help to develop correct and efficient solutions for spatial data manipulations.

KEY TERMS

Multidimensional Model: A model for representing the information requirements of analytical applications. It comprises facts, measures, dimensions, and hierarchies.

Spatial Data Warehouse: A data warehouse that includes spatial dimensions, spatial measures, or both, thus allowing spatial analysis.

Spatial Dimension: An abstract concept for grouping data that shares a common semantics within the

domain being modeled. It contains one or more spatial hierarchies.

Spatial Fact Relationship: An n-ary relationship between two or more spatial levels belonging to different spatial dimensions.

Spatial Hierarchy: One or several related levels where at least one of them is spatial.

Spatial Level: A type defining a set of attributes, one of them being the geometry, keeping track of the spatial extent and location of the instances, or members, of the level.

Spatial Measure: An attribute of a (spatial) fact relationship that can be represented by a geometry or calculated using spatial operators.

Facial Recognition

INTRODUCTION

Over the past decade Facial Recognition has become more cohesive and reliable than ever before. We begin with an analysis explaining why certain facial recognition methodologies examined under FERET, FRVT 2000, FRVT 2002, and FRVT 2006 have become stronger and why other approaches to facial recognition are losing traction. Second, we cluster the stronger approaches in terms of what approaches are mutually inclusive or exclusive to surrounding methodologies. Third, we discuss and compare emerging facial recognition technology in light of the aforementioned clusters. In conclusion, we suggest a road map that takes into consideration the final goals of each cluster, that given each clusters weakness, will make it easier to combine methodologies with surrounding clusters.

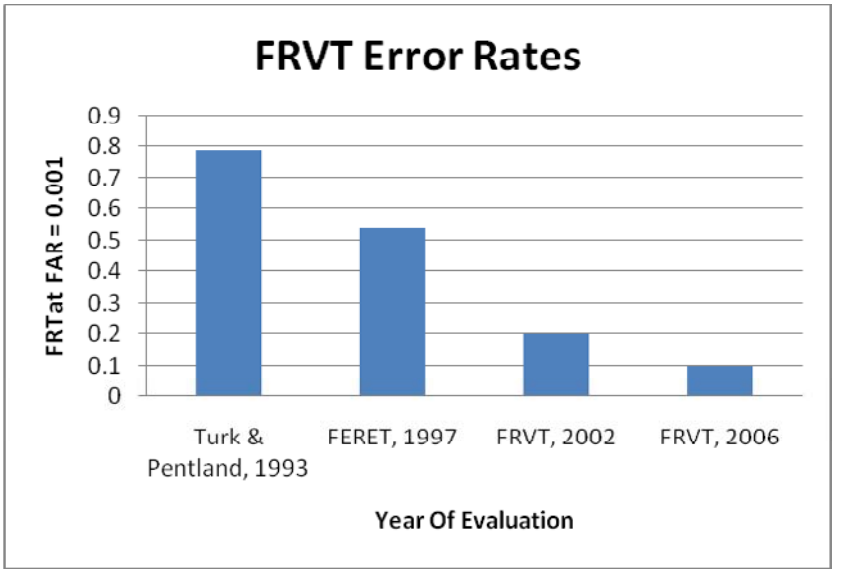
BACKGROUND

The National Institute of Standards and Technology (NIST) sponsored 2006 Face Recognition Vendor Test (FRVT) which is the most recent large scale independent synopsis of the state-of-the-art for face recognition systems. The previous tests in the series were the FERET, FRVT 2000, and FRVT 2002. The following organizations participated in the FRVT 2006 evaluation: Animetrics, Inc., Carnegie Mellon University, Cognitec Systems GmbH, Diamond Information Systems (DIS), Geometrix, Inc., Guardia, Identix, Inc., Neven Vision, New Jersey Institute of Technology (NJIT), Nivis, LLC, Old Dominion University, Panvista Limited, Peking University, Center for Information Science, PeopleSpot Inc., Rafael Armament Development Authority Ltd., SAGEM SA, Samsung Advanced Institute of Technology (SAIT), Tsinghua University, Tili Technology Limited, Toshiba Corporation, University of Houston, and Viisage. It should be noted that while the FRVT 2006 was conducted by the National Institute of Standards and Technology (NIST), it was jointly sponsored by five other U.S. Government agencies which share NIST's interest in measuring the improvements in face recognition technologies: Federal Bureau of Investigation, National Institute of Justice, National Institute of Standards and Technology, U.S. Department of Homeland Security, and the Transportation Security Administration.

The FRVT 2006 measured the progress of facial recognition systems including commercial systems that used Windows or Linux based algorithms. The sequestered data comprised a large standard dataset of "full frontal" pictures provided to NIST by the U.S. State Department using non-conforming pixel resolutions and lighting angles of 36,000 pictures of persons applying for non-immigrant visas at U.S. consulates in Mexico. The tests evaluated 4 dimensions of facial recognition: high resolution still imagery, 3D facial scans, multi-sample still facial imagery, and pre-processing algorithms that compensate for pose and illumination. The results of the best of the 13 groups that entered have improved remarkably; the best algorithms in the FRVT 2002 computed 20% false rejections compared to only 1% false rejections in the FRVT 2006 tests. However, some of the groups that entered FRVT 2006 had results no better than that of 2002. In the tests, the rejection was less palatable: 12% for the best algorithms which still it is better than the 29% rejection rate of the 2002 tests.

FRVT tests digress from the traditional facial recognition tests of the 1990's in two ways: First, speed was not the issue in the tests, some of the algorithms took hundreds of hours to find matches in the database. The correct identification (precision) is the issue. Secondly, rather than the traditional ID searches of comparing a face in the camera with every face in the database for a match, the FRVT tests comprised security verification: is the face of the person standing in front of the

Figure 1. The reduction in error rates of facial recognition algorithms



camera claiming to be Mr. Whomever indeed the Mr. Whomever whose picture is in the database?

THE STATE-OF-THE-ART OF THE 13 GROUPS IN FRVT 2006

The three well known facial recognition corporations, Google owned Neven Vision, Viisage Technology (owned by L-1 Identity Solutions), and Cognitec Systems of Germany performed the best. The two universities that excelled were the University of Houston and Tsinghua University in China. The four methodology clusters are (i) Support Vector Machines, (ii) Manifold/Eigenface, (iii) Principal Component Analysis with Modified Sum Square Error (PCA/SSE), and Pure Eigenface technology:

1. *Cognitec Systems* - Cognitec Systems FaceVACS-incorporates Support Vector Machines (SVM) to capture facial features. In the event of a positive match, the authorized person is granted access to a PC (Thalheim, 2002).
2. *Neven Vision* - In 2002, Neven's Eyematic team achieved high scores in the Face Recognition Vendor Test (Neven, 2004). Neven Vision incorporates Eigenface Technology. The Neven methodology trains an RBF network which constructs a full manifold representation in a universal Eigenspace from a single view of an arbitrary pose.
3. *L-1 Identity Solutions Inc* – L-1's performance ranked it near or at the top of every NIST test. This validated the functionality of the algorithms that drive L-1's facial and iris biometric solutions. L-1 was formed in 2006 when Viisage Technology Inc. bought Indentix Inc. The NIST evaluations of facial and iris technology covered algorithms submitted by Viisage and Indentix, both of which utilize variations of Eigenvalues, one called the principal component analysis (PCA)-based face recognition method and the other, the modified sum square error (SSE)-based distance technique.
4. *M A. Turk and A P. Pentland* – they wrote a paper that changed the facial recognition world - "*Face*

Recognition Using Eigenfaces" (Turk & Pentland, 1991) which won the "Most Influential Paper of the Decade" award from the IAPR MVA. In short, the new technology reconstructed a face by superimposing a set of "Eigenfaces". The similarity between the two facial images is determined based on the coefficient of the relevant Eigenfaces. The images consist of a set of linear eigenvectors wherein the operators are non-zero vectors which result in a scalar multiple of themselves (Pentland, 1993). It is the scalar multiple which is referred to as the Eigenvalue associated with a particular eigenvector (Pentland & Kirby, 1987). Turk assumes that any human face is merely a combination of parts of the Eigenfaces. One person's face may consist of 25% from face 1, 25% from face 2, 4% of face 3, n% of face X (Kirby, 1990).

The authors propose that even though the technology is improving, as exemplified by the FRVT 2006 test results, the common dominator for problematic recognition is based on faces with erroneous and varying light source conditions. Under this assumption, 3-D models were compared with the related 2-D images in the data set. All four of the aforementioned primary methodologies of facial recognition across the board, performed poorly in this context: for the controlled illumination experiments, performance of the very-high resolution dataset was better than the high-resolution dataset. Also, from comparing the photos of faces in the database to the angle of view of the person in 3-d/real life, an issue FRVT did not even consider, leads one to believe that light source variation on 3-d models compromises the knowledge discovery abilities of all the facial recognition algorithms at FRVT 2006.

Figure 2. Original picture set

Figure 3. RGB normalization

Figure 4. Grayscale and posturization

INNERTRON TECHNOLOGY

Major components of interactive visual data analysis and their functions that make knowledge extraction more effective are the current research theme in this field. Consider the 8 images of the subject photographed in Figure 2. These photos were taken at four different times over the period of 18 months under 4 varying sets of light sources. To the human brain – this is clearly the same person – without a doubt. However, after normalizing the light in RGB in each of the four sets, we yield the results displayed in Figure 3. Note that this normalization process is normalizing each group of four until the desired, empirical normalization matrix in RGB is achieved – as in the manner that a machine would render the normalization process. Note that in Figure 2 the bottom right hand figure is not darkened at all but after normalization in Figure 3 it appears darker. In Figure 4, a simple Grayscale and 6-level posturization is performed. In Figure 5, as in the FRVT 2006 tests, shadow is added to compensate for distance measures. It is evident that varying light conditions change the dynamics of a face in a far more complex manner than facial surgery could. This is evident when one looks at the 2-d images in terms of what is white and what is black, measuring and storing where they are black and white.

Innertron facial recognition technology proposes a solution to the core, common denominator problem of the FRVT 2006 tests as illustrated in Figures 2 through 5, where classical lighting and shadow normalization can corrupt lighting on some good images in order to compensate for bad lighting at the level of the median lighting parameters. The Lambertian model states that the image of a 3D object is subject to three factors, namely the surface normal, albedo, and lighting. These can be factorized into an intrinsic part of the surface normal and albedo, and an extrinsic part of lighting (Wang 2004).

Figure 5. Distance configuration

Figure 6. Difference Eigen

$$I(x,y) = \rho(x,y)n(x,y)^T s$$

where *p* is the surface texture (albedo) of the face, $\boldsymbol{n(x,y)^T}$ represents the 3-D rendering of the normal surface of the face, which will be the same for all objects of the class, and *s* is the position of the light source, which may vary arbitrarily. The quotient image $\boldsymbol{Q_y}$ of face ***y*** against face ***a*** is defined by

$$Q_y(u,v) = \frac{\rho_y(u,v)}{\rho_a(u,v)} = \frac{\rho_y(u,v)n(u,v)^T s_y}{\rho_a(u,v)n(u,v)^T s_y}$$
$$= \frac{I_y}{\rho_a(u,v)n(u,v)^T \sum_j x_j s_j}$$
$$= \frac{I_y}{\sum_{j=1}^{3} I_j x_j}$$

where ***u*** and ***v*** range over the image, $\boldsymbol{I_y}$ is an image of object ***y*** with the illumination direction $\boldsymbol{s_y}$, and $\boldsymbol{x_j}$ are combining coefficients estimated by Least Square based on training set (Shashua, 2001), (Raviv, 1999), and $\boldsymbol{I_1}$, $\boldsymbol{I_2}$, $\boldsymbol{I_3}$ are three non-collinearly illuminated images. This is shown in Figure 6 where we superimpose, using negative alpha values, face ***y*** onto face ***a*** with the higher level image additionally set to a basic Eigenvector exposing the differences of itself ***a*** and the image below it ***y***. This cancels out erroneous shadows, and only keeps constant data. The color of the images has changed from that of the original images in Figure 2. This is because of the effect the Eigenvector has on two samples from almost the same place and time. One can also see in Figure 7 that the large amount of shadows that were present in Figures 3 through 4 are almost gone. In Figure 7 and Figure 8 the innertron based strategy has normalized the face. *See* details in (Lewis, Ras 2005). In our approach, we use training database of human faces described by a set of innertron features to built classifiers for face recognition.

Figure 8. Normalize - grid

FUTURE TRENDS

There are many projects focused on creation of intelligent methods for solving many difficult high-level image feature extraction and data analysis problems in which both local and global properties as well as spatial relations are taken into consideration. Some of these new techniques work in pixel and compressed domain (avoiding the inverse transform in decompression), thus speeding up the whole process (Delac & Grgic, 2007), (Deniz et al., 2001), (Du et al., 2005). The development of these new high-level image features is essential for the successful construction of new classifiers for the face recognition. Knowledge discovery techniques are especially promising in providing tools to build classifiers for recognizing emotions associated with human faces (happy, sad, surprised, …..). But this area is still at the very beginning stage.

CONCLUSION

Overcoming the challenges of shadow elimination seems promising with the use of negative alpha values set to basic Eigenvectors particularly when used with the Lambertian methodology. Mining these images in a 2-D database is easier because the many levels of grey will be "normalized" to a specific set allowing a

more precise vector value for distance functions. Pure Eigenvector technology, also fails when huge amounts of "negatives" are superimposed onto one another, once again pointing to normalization as the key. Data in the innertron database need to be consistent in tilt and size of the face. This means that before a face is submitted to the database, it also needs tilt and facial size normalization.

KEY TERMS

Classifier: Compact description of a set of instances that have common behavioral and structural features (attributes and operations, respectively).

Eigenfaces: Set of eigenvectors used in the computer vision problem of human face recognition.

Eigenvalue: Scalar associated with a given linear transformation of a vector space and having the property that there is some nonzero vector which when multiplied by the scalar is equal to the vector obtained by letting the transformation operate on the vector.

Facial Recognition: Process which automatically identifies a person from a digital image or a video frame from a video source.

Knowledge Discovery: Process of automatically searching large volumes of data for patterns that can be considered as knowledge about the data.

Support Vector Machines (SVM): Set of related supervised learning methods used for classification and regression. They belong to a family of generalized linear classifiers. A special property of SVMs is that they simultaneously minimize the empirical classification error and maximize the geometric margin; hence they are also known as maximum margin classifiers.

F

Feature Extraction/Selection in High-Dimensional Spectral Data

Seoung Bum Kim
The University of Texas at Arlington, USA

INTRODUCTION

Development of advanced sensing technology has multiplied the volume of spectral data, which is one of the most common types of data encountered in many research fields that require advanced mathematical methods with highly efficient computation. Examples of the fields in which spectral data abound include near-infrared, mass spectroscopy, magnetic resonance imaging, and nuclear magnetic resonance spectroscopy.

The introduction of a variety of spectroscopic techniques makes it possible to investigate changes in composition in a spectrum and to quantify them without complex preparation of samples. However, a major limitation in the analysis of spectral data lies in the complexity of the signals generated by the presence of a large number of correlated features. Figure 1 displays a high-level diagram of the overall process of modeling and analyzing spectral data.

The collected spectra should be first preprocessed to ensure high quality data. Preprocessing steps generally include denoising, baseline correction, alignment, and normalization. Feature extraction/selection identifies the important features for prediction, and relevant models are constructed through the learning processes. The feedback path from the results of the validation step enables control and optimization of all previous steps. Explanatory analysis and visualization can provide initial guidelines that make the subsequent steps more efficient.

This chapter focuses on the feature extraction/selection step in the modeling and analysis of spectral data. Particularly, throughout the chapter, the properties of feature extraction/selection procedures are demonstrated with spectral data from high-resolution nuclear magnetic resonance spectroscopy, one of the widely used techniques for studying metabolomics.

BACKGROUND

Metabolomics is global analysis for the detection and recognition of metabolic changes in biological systems in response to pathophysiological stimuli and to the intake of toxins or nutrition (Nicholson et al., 2002). A variety of techniques, including electrophoresis, chromatography, mass spectroscopy, and nuclear magnetic resonance, are available for studying metabolomics. Among these techniques, proton nuclear magnetic resonance (^{1}H-NMR) has the advantages of high-resolution, minimal cost, and little sample preparation (Dunn & Ellis, 2005). Moreover, the tech-

Figure 1. Overall process for the modeling and analysis of high-dimensional spectra data

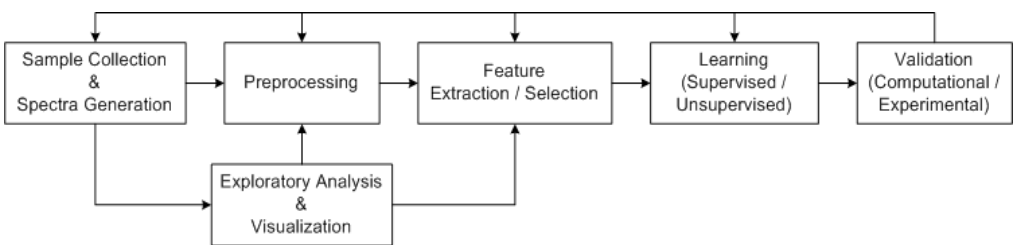

Figure 2. Multiple spectra generated by a 600MHz ^{1}H-NMR spectroscopy

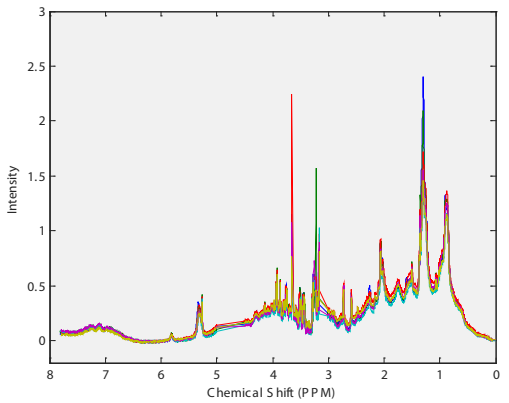


nique generates high-throughput data, which permits simultaneous investigation of hundreds of metabolite features. Figure 2 shows a set of spectra generated by a 600MHz ^{1}H-NMR spectroscopy. The *x*-axis indicates the chemical shift within units in parts per million (ppm), and the *y*-axis indicates the intensity values corresponding to each chemical shift. Traditionally, chemical shifts in the *x*-axis are listed from largest to smallest. Analysis of high-resolution NMR spectra usually involves combinations of multiple samples, each with tens of thousands of correlated metabolite features with different scales.

This leads to a huge number of data points and a situation that challenges analytical and computational capabilities. A variety of multivariate statistical methods have been introduced to reduce the complexity of metabolic spectra and thus help identify meaningful patterns in high-resolution NMR spectra (Holmes & Antti, 2002). Principal components analysis (PCA) and clustering analysis are examples of unsupervised methods that have been widely used to facilitate the extraction of implicit patterns and elicit the natural groupings of the spectral dataset without prior information about the sample class (e.g., Beckonert et al., 2003). Supervised methods have been applied to classify metabolic profiles according to their various conditions (e.g., Holmes et al., 2001). The widely used supervised methods in metabolomics include Partial Least Squares (PLS) methods, *k*-nearest neighbors, and neural networks (Lindon et al., 2001).

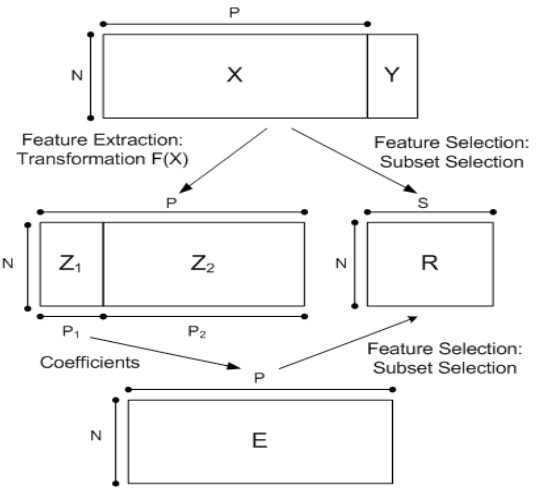
Although supervised and unsupervised methods have been successfully used for descriptive and predictive analyses in metabolomics, relatively few attempts have been made to identify the metabolite features that play an important role in discriminating between spectra among experimental conditions. Identifying important features in NMR spectra is challenging and poses the following problems that restrict the applicability of conventional methods. First, the number of features present usually greatly exceeds the number of samples (i.e., tall and wide data), which leads to ill-posed problems. Second, the features in a spectrum are correlated with each other, while many conventional multivariate statistical approaches assume the features are independent. Third, spectra comprise a number of local bumps and peaks with different scales.

MAIN FOCUS OF CHAPTER

Feature Extraction/Selection Process

It is important to distinguish between feature extraction and feature selection, although much of the literature

Figure 3. Overview of feature extraction, feature selection, and a combination of feature extraction and selection



fails to make a clear distinction between feature extraction and feature selection processes. Figure 3 displays a schematic diagram of the processes in feature extraction, feature selection, and a combination of feature extraction and feature selection.

Feature extraction techniques attempt to create new features based on transformations of the original features to extract the useful information for the model. Given the set of original features $\mathbf{X}_{(N\times P)}$, the main purpose of feature extraction is to find the function of $\mathbf{X}$, $\mathbf{Z}_{(N\times P1)} = F(\mathbf{X})$ to lower the original dimension. Generally, the first few dimensions are sufficient to account for the key information of the entire spectral data ($\mathbf{Z}_1$ in Figure 3). Widely used feature extraction methods include PCA, PLS, and Fisher discriminant analysis (FDA). Among these, PCA is an unsupervised feature extraction method because the process depends solely upon $\mathbf{X}$, while PLS and FDA are supervised methods because to extract features from X, they take into account the response variable. Recent study conducts an analysis and a comparison of several unsupervised linear feature selection methods in hyperspectral data (Jiménez-Rodríguez et al., 2007).

Feature selection techniques attempt to pick the subset of original features (with dimension S, where S « P, see Figure 3) that leads to the best prediction or classification. Feature selection methods have not been investigated as thoroughly as those for feature extraction because conventional feature selection methods cannot fully accommodate the correlation structure of features in a spectrum. This chapter presents two feature selection approaches that have the potential to cope with correlated features. These methods are based on a genetic algorithm and a multiple hypothesis testing procedure, respectively. Feature extraction is often the forerunner of feature selection. The coefficients that constitute the extracted features reflect the contribution of each feature and can be used to determine whether or not each feature is significant. These methods use loading vectors of PCA, the optimal discriminant direction of FDA, and index values of variable importance in projection in PLS.

Feature Extraction Techniques

Principal Component Analysis: PCA identifies a lower dimensional space that can explain most of the variability of the original dataset (Jollife, 2002). Let the random vector that has a sample of observations (n) for a set of p variables (i.e., $X^T=[X_1, X_2, \ldots, X_p]$) and its covariance matrix C. This lower dimensional space contains linear combinations of original features called principal components (PCs; i.e., $Z = a^TX$, where $a^T= [a_1, a_2, \ldots, a_p]$, $Z^T= [Z_1, Z_2, \ldots, Z_p]$). The first PC, Z_1, is obtained by identifying a projection vector a_1 that maximizes the variance Z_1 equivalent to maximize $a_1^T C a_1$. The second PC, Z_2, is obtained to find a_2 that maximizes the variance Z_2 with a constraint that Z_1 and Z_2 are orthogonal. This process is repeated p times to obtain p PCs. Let E ($E^T= [E_1, E_2, \ldots, E_p]$) is a set of eigenvectors of C, with corresponding ordered eigenvalues ($\lambda_1 > \lambda_2 > \ldots > \lambda_p$). Using some properties of linear algebra, the projection vectors are E. That is, the PCs of X are calculated by the transformation process, $Z=EX$. PCA is efficient in facilitating visualization of high-dimensional spectral data if only the first few PCs are needed to represent most of the variability in the original high-dimensional space. However, PCA has several limitations in the analysis of spectral data. First, extracted PCs are linear combinations of a large number of original features. Thus, PCs cannot be readily interpreted. Second, the PCs may not produce maximum discrimination between sample classes because the transformation process of PCA relies solely on input variables and ignores class information. Third, determination of the number of PCs to retain is subjective.

The contribution of each feature to form PCs can be represented using loading vectors $\boldsymbol{k}$.

$$PC_i = \mathbf{x}_1 k_{i1} + \mathbf{x}_2 k_{i2} + \ldots + \mathbf{x}_N k_{ip} = \mathbf{X} k_i,\ i = 1, 2, \ldots, p. \quad (1)$$

For example, k_{i1} indicates the degree of importance of the first feature in the i^{th} PC domain. Typically, the first few PCs are sufficient to account for most of the variability in the data. Thus, a PCA loading value for the j^{th} original feature can be computed from the first k *PC*s.

$$Loading_j^{PCA} = \sum_{i=1}^{k} |k_{ij}| \omega_i,\ j=1, 2, \ldots, p, \quad (2)$$

where p is the total number of features of interest and ω_i represents the weight of the i^{th} PC. The simple way to determine ω_i is to compute the proportion of total variance explained by i^{th} PC.

Partial Least Squares: Similar to PCA, PLS uses transformed variables to identify a lower dimensional variable set (Boulesteix & Strimmer, 2007). PLS is a multivariate projection method for modeling a relation-

ship between independent variables **X** and dependent variable(s) **Y**. PLS seeks to find a set of latent features that maximizes the covariance between **X** and **Y**. It decomposes **X** and **Y** into the following forms:

$$\mathbf{X} = \mathbf{T}\mathbf{P}^T + \mathbf{E}, \quad (3)$$

$$\mathbf{Y} = \mathbf{T}\mathbf{Q}^T + \mathbf{F}, \quad (4)$$

where **T** is ($n \times A$) the score matrix of the extracted A score vectors that can be represented as $\mathbf{T}=\mathbf{X}\mathbf{w}$. **P** ($N \times A$) and **Q** ($M \times A$) loading matrices, and **E** ($n \times N$) and **F** ($n \times M$) residual matrices. The PLS method searches for weight vector **w** that maximizes the covariance between **Y** and **T.** By regressing **T** on **Y**, **Q** can be computed as follows:

$$\mathbf{Q} = (\mathbf{T}^T\mathbf{T})^{-1}\mathbf{T}^T\mathbf{Y}. \quad (5)$$

Then, the PLS regression model can be expressed as $\mathbf{Y} = \mathbf{X}\mathbf{B} + \mathbf{G}$, where $\mathbf{B} (=\mathbf{w}\mathbf{Q}^T)$ and **G** represent regression coefficients and a residual matrix, respectively. When the response variable is available in the spectral data, transformed variables obtained from PLS are more informative than those from PCA because the formal variables account for the distinction among different classes. However, the reduced dimensions from PLS do not provide a clear interpretation with respect to the original features for the same reason described for PCA

Fisher Discriminant Function: Fisher discriminant analysis (FDA) is a widely used technique for achieving optimal dimension reduction in classification problems in which the response variables are categorical. FDA provides an efficient lower dimensional representation of **X** for discrimination among groups. In other words, FDA uses the dependent variable to seek directions that are optimal for discrimination. This process is achieved by maximizing the between-group-scatter matrix $\mathbf{S}_b$ (see Equation (6)) while minimizing the within-group-scatter matrix $\mathbf{S}_w$ (see Equation (7)) (Yang et al., 2004). Thus, FDA finds optimal discriminant weight vectors φ by maximizing the following Fisher criterion:

$$J(\varphi) = \frac{\varphi^T \mathbf{S}_b \varphi}{\varphi^T \mathbf{S}_w \varphi}. \quad (6)$$

It can be shown that this maximization problem can be reduced to a generalized eigenvalue problem: $\mathbf{S}_b\boldsymbol{\varphi} = \lambda\mathbf{S}_w\boldsymbol{\varphi}$ (Yang et al., 2004). The main idea of using FDA for feature extraction is to use its weight vector (i.e., $\boldsymbol{\varphi} = [\phi_1, \phi_2, ..., \phi_N]^T$). FDA is the most efficient because transformed features provide better classification capability. However, by using FDA the feature extraction process may encounter computational difficulty because of the singularity of the scatter matrix when the number of samples is smaller than the number of features (Chen et al., 2000). Furthermore, the extracted features have the same interpretation problem as PCA and PLS.

The features selected by PCA, PLS, and FDA are evaluated and compared based on an ability of classification of high-resolution NMR spectra (Cho et al., in press).

Feature Selection Techniques

Genetic Algorithm: Interpretation problems posed by the transformation process in feature extraction can be overcome by selecting the best subset of given features in a spectrum. Genetic algorithms (GAs) have been successfully used as an efficient feature selection technique for PLS-based calibration (e.g., Esteban-Díez et al., 2006) and for other problems such as classification and feature selection for calibration (e.g., Kemsley, 2001). Recently, a two-stage genetic programming method was developed for selecting important features in NMR spectra for the classification of genetically modified barley (Davis et al., 2006). A major advantage of using GAs for feature selection in spectral data is that GAs take into account autocorrelation of features that make the selected features less dispersed. In other words, if the feature p is selected, features p-1 and p+1 are selected with high probability. However, GAs are known to be vulnerable to overfitting when the features are noisy or the dimension of the features is high. Also, too many parameters in GAs often prevent us from obtaining robust results.

Multiple Hypothesis Testing: The feature selection problem in NMR spectra can be formulated by constructing multiple hypothesis tests. Each null hypothesis states that the average intensities of the i^{th} features are equal among different experimental conditions, and the alternative hypothesis is that they differ. In multiple testing problems, it is traditional to choose a p-value threshold

τ and declare the feature x_j significant if and only if the corresponding *p*-value $p_j \leq \tau$. Thus, it is important to find an appropriate threshold that compromises the tradeoff between false positives and false negatives. A naive threshold is to use the traditional *p*-value cutoff of $\alpha = 0.01$ or 0.05 for individual hypothesis. However, applying a single testing procedure to a multiple testing problem leads to an exponential increase in false positives. To overcome this, the Bonferroni method uses a more stringent threshold (Shaffer, 1995). However, the Bonferroni method is too conservative and often fails to detect the truly significant feature. In a seminal paper, Benjamini & Hochberg (1995) proposed an efficient procedure to determine a suitable threshold that controls the false discovery rate (FDR), defined as the expected proportion of false positives among all the hypotheses rejected. A summary of the procedure is as follows:

- Select a desired FDR level (=α) between 0 and 1.
- Find the largest *i* denoted as w, where

$$w = \max\left[i : p(i) \leq \frac{i}{m}\frac{\alpha}{\delta}\right].$$

  m is the total number of hypotheses, and δ denotes the proportion of true null hypotheses. Several studies discuss the assignment of δ where δ=1 is the most conservative choice.
- Let the *p*-value threshold be $p_{(w)}$, and declare the metabolite feature t_i significant if and only if $p_i \leq p_{(w)}$.

The FDR-based procedure treats all the features simultaneously by constructing multiple hypotheses and the ability of the procedure to control FDR provides the logical interpretation of feature selection results. In addition, the effect of correlated features in a spectrum can be automatically accommodated by the FDR procedure through a simple modification (Benjamini & Yekutieli, 2001).

To demonstrate the effectiveness of the FDR procedure, we conduct a simple case study using 136 NMR spectra (each with 574 metabolite features) extracted from two different experimental conditions. A multiple testing procedure controlling FDR (at α= 0.01) is performed to find the potentially significant metabolite features that differentiate two different experimental conditions. The FDR procedure identifies 75 metabolite features as potentially significant ones. To demonstrate the advantage of FDR, we compare the classification capability between the features selected by FDR and full features using a *k*-nearest neighbor (KNN) algorithm. Different values of *k* are run with Euclidean distance to find the optimal KNN model that has minimum misclassification rate. The results show the KNN model constructed with the features selected by FDR yield smaller misclassification rate (32%) than the model with full features (38%). This implies that feature selection by FDR adequately eliminates non-informative features for classification.

FUTURE TRENDS

Developing highly efficient methods to identify meaningful features from spectral data is a challenge because of their complicated formation. The processes of the presented features extraction/selection methods are performed on original spectra that are considered a single scale, although the optimal scales of the spectral regions associated with different chemical species vary. In other words, spectral data usually comprise a number of local bumps or peaks with different scales (i.e., peaks of different sizes). Thus, efficient analytical tools are needed to handle the multiscale nature of NMR spectra. Wavelet transforms are the most useful method to use with NMR spectra because such transforms have the advantage of locality of analysis and the capability to handle multiscale information efficiently (Bruce et al., 2002). Wavelet transforms have numerous advantages over conventional feature extraction methods. First, the extracted coefficients from wavelet transforms are combinations of a small number of local features that can provide the physical meaning of features in spectra. Second, the capability of wavelets to break down the original spectra into different resolution levels can efficiently handle the multiscale nature of spectral data. Third, wavelets have the highly desirable property of reducing the serial correlation between the features in a spectrum (Wornell, 1996). Finally, wavelet transforms coupled with a relevant thresholding method can remove noise, thus, enhancing the feature selection process.

CONCLUSION

This chapter presents feature extraction and feature selection methods for identifying important features in spectral data. The present feature extraction and feature selection methods have their own advantages and disadvantages, and the choice between them depends upon the purpose of the application. The transformation process in feature extraction takes fully into account the multivariate nature of spectral data and thus provides better discriminative ability but suffers from the lack of interpretability. This problem of interpretation may be overcome with recourse to feature selection because transformations are absent from the process, but then the problem arises of incorporating the correlation structure present in spectral data. Wavelet transforms are a promising approach as the compromise between feature extraction and feature selection. Extracted coefficients from wavelet transforms may have a meaningful physical interpretation because of their locality. Thus, minimal loss of interpretation occurs when wavelet coefficients are used for feature selection.

KEY TERMS

False Discovery Rate: The expected proportion of false positives among all the hypotheses rejected.

Feature: Measurable values that characterize an individual observation.

Feature Extraction: The process of creating new features based on transformations of the original features.

Feature Selection: The process of identifying a subset of important features that leads to the best prediction or classification.

Metabolomics: The global analysis for the detection and recognition of metabolic changes in response to pathophysiological stimuli, genetic modification, nutrition intake, and toxins in integrated biological systems.

Nuclear Magnetic Resonance Spectroscopy: The technique that uses the magnetic properties of nuclei to understand the structure and function of chemical species.

Wavelet Transforms: The process of approximating a signal at different scales (resolutions) and space simultaneously.

Feature Reduction for Support Vector Machines

Shouxian Cheng
Planet Associates, Inc., USA

Frank Y. Shih
New Jersey Institute of Technology, USA

INTRODUCTION

The *Support Vector Machine* (SVM) (Cortes and Vapnik,1995; Vapnik, 1995; Burges, 1998) is intended to generate an optimal separating hyperplane by minimizing the generalization error without the assumption of class probabilities such as Bayesian classifier. The decision hyperplane of SVM is determined by the most informative data instances, called *Support Vectors* (SVs). In practice, these SVMs are a subset of the entire training data. By now, SVMs have been successfully applied in many applications, such as face detection, handwritten digit recognition, text classification, and data mining. Osuna et al. (1997) applied SVMs for face detection. Heisele *et al*. (2004) achieved high face detection rate by using 2nd degree SVM. They applied hierarchical classification and feature reduction methods to speed up face detection using SVMs.

Feature extraction and reduction are two primary issues in feature selection that is essential in pattern classification. Whether it is for storage, searching, or classification, the way the data are represented can significantly influence performances. Feature extraction is a process of extracting more effective representation of objects from raw data to achieve high classification rates. For image data, many kinds of features have been used, such as raw pixel values, Principle Component Analysis (PCA), Independent Component Analysis (ICA), wavelet features, Gabor features, and gradient values. Feature reduction is a process of selecting a subset of features with preservation or improvement of classification rates. In general, it intends to speed up the classification process by keeping the most important class-relevant features.

BACKGROUND

Principal Components Analysis (PCA) is a multivariate procedure which rotates the data such that the maximum variabilities are projected onto the axes. Essentially, a set of correlated variables are transformed into a set of uncorrelated variables which are ordered by reducing the variability. The uncorrelated variables are linear combinations of the original variables, and the last of these variables can be removed with a minimum loss of real data. PCA has been widely used in image representation for dimensionality reduction. To obtain m principal components, a transformation matrix of $m \times N$ is multiplied by an input pattern of $N \times 1$. The computation is costly for high dimensional data.

Another well-known method of feature reduction uses Fisher's criterion to choose a subset of features that possess a large between-class variance and a small within-class variance. For two-class classification problem, the within-class variance for i-th dimension is defined as

$$\sigma_i^2 = \frac{\sum_{j=1}^{l} (g_{j,i} - m_i)^2}{l-1}, \tag{1}$$

where l is the total number of samples, $g_{j,i}$ is the i-th dimensional attribute value of sample j, and m_i is the mean value of the i-th dimension for all samples. The Fisher's score for between-class measurement can be calculated as

$$S_i = \left| \frac{m_{i,class1} - m_{i,class2}}{\sigma_{i,class1}^2 + \sigma_{i,class2}^2} \right| . \tag{2}$$

By selecting the features with the highest Fisher's scores, the most discriminative features between class 1 and class 2 are retained.

Weston et al. (2000) developed a feature reduction method for SVMs by minimizing the bounds on the leave-one-out error. Evgenious et al. (2003) introduced a method for feature reduction for SVMs based on the observation that the most important features are the ones that separate the hyperplane the most. Shih and Cheng (2005) proposed an improved feature reduction method in input and feature space for the 2nd degree polynomial SVMs.

MAIN FOCUS

In this section, we present an improved feature reduction method for the 2nd degree polynomial SVMs. In the input space, a subset of input features is selected by ranking their contributions to the decision function. In the feature space, features are ranked according to the weighted support vector in each dimension. By applying feature reduction in both input and feature space, a fast non-linear SVM is designed without a significant loss in performance. Here, the face detection experiment is used to illustrate this method.

Introduction to Support Vector Machines

Consider a set of l labeled training patterns $(\mathbf{x}_1, y_1)$, $(\mathbf{x}_2, y_2)$, ..., $(\mathbf{x}_i, y_i)$, ..., $(\mathbf{x}_l, y_l)$ where $\mathbf{x}_i$ denotes the i-th training sample and $y_i \in \{1, -1\}$ denotes the class label. For two-class classification, SVMs use a hyperplane that maximizes the margin (i.e., the distance between the hyperplane and the nearest sample of each class). This hyperplane is viewed as the *Optimal Separating Hyperplane* (OSH).

If the data are not linearly separable in the input space, a non-linear transformation function $\Phi(\cdot)$ is used to project $\mathbf{x}_i$ from the input space to a higher dimensional feature space. An OSH is constructed in the feature space by maximizing the margin between the closest points $\Phi(\mathbf{x}_i)$ of two classes. The inner-product between two projections is defined by a kernel function $K(\mathbf{x}, \mathbf{y}) = \Phi(\mathbf{x}) \cdot \Phi(\mathbf{y})$. The commonly-used kernels include polynomial, Gaussian RBF, and Sigmoid kernels.

The decision function of the SVM is defined as

$$f(\mathbf{x}) = \mathbf{w} \cdot \Phi(\mathbf{x}) + b = \sum_{i=1}^{l} \alpha_i y_i K(\mathbf{x}, \mathbf{x}_i) + b\,, \tag{3}$$

where $\mathbf{w}$ is the support vector, α_i is the Lagrange multiplifier, and b is a constant. The optimal hyperplane can be obtained by maximizing

$$W(\boldsymbol{\alpha}) = \sum_{i=1}^{l} \alpha_i - \frac{1}{2} \sum_{i=1}^{l} \sum_{j=1}^{l} \alpha_i\, \alpha_j y_i y_j K(\mathbf{x}_i, \mathbf{x}_j)\,, \tag{4}$$

subject to

$$\sum_{i=1}^{l} \alpha_i y_i = 0 \text{ and } 0 \le \alpha_i \le C,$$

where C is regularization constant that manages the tradeoff between the minimization of the number of errors and the necessity to control the capacity of the classifier.

Feature Reduction in Input Space

A feature reduction method is proposed for the 2nd-degree polynomial SVM with kernel $K(\mathbf{x}, \mathbf{y}) = (1 + \mathbf{x} \cdot \mathbf{y})^2$ After training, the decision function for a pattern $\mathbf{x}$ is defined in Box 1, where s is the total number of support vectors, $\mathbf{x}_i$ is the i-th support vector, and $x_{i,k}$ and x_k are respectively the k-th dimension for the support vector $\mathbf{x}_i$ and the pattern $\mathbf{x}$. The component in the k-th dimension (where $k = 1, 2, \ldots, N$) is shown in Box 2.

The m features with the largest contributions to the decision function are selected from the original N features. The contribution can be obtained by

$$F(k) = \int_V f(\mathbf{x}, k)\, dP(\mathbf{x}), \tag{7}$$

where V denotes the input space and $P(\mathbf{x})$ denotes the probability distribution function. Since $P(\mathbf{x})$ is unknown, we approximate $F(k)$ using a summation over the support vectors as shown in Box 3.

Box 1.

$$f(\mathbf{x}) = \sum_{i=1}^{s} \alpha_i y_i (1 + \mathbf{x}_i \cdot \mathbf{x})^2 + b$$

$$(= \sum_{i=1}^{s} \alpha_i y_i \ 1 + x_{i,1}x_1 + x_{i,2}x_2 + \ldots + x_{i,k}x_k + \ldots + x_{i,N}x_N)^2 + b \quad (5)$$

Box 2.

$$f(\mathbf{x}, k) = \sum_{i=1}^{s} \alpha_i y_i \left[2x_k x_{i,k} (1 + x_{i,1}x_1 + \ldots + x_{i,k-1}x_{k-1} + x_{i,k+1}x_{k+1} + \ldots + x_{i,N}x_N) + x_k^2 x_{i,k}^2 \right]$$

$$2 = \sum_{i=1}^{s} \alpha_i y_i \left[\ x_k x_{i,k} (1 + x_{i,1}x_1 + \ldots + x_{i,N}x_N) - x_k^2 x_{i,k}^2 \right]. \quad (6)$$

Box 3.

$$F(k) = \sum_{i=1}^{s} \left| \sum_{j=1}^{s} \alpha_j y_j [2x_{i,k}x_{j,k}(1 + x_{j,1}x_{i,1} + \ldots + x_{j,N}x_{i,N}) - x_{i,k}^2 x_{j,k}^2] \right| \quad (8)$$

For experiment, a face image database from the Center for Biological and Computational Learning at Massachusetts Institute of Technology (MIT) is adopted, which contains 2,429 face training samples, 472 face testing samples, and 23,573 non-face testing samples. The 15,228 non-face training samples are randomly collected from the images that do not contain faces. The size of all these samples is 19 × 19.

In order to remove background pixels, a mask is applied to extract only the face. Prior to classification, we perform image normalization and histogram equalization. The image normalization is used to normalize the gray-level distribution by the Gaussian function with zero mean and one variance. Histogram equalization uses a transformation function equal to the cumulative distribution to produce an image whose gray levels have a uniform density. Figure 1 shows a face image, the mask, the image after normalization, and the image after histogram equalization.

Different preprocessing methods have been tested: image normalization, histogram equalization, and without preprocessing. We obtain that using normalization or equalization can produce almost the same but much better results than without preprocessing. Therefore, in the following experiments, image normalization is used as the pre-processing method. To calculate PCA values, only positive training samples are used to calculate transformation matrix. The reason is that only training face samples are used in the calculation of the transformation matrix, and for testing the input samples are projected on the face space. Therefore, better classification results can be achieved in separating face and non-face classes

Using the normalized 2,429 face and 15,228 non-face training samples and taking all the 283 gray values as input to train the 2nd-degree SVM, we obtain 252 and 514 support vectors for face and non-face classes, respectively. Using these support vectors in Eq. (8), we obtain $F(k)$, where k = 1, 2, …, 283. Figure 2 shows the Receiver Operating Characteristic (ROC) curves for different kinds of features in input space. The ROC curve is defined as shifting the SVM hyperplane by changing the threshold value b to obtain corresponding detection rates and false positive rates. Face classification is performed on the testing set to calculate the false positive and the detection rates. The horizontal

Figure 1.

(a) Original face image

(b) the mask

(c) normalized image

(d) histogram equalized image

axis shows the false positive rate over 23,573 non-face testing samples. The vertical axis shows the detection rate over 472 face testing samples.

Using 100 gray values selected by the ranking method is compared with the methods of using all the 283 gray values, 100 PCA features, Fisher's scores, and the 100 features selected by Evgenious *et al.* (2003). It is observed that our method performs similarly as using all the 283 features and using 100 PCA values; however, it is better than using the 100 features by Fisher's scores and by Evgenious *et al.* (2003).

Feature Reduction in Feature Space

In feature space, the decision function $f(\mathbf{x})$ of SVMs is defined as

$$f(\mathbf{x}) = \sum_{i=1}^{s} \alpha_i y_i (\Phi(\mathbf{x}) \cdot \Phi(\mathbf{x}_i)) + b = \mathbf{w} \cdot \Phi(\mathbf{x}) + b, \tag{9}$$

where $\mathbf{w}$ is the support vector. For a 2nd-degree polynomial SVM with the input space of dimension N and kernel $K(\mathbf{x}, \mathbf{y}) = (1 + \mathbf{x} \cdot \mathbf{y})^2$ the feature space is given by

$$\Phi(\mathbf{x}) = (\sqrt{2}x_1, ..., \sqrt{2}x_N, x_1^2, ..., x_N^2, \sqrt{2}x_1x_2, ..., \sqrt{2}x_{N-1}x_N) \tag{10}$$

of dimension $P = N(N+3)/2$.

Suppose a 2nd-degree SVM using face and non-face samples is trained to obtain s support vectors. The support vector in the feature space can be represented as

$$\mathbf{w} = \sum_{i=1}^{s} \alpha_i y_i \Phi(\mathbf{x}_i) = (w_1, w_2, ..., w_P). \tag{11}$$

One way to select a subset of features is to rank $|w_k|$, for $k = 1, 2, ..., P$. An improved method of using is proposed,

$$\left| w_k \int_V | x_k^* | \, dp(x_k^*) \right|$$

where x_k^* denotes the k-th dimension of $\mathbf{x}$ in the feature space V. Since the distribution function $dp(x_k^*)$ is unknown, the ranking function $R(k)$ is calculated as

$$R(k) = \left| w_k \sum_{i=1}^{s} | x_{i,k}^* | \right|, \tag{12}$$

where $x_{i,k}^*$ denotes the k-th dimension of $\mathbf{x}_i$. The decision function of q features is calculated as

$$f(\mathbf{x}, q) = \mathbf{w}(q) \cdot \Phi(\mathbf{x}, q) + b,$$

where $\mathbf{w}(q)$ is the selected q features in $\mathbf{w}$ and $\Phi(\mathbf{x}, q)$ is the corresponding q features in $\mathbf{x}$.

In the experiments, a 2nd-degree polynomial SVM is trained using 60 PCA values in the input space. We obtain 289 and 412 support vectors for face and non-face classes, respectively. The 1,890 features in the feature space can be calculated by Eq. (10). The support vector in the feature space, $\mathbf{w} = (w_1, w_2, ..., w_{1890})$ can be calculated by Eq. (11). Given a pattern $\mathbf{x}$, the decision value of using the selected q features can be calculated by Eq. (13). When q = 300, 500, and 1000, we illustrate the results in Figure 3. It is observed that using the selected 500 or 1,000 features can achieve almost the same performance as using all the 1,890 features. However, using 300 features is insufficient to achieve a good performance.

Figure 2. ROC curves for comparisons of using different features in input space

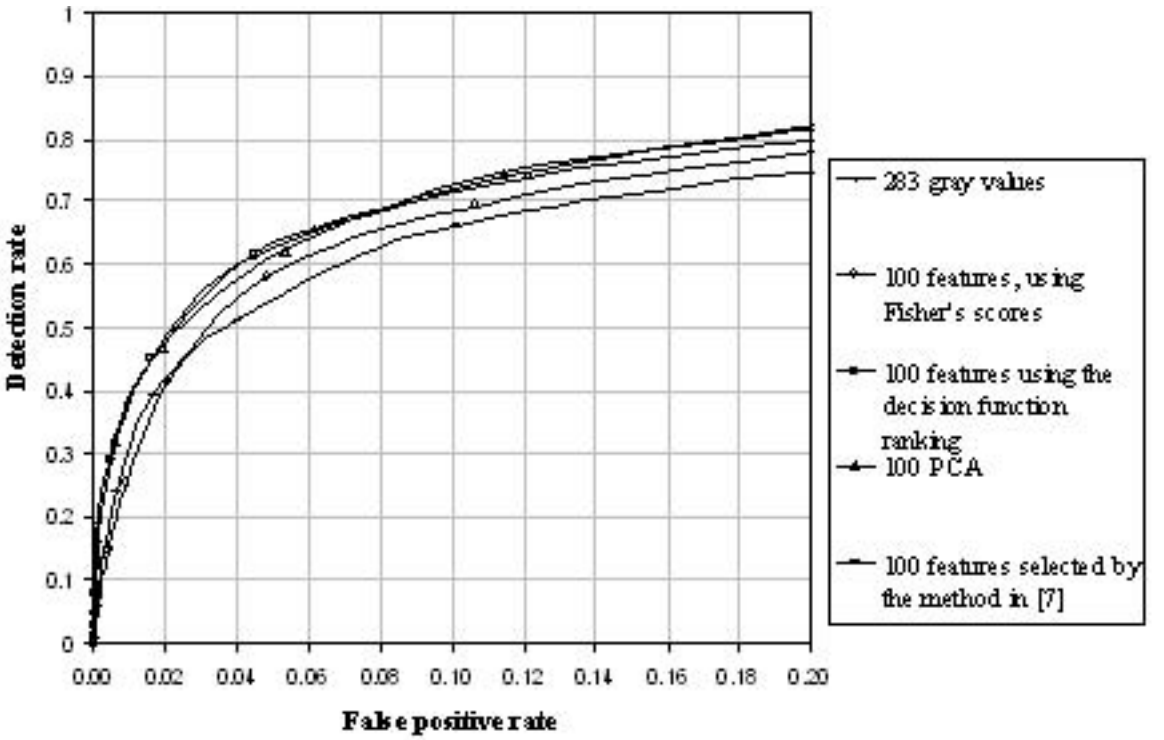

Figure 3. ROC curves for different numbers of features in the feature space

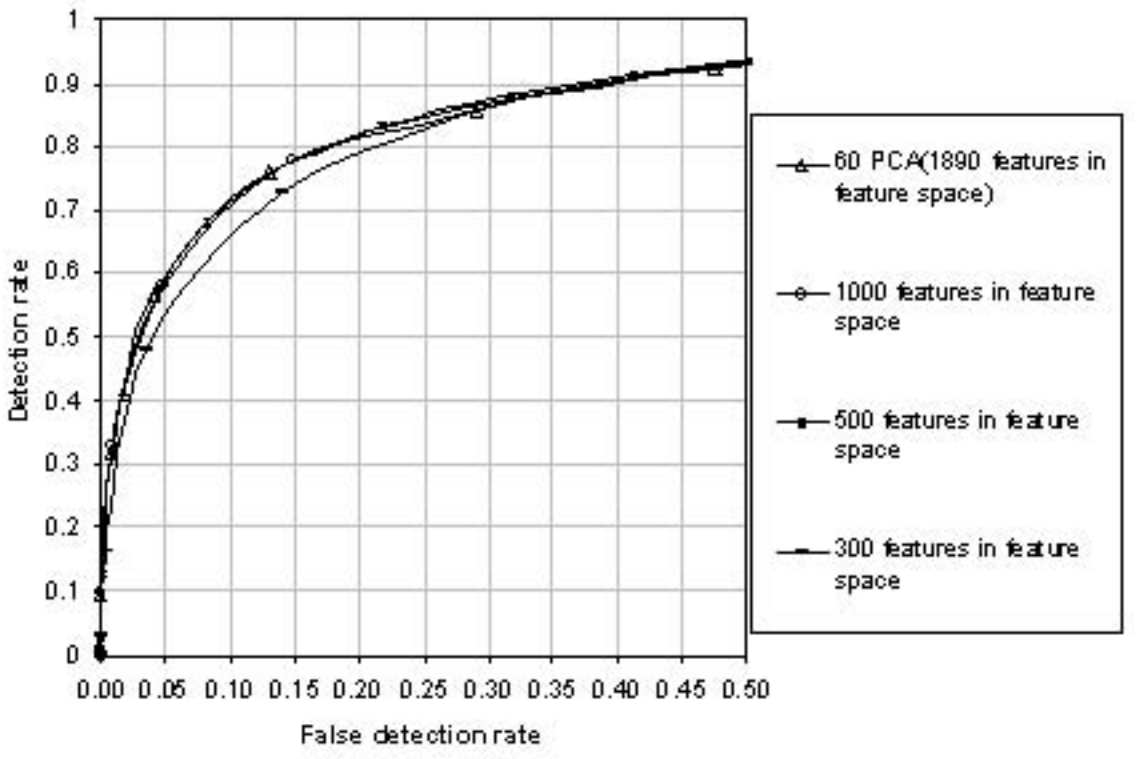

Combinational Feature Reduction in Input and Feature Spaces

First, we choose m features from the N input space, and train the 2nd-degree polynomial SVM. Next, we select q features from $P = m(m + 3)/2$ features in the feature space to calculate the decision value. We use two following methods to compute the decision values: one by Eq. (3) in input space and the other by Eq. (5) in feature space. In Eq. (3), the number of multiplications required to calculate the decision function is $(N + 1)s$. Note that s is the total number of support vectors. In Eqs. (5) , the total number of multiplications required is $(N + 3)N$. If $(N + 1)s > (N + 3)N$, it is more efficient to implement the 2nd-degree polynomial SVM in the feature space; otherwise, in the input space. This is evidenced by our experiments because the number of support vectors is more than 700, that is much larger than N. Note that $N = 283$, 60, or 100 indicates all the gray-value features, 60 PCA values, or 100 features, respectively.

The SVM is trained using the selected 100 features as described above and 244 and 469 support vectors are obtained for face and non-face classes, respectively. Fig. 4 shows the comparisons of our combinational method using 3,500 features in feature space, 60 PCA values, and all the 283 gray values. It is observed that using our combinational method can obtain competitive results as using 60 PCA values or all 283 gray values. Apparently, our method gains the advantage of speed.

Table 1 lists the number of features used in the input and feature space and the number of multiplications required in calculating the decision values for comparing our method with the methods of using all the gray values and using PCA features.

From Table 1, it is observed that using PCA for feature reduction in the input and feature space, a speed-up factor of 4.08 can be achieved. However, using our method, a speed-up factor of 9.36 can be achieved. Note that once the features in the feature space are determined, we do not need to project the input space on the whole feature space, but on the selected feature space. This

Figure 4. ROC curves of using the proposed feature reduction method, 60 PCA, and all the 283 gray values

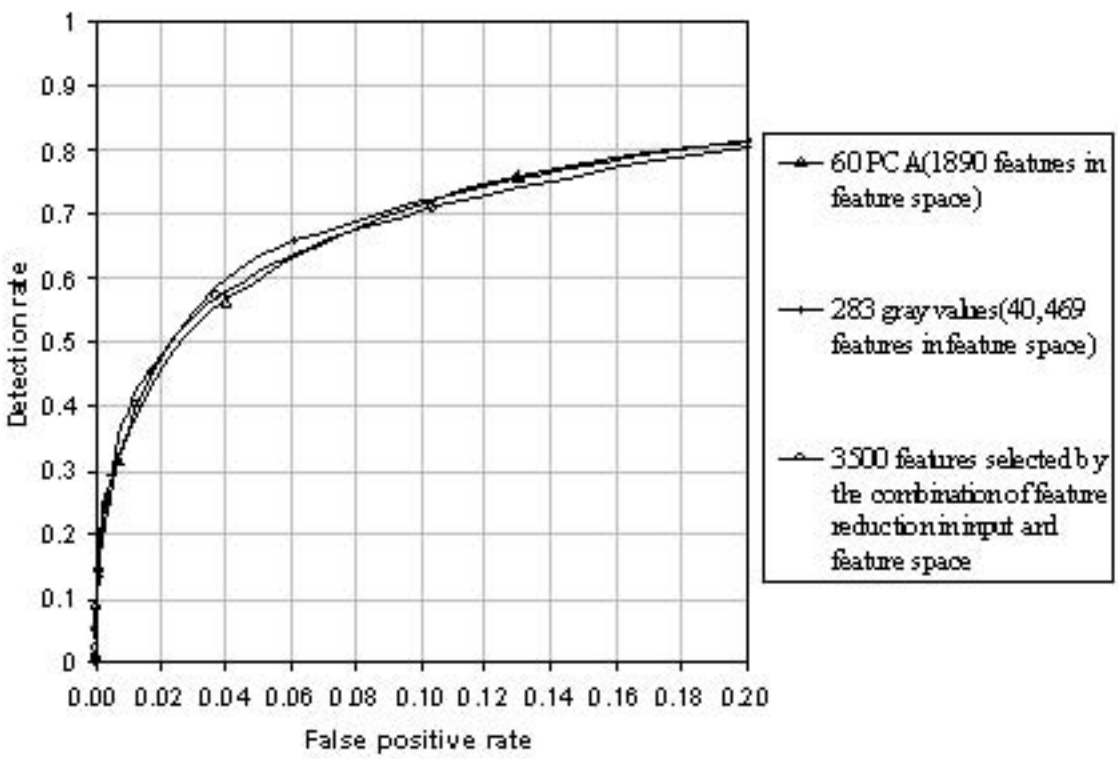

Table 1. Comparisons of the number of features and the number of multiplications

Methods	Number of features in input space	Number of features in feature space	Number of multiplications
All gray values	283	40,469	80,938
PCA	60	1,890	20,760
Our method	100	3,500	8,650

can further reduce the computation, i.e., only 7,000 multiplications are required instead of 8,650.

FUTURE TRENDS

SVMs have been widely used in many applications. In many cases, SVMs have achieved either better or similar performance as other competing methods. Due to the time-consuming training procedure and high dimensionality of data representation, feature extraction and feature reduction will continue to be important research topics in pattern classification field. An improved feature reduction method has been proposed by combining both input and feature space reduction for the 2nd degree SVM. Feature reduction methods for Gaussian RBF kernel need to be studied. Also it is an interesting research topic to explore how to select and combine different kind features to improve classification rates for SVMs.

CONCLUSION

An improved feature reduction method in the combinational input and feature space for Support Vector Machines (SVMs) has been described. In the input space, a subset of input features is selected by ranking their contributions to the decision function. In the feature space, features are ranked according to the weighted support vector in each dimension. By combining both input and feature space, we develop a fast non-linear SVM without a significant loss in performance. The proposed method has been tested on the detection of face, person, and car. Subsets of features are chosen from pixel values for face detection and from Haar wavelet features for person and car detection. The experimental results show that the proposed feature reduction method works successfully.

KEY TERMS

Feature Extraction: Feature extraction is a process of extracting more effective representation of objects from raw data to achieve high classification rates.

Feature Reduction: Feature reduction is a process of selecting a subset of features with preservation or improvement of classification rates.

Machine Learning: As a subfield of artificial intelligence, machine learning is concerned with the development of algorithms and techniques that allow computers to learn and to recognize patterns that have occurred repeatedly and improve its performance based on past experience.

Principle Component Analysis (PCA): PCA is a multivariate procedure which rotates the data such that the maximum variabilities are projected onto the axes. PCA has been widely used in image representation for dimensionality reduction.

Receiver Operating Characteristic (ROC) curves: The ROC curve for SVM is defined as shifting the SVM hyperplane by changing the threshold value b to obtain corresponding detection rates and false positive rates.

Support Vector Machine: For two-class classification, SVMs use a hyperplane that maximizes the margin (i.e., the distance between the hyperplane and the nearest sample of each class). This hyperplane is viewed as the *Optimal Separating Hyperplane* (OSH).

Feature Selection

Damien François
Université catholique de Louvain, Belgium

INTRODUCTION

In many applications, like function approximation, pattern recognition, time series prediction, and data mining, one has to build a model relating some features describing the data to some response value. Often, the features that are relevant for building the model are not known in advance. Feature selection methods allow removing irrelevant and/or redundant features to only keep the feature subset that are most useful to build a prediction model. The model is simpler and easier to interpret, reducing the risks of overfitting, non-convergence, etc. By contrast with other dimensionality reduction techniques such as principal component analysis or more recent nonlinear projection techniques (Lee & Verleysen 2007), which build a new, smaller set of features, the features that are selected by feature selection methods preserve their initial meaning, potentially bringing extra information about the process being modeled (Guyon 2006).

Recently, the advent of high-dimensional data has raised new challenges for feature selection methods, both from the algorithmic point of view and the conceptual point of view (Liu & Motoda 2007). The problem of feature selection is exponential in nature, and many approximate algorithms are cubic with respect to the initial number of features, which may be intractable when the dimensionality of the data is large. Furthermore, high-dimensional data are often highly redundant, and two distinct subsets of features may have very similar predictive power, which can make it difficult to identify the best subset.

BACKGROUND

Feature selection methods are often categorized as 'filters,' 'wrappers,' or 'embedded' methods. Roughly stated, filters use statistical measures to 'filter out' unneeded features before building the model. Wrappers, by contrast, use the prediction error of the model to select the features. Embedded methods are actually prediction models that propose, as a by-product, a scoring, or even a selection of the features; like for instance decision trees (Breiman, 2001) and LASSO models (Efron, 2004).

This distinction between filters and wrappers, which has historical roots (Kohavi & John, 1997), is less and less relevant now because many new methods are very difficult to label with either name. More generally, all feature selection methods share the same structure; they need (1) a criterion that scores a feature or a set of features according to its (their) predictive power, and (2) a method to find the optimal subset of features according to the chosen criterion. This method comprises an exploration algorithm, which generates new subsets for evaluation, and a stopping criterion to help deciding when to stop the search.

Criteria for scoring a single feature include the well-known correlation, chi-squared measure, and many other statistical criteria. More powerful methods, like mutual information (Battiti, 1994), and the Gamma test (Stefansson *et al*, 1997) (for regression) and the RELIEF algorithm (Kira & Rendell, 1992) (for classification), allow scoring a whole subset of features. In a more wrapper-like approach, the performances of a prediction model can also be used to assess the relevance of a subset of features.

Algorithms for finding the optimal subset, which is a combinatorial problem, can be found in the Artificial Intelligence literature (Russel & Norvig, 2003). In the context of feature selection, greedy algorithms, which select or exclude one feature at a time, are very popular. Their reduced complexity still allows them to find near optimal subsets that are very satisfactory (Aha & Bankert, 1996).

MAIN FOCUS

This section discusses the concepts of relevance and redundancy, which are central to any feature selection method, and propose a step-by-step methodology along with some recommendations for feature selection on real, high-dimensional, and noisy data.

Relevance and Redundancy

What do we mean precisely by "relevant"? See Kohavi & John (1997); Guyon & Elisseeff (2003); Dash & Liu (1997); Blum & Langley (1997) for a total of nearly ten different definitions for the relevance of a feature subset. The definitions vary depending on whether a particular feature is relevant but not unique, etc. Counter-intuitively, a feature can be useful for prediction and at the same time irrelevant for the application. For example, consider a bias term. Conversely, a feature that is relevant for the application can be useless for prediction if the actual prediction model is not able to exploit it.

Is redundancy always evil for prediction? Surprisingly, the answer is no. First, redundant features can be averaged to filter out noise to a certain extent. Second, two correlated features may carry information about the variable to predict, precisely in their difference.

Can a feature be non relevant individually and still useful in conjunction with others? Yes. The typical example is the XOR problem (Y = X1 XOR X2), or the sine function over a large interval (Y = sin (2 π (X1 + X2)). Both features X1 and X2 are needed to predict Y, but each of them is useless alone; knowing X1 perfectly, for instance, does not allow deriving any piece of information about Y. In such case, only multivariate criteria (like mutual information) and exhaustive or randomized search procedures (like genetic algorithms) will provide relevant results.

A Proposed Methodology

Mutual information and Gamma test for feature subset scoring. The mutual information and the Gamma test are two powerful methods for evaluating the predictive power of a subset of features. They can be used even with high-dimensional data, and are theoretically able to detect any nonlinear relationship. The mutual information estimates the loss of entropy of the variable to predict, in the information-theoretical sense, when the features are known, and actually estimates the degree of independence between the variables. The mutual information, associated with a non-parametric test such as the permutation test, makes a powerful tool for excluding irrelevant features (François et al., 2007). The Gamma test produces an estimate of the variance of the noise that a nonlinear prediction model could reach using the given features. It is very efficient when totally irrelevant features have been discarded. Efficient implementations for both methods are available free for download (Kraskov et al, 2004; Stefansson et al, 1997).

Greedy subset space exploration. From the simple ranking (select the K features that have the most individual score), to more complex approaches like genetic algorithms (Yang & Honavar, 1998) or simulated annealing (Brooks et al, 2003), the potentially useful exploration techniques are numerous. Simple ranking is very efficient from a computational point of view, it is however not able to detect that two features are useful together while useless alone. Genetic algorithms, or simulated annealing, are able to find such features, at the cost of a very large computational burden.

Greedy algorithms are often a very suitable option. Greedy algorithms, such as Forward Feature Selection, work incrementally, adding (or removing) one feature at a time, and never questioning the choice of that feature afterwards. These algorithms, although being sub-optimal, often finds feature subsets that are very satisfactory, with acceptable computation times.

A step-by step methodology. Although there exists no ideal procedure that would work in all situations, the following practical recommendations can be formulated.

1. Exploit any domain knowledge to eliminate obviously useless features. Use an expert, either before selecting features to avoid processing obviously useless features. Removing two or three features a priori can make a huge difference for an exponential algorithm, but also for a cubic algorithm! You can also ask the expert after the selection process, to check whether the selected features make sense.
2. Perform simple ranking with the correlation coefficient. It is important to know if there is a strong linear link between features and the response value, because nonlinear models are seldom good at modeling linear mappings, and will certainly not outperform a linear model in such a case.

3. Perform simple ranking first using mutual information to get baseline results. It will identify the most individually relevant features, and maybe also identify features that are completely independent from the response value. Excluding them might be considered only if it leads to a significant reduction in computation time. Building a prediction model with the first three up to, say, the first ten relevant features, will give approximate baseline prediction results and will provide a rough idea of the computation time needed. This is an important piece of information that can help decide which options to consider.
4. If tractable, consider the exhaustive search of all pairs or triplets of features with a Gamma test and/or mutual information. This way, risks of ignoring important features that are useful together only, are reduced. If it is not tractable, consider only pairs or triplets involving at least one individually relevant feature, or even only relevant features. The idea is always to trade comprehensiveness of the search against computational burden.
5. Initiate a forward strategy with the best subset from previous step. Starting from three features instead of one will make the procedure less sensitive to the initialization conditions.
6. End with a backward search using the actual prediction model, to remove any redundant features and further reduce the dimensionality. It is wise at this stage to use the prediction model because (i) probably few iterations will be performed and (ii) this focuses the selection procedure towards the capabilities/flaws of the prediction model.
7. If the forward-backward procedure gives results that are not much better than those obtained with the ranking approach, resort to a randomized algorithm like the genetic algorithm first with mutual information or gamma test, then with the actual model if necessary. Those algorithms will take much more time than the incremental procedure but they might lead to better solutions, as they are less restrictive than the greedy algorithms.

Finally, the somewhat philosophical question "*What to do with features that are discarded ?"* can be considered. Caruana has suggested using them as extra outputs to increase the performances of the prediction model (Caruana & de Sa, 2003). These extra outputs force the model to learn the mapping from the selected features to the discarded ones. Another interesting idea is to use the discarded features, especially those discarded because of redundancy, along with some other relevant features to build one or several other models and group them into an ensemble model (Gunter & Bunke, 2002). This ensemble model combines the results of several different models (built on different feature subsets) to provide a more robust prediction.

FUTURE TRENDS

Feature selection methods will face data of higher and higher dimensionality, and of higher complexity, and therefore will need to adapt. Hopefully the process of feature selection can be relatively easily adapted for parallel architectures. Feature selection methods will also be tuned to handle structured data (graphs, functions, etc.). For instance, when coping with functions, intervals rather than single features should be selected (Krier, forthcoming).

Another grand challenge about feature selection is to assess the stability of the selected subset, especially if the initial features are highly correlated. How likely is the optimal subset to change if the data slightly change? Cross-validation and other resampling techniques could be used to that end, but at a computational cost that is, at the moment, not affordable.

CONCLUSION

The ultimate objective of feature selection is to gain both time and knowledge about a process being modeled for prediction. Feature selection methods aim at reducing the data dimensionality while preserving the initial interpretation of the variables, or features. This dimensionality reduction allows building simpler models, hence less prone to overfitting and local minima for instance, but it also brings extra information about the process being modeled.

As data are becoming higher- and higher-dimensional nowadays, feature selection methods need to adapt to cope with the computational burden and the problems induced by highly-correlated features. The mutual information, or the Gamma test, along with a greedy forward selection, is a very tractable option in such cases. Even though these criteria are much simpler than building a prediction model, like in a pure wrapper

approach, they can theoretically spot relationships of any kind between features and the variable to predict. Another challenge about feature selection methods is to assess their results through resampling methods, to make sure that the selected subset is not dependent on the actual sample used.

KEY TERMS

Embedded Method: Method for feature selection that consists in analyzing the structure of a prediction model (usually a regression of classification tree) to identify features that are important.

Feature: Attribute describing the data. For instance, in data describing a human body, features could be length, weight, hair color, etc. Is synonym with 'input', 'variable', "attribute", 'descriptor', among others.

Feature Extraction: Feature extraction is the process of extracting a reduced set of features from a larger one (dimensionality reduction). Feature extraction can be performed by feature selection, linear or nonlinear projections, or by ad-hoc techniques, in the case of image data for instance.

Feature Selection: Process of reducing the dimensionality of the data by selecting a relevant subset of the original features and discarding the others.

Filter: Method for feature selection that is applied before any prediction model is built.

Gamma Test: Method for estimating the variance of the noise affecting the data. This estimator is non-parametric, and can be used for assessing the relevance of a feature subset.

Mutual Information: Information-theoretic measure that estimates the degree of independence between two random variables. This estimator can be used for assessing the relevance of a feature subset.

Nonlinear Projection: Method for dimensionality reduction by creating a new, smaller, set of features that are nonlinear combinations of the original features.

Wrapper: Method for feature selection that is based on the performances of a prediction model to evaluate the predictive power of a feature subset.

Financial Time Series Data Mining

INTRODUCTION

Movement of stocks in the financial market is a typical example of financial time series data. It is generally believed that past performance of a stock can indicate its future trend and so stock trend analysis is a popular activity in the financial community. In this chapter, we will explore the unique characteristics of financial time series data mining. Financial time series analysis came into being recently. Though the world's first stock exchange was established in the 18th century, stock trend analysis began only in the late 20th century. According to Tay et al. (2003) analysis of financial time series has been formally addressed only since 1980s.

It is believed that financial time series data can speak for itself. By analyzing the data, one can understand the volatility, seasonal effects, liquidity, and price response and hence predict the movement of a stock. For example, the continuous downward movement of the S&P index during a short period of time allows investors to anticipate that majority of stocks will go down in immediate future. On the other hand, a sharp increase in interest rate makes investors speculate that a decrease in overall bond price will occur. Such conclusions can only be drawn after a detailed analysis of the historic stock data. There are many charts and figures related to stock index movements, change of exchange rates, and variations of bond prices, which can be encountered everyday. An example of such a financial time series data is shown in Figure 1. It is generally believed that through data analysis, analysts can exploit the temporal dependencies both in the deterministic (regression) and the stochastic (error) components of a model and can come up with better prediction models for future stock prices (Congdon, 2003).

BACKGROUND

Financial time series are a sequence of financial data obtained in a fixed period of time. In the past, due to technological limitations, data was recorded on a weekly basis. Nowadays, data can be gathered for very short durations of time. Therefore, this data is also called high frequency data or tick by tick data. Financial time series data can be decomposed into several components. Kovalerchuk and Vityaev (2005) defined financial time series data as the summation of long term trends, cyclical variations, seasonal variations, and irregular movements. These special components make financial time series data different from other statistical data like population census that represents the growth trends in the population.

In order to analyze complicated financial time series data, it is necessary to adopt data mining techniques.

Figure 1. A typical movement of a stock index

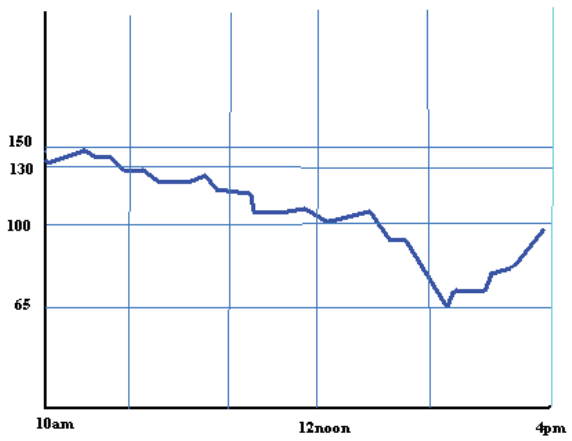

Table 1. Comparison of statistical and machine learning techniques

	Statistical techniques	Machine learning techniques
Advantages	• Relatively simple to use • Uni-variate and multi-variate analysis enable use of stationary and non-stationary models • Users can select different models to fit data and estimate parameters of models	• Easy to build model based on existing data • Computation carried out in parallel to model building which allows real time operations • Able to create own information representation during learning stages • More tolerant to noise in data
Disadvantages	• Performance and accuracy are negatively influenced by noise and non-linear components • The assumption of repeat patterns is unrealistic and may cause large errors in prediction	• Unstable for very large problems • Black box functions often do not provide any explanation of derived results

Currently, the commonly used data mining techniques are either statistics based or machine learning based. Table 1 compares the two types of techniques.

In the early days of computing, statistical models were popular tools for financial forecasting. According to Tsay (2002), the statistical models were used to solve linear time series problems, especially the stationarity and correlation problems of data. Models such as linear regression, autoregressive model, moving average, and autoregressive moving average dominated the industry for decades. However, those models were simple in nature and suffered from several shortcomings. Since financial data is rarely linear, these models were only useful to a limited extent. As a result sophisticated non-linear models like bilinear, threshold autoregression, smoothing transition autoregression, and conditional heteroscedastic autoregressions were developed to address the non-linearity in data. Those models could meet user requirements to a great extent. However, they were restricted in terms of the assumptions made by the models and were severely affected by the presence of noise in the data. It was observed that the correlation coefficient of diversification of a stock portfolio was adversely affected by the linear dependency of time series data (Kantardzic et al., 2004).

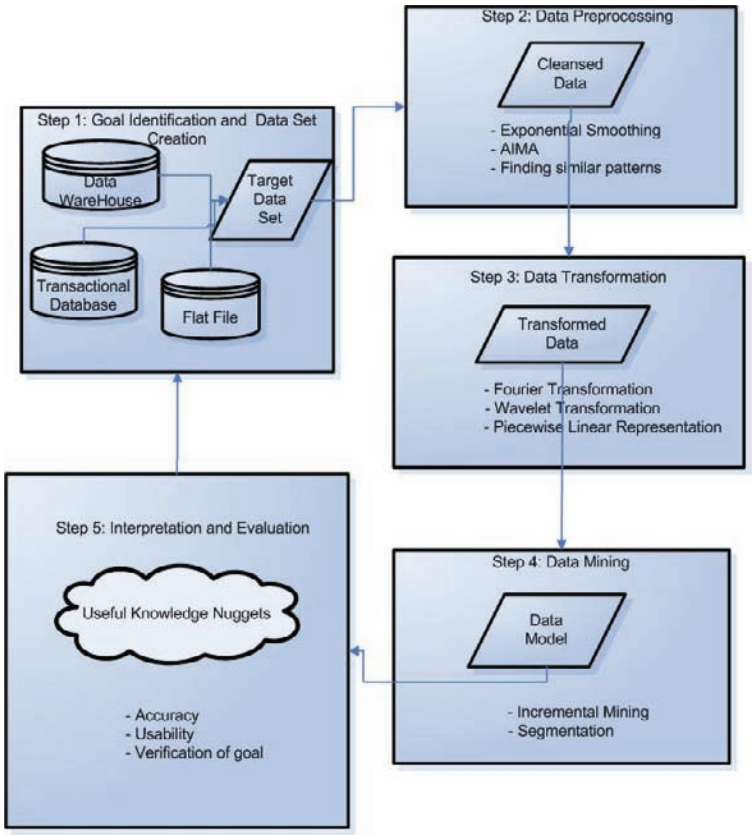
In the early 1990s, with the advent of machine learning new techniques were adopted by the field of financial forecasting. The machine learning techniques included artificial neural networks (ANN), genetic algorithms, decision trees, among others. ANNs soon became a very popular technique for predicting options prices, foreign exchange rates, stock and commodity prices, mutual funds, interest rates, treasury bonds etc. (Shen et al., 2005). The attractive features of ANNs were that it was data-driven, did not make any prior assumptions about the data, and could be used for linear and non-linear analysis. Also its tolerance to noise was high.

FINANCIAL TIME SERIES DATA MINING

In order to make useful predictions about future trends of financial time series, it is necessary to follow a number of steps of Knowledge Discovery in Databases (KDD) as shown in Figure 2. We can classify KDD into four important steps, namely, goal identification, preprocessing, data mining, and post-processing (Last et al., 2001). In order to conduct KDD, analysts have to establish a clear goal of KDD and prepare necessary data sets. Secondly, they have to preprocess the data to eliminate noise. Thirdly, it is necessary to transform the format of the data so as to make it amenable for data analysis. In the step of data mining, analysts have to supply a series of training data to build up a model, which can be subsequently tested using testing data. If the error of prediction for the training data does not exceed the tolerance level, the model will be deployed for use. Otherwise, the KDD process will be redone.

Step 1: Goal identification and data creation. To begin with KDD, users need to establish a clear goal

Figure 2. Steps involved in KDD



that serves as the guiding force for the subsequent steps. For example, users may set up a goal to find out which time period is best to buy or sell a stock. In order to achieve this goal, users have to prepare relevant data and this can include historical data of stocks. There are many financial time series data readily available for sale from vendors such as Reuters and Bloomberg. Users may purchase such data and analyze them in subsequent steps.

Step 2: Data preprocessing. Time series data can be classified into five main categories, namely, seasonal, trended, seasonal and trended, stationary, and chaotic (Cortez et al., 2001). If the noisy components in the data are not preprocessed, data mining cannot be conducted. De-noising is an important step in data preprocessing. Yu et al. (2006) showed that preprocessed data can increase the speed of learning for ANN. Several de-noising techniques are listed below.

Exponential smoothing: It is one of the most popular de-noising techniques used for time series data. By averaging historical values, it can identify random noise and separate it to make the data pattern consistent (Cortez et al., 2001). It is easy to use and is accurate for short term forecasting. It is able to isolate seasonal effects, shocks, psychological conditions like panic, and also imitation effects.

Autoregressive integrated moving average (ARIMA): Based on the linear combination of past values and errors, this technique makes use of the least squares method to identify noise in data (Cortez et al., 2001). Though this method is complex, it exhibits high accuracy of prediction over a wide range of time series domains.

Finding similar patterns: Apart from removing inconsistent data from databases, another method to generate clean time series data is by finding similar

patterns. Several techniques like longest common subsequence, Euclidean and time warping distance functions, and indexing techniques such as nearest neighbor classification are used for this purpose. Making use of estimation, the techniques mentioned above find similar patterns and can be used to facilitate pruning of irrelevant data from a given dataset. These techniques have shown their usefulness in discovering stocks with similar price movements (Vlachos et al., 2004).

Step 3: Data transformation. In order to provide a strong foundation for subsequent data mining, time series data needs to be transformed into other formats (Lerner et al., 2004). The data to be transformed include daily transaction volumes, turnovers, percentage change of stock prices, etc. Using data transformation, a continuous time series can be discretized into meaningful subsequences and represented using real-valued functions. (Chung et al., 2004) Three transformation techniques are frequently used and they are Fourier transformation, wavelet transformation, and piecewise linear representation.

Fourier Transformation: This method decomposes the input values into harmonic wave forms by using sine or cosine functions. It guarantees generation of a continuous and finite dataset.

Wavelet Transformation: This is similar to the above technique. Wavelet is a powerful data reduction technique that allows prompt similarity search over high dimensional time series data (Popivanov and Miller, 2002).

Piecewise Linear Representation: It refers to the approximation of time series 'T', of length 'n' with 'K' straight lines. Such a representation can make the storage, transmission and computation of data more efficient (Keogh et al., 2004).

Step 4: Data mining. Time series data can be mined using traditional data mining techniques such as ANN and other machine learning methods (Haykin, 1998). An important method of mining time series data is incremental learning. As time series data is on-going data, the previously held assumptions might be invalidated by the availability of more data in future. As the volume of data available for time series analysis is huge, re-mining is inefficient. Hence incremental learning to detect changes in an evaluated model is a useful method for time series data mining. There are many relevant methods for incremental mining, and they include induction of decision trees, semi-incremental learning methods, feed forward neural networks (Zeira et al., 2004) and also incremental update of specialized binary trees (Fu et al., 2005).

After incremental mining, time series data needs to be segmented into several categories. For example, highly volatile stocks and stocks that are responsive to movements of a particular index can be grouped into one category. There are three types of algorithms which help in such categorization. They are sliding windows, top-down, and bottom-up algorithms.

Sliding windows: Using this technique, an initial segment of the time series is first developed. Then it is grown incrementally till it exceeds some error bound. A full segment results when the entire financial time series data is examined (Keogh et al., 2004). The advantage of this technique is that it is simple and allows examination of data in real time. However, its drawbacks are its inability to look ahead and its lack of global view when compared to other methods.

Top-down: Unlike the previous technique, top-down algorithm considers every possible partitioning of time series. Time series data is partitioned recursively until some stopping criteria are met. This technique gives the most reasonable result for segmentation but suffers from problems related to scalability.

Bottom-up: This technique complements the top-down algorithm. It begins by first creating natural approximations of time series, and then calculating the cost of merging neighboring segments. It merges the lowest cost pair and continues to do so until a stopping criterion is met (Keogh et al., 2004). Like the previous technique, bottom-up is only suitable for offline datasets.

Step 5: Interpretation and evaluation. Data mining may lead to discovery of a number of segments in data. Next, the users have to analyze those segments in order to discover information that is useful and relevant for them. If the user's goal is to find out the most appropriate time to buy or sell stocks, the user must discover the relationship between stock index and

period of time. As a result of segmentation, the user may observe that price of a stock index for a particular segment of the market is extremely high in the first week of October whereas the price of another segment is extremely low in the last week of December. From that information, the user should logically interpret that buying the stock in the last week of December and selling it in the first week of October will be most profitable. A good speculation strategy can be formulated based on the results of this type of analysis. However, if the resulting segments give inconsistent information, the users may have to reset their goal based on the special characteristics demonstrated for some segments and then reiterate the process of knowledge discovery.

FUTURE TRENDS

Although statistical analysis plays a significant role in the financial industry, machine learning based methods are making big inroads into the financial world for time series data mining. An important development in time series data mining involves a combination of the sliding windows and the bottom-up segmentation. Keogh et al. (2004) have proposed a new algorithm by combining the two. It is claimed that the combination of these two techniques can reduce the runtime while retaining the merits of both methods.

Among machine learning techniques, ANNs seem to be very promising. However, in the recent literature, soft computing tools such as fuzzy logic, and rough sets have proved to be more flexible in handling real life situations in pattern recognition. (Pal & Mitra, 2004). Some researchers have even used a combination of soft computing approaches with traditional machine learning approaches. Examples of such include Neuro-fuzzy computing, Rough-fuzzy clustering and Rough self-organizing map (RoughSOM). Table 2 compares these three hybrid methods.

CONCLUSION

Financial time series data mining is a promising area of research. In this chapter we have described the main characteristics of financial time series data mining from the perspective of knowledge discovery in databases and we have elaborated the various steps involved in financial time series data mining. Financial time series data is quite different from conventional data in terms of data structure and time dependency. Therefore, traditional data mining processes may not be adequate for mining financial time series data. Among the two main streams of data analysis techniques, statistical models seem to be the more dominant due to their ease of use. However, as computation becomes cheaper and more data becomes available for analysis, machine learning techniques that overcome the inadequacies of statistical models are likely to make big inroads into the financial market. Machine learning tools such as

Table 2. Examples of hybrid soft computing methods for mining financial time series

New methods	Neuro-fuzzy computing	Rough-fuzzy clustering	RoughSOM
Description	An intelligent computing mechanism that integrates ANN with fuzzy logic.	A method which defines clusters using rough set theory and represents member values using fuzzy logic (Asharaf & Murty, 2004).	An SOM which classifies a new object by matching rules generated by rough sets (Shen & Loh, 2004)
Mechanism	Combination of neural network and fuzzy logic	Combination of rough sets and fuzzy logic	Combination of rough sets and self-organization maps
Advantages	Retained the advantage of ANN such as massive parallelism, robustness, and learning in data-rich environments and made modelling of imprecise and qualitative knowledge possible by using fuzzy logic (Pal & Mitra, 2004)	Proved to be scalable to large data sets and offered a faster and more robust solution to initialization and local minima problem of iterative refinement clustering (Pal & Mitra, 2004)	Took less initialization time and learning time and offered better cluster quality and more compact data representation (Pal & Mitra, 2004)

ANN as well as several soft computing approaches are gaining increasing popularity in this area due to their ease of use and high quality of performance. In future, it is anticipated that machine learning based methods will overcome statistical methods in popularity for time series analysis activities in the financial world.

KEY TERMS

Data Preprocessing: A procedure to make input data more suitable for data analysis so as to generate accurate results. Usual procedures for data preprocessing include de-noising and removing missing data.

Data Transformation: A procedure which transforms data from one format to another so that the latter format is more suitable for data mining.

Fuzzy Logic: A logic which models imprecise and qualitative knowledge in the form of degree of truth and allows objects to be members of overlapping classes.

Knowledge Discovery Process: A series of procedures which extract useful knowledge from a set of data.

Rough Set (RS): A representation of a conventional set using upper and lower approximation of the set and is to represent uncertainty or vagueness in the membership of objects to sets.

Self-Organizing Map (SOM): A single layer feedforward neural network, which is used for unsupervised learning or discovering similar clusters among data.

Soft Computing: A consortium of computational techniques which give the most optimal solution based on given tolerance level of imprecision and conventional logic system.

Time Series Segmentation: A process which classifies input time series data into different segments for the purpose of data classification.

Flexible Mining of Association Rules

Hong Shen
Japan Advanced Institute of Science and Technology, Japan

INTRODUCTION

The discovery of association rules showing conditions of data co-occurrence has attracted the most attention in data mining. An example of an association rule is the rule "the customer who bought bread and butter also bought milk," expressed by *T(bread; butter)→ T(milk)*.

Let $I = \{x_1, x_2, \ldots, x_m\}$ be a set of (data) items, called the domain; let D be a collection of records (transactions), where each record, T, has a unique identifier and contains a subset of items in I. We define *itemset* to be a set of items drawn from I and denote an itemset containing k items to be k-itemset. The support of itemset X, denoted by $\tilde{A}(X/D)$, is the ratio of the number of records (in D) containing X to the total number of records in D. An *association rule* is an implication rule $\Rightarrow Y$, where $X; \subseteq I$ and $X \bigcap Y=0$. The confidence of $\Rightarrow Y$ is the ratio of $\sigma(\bigcup Y/D)$ to $\sigma(X/D)$, indicating that the percentage of those containing X also contain Y. Based on the user-specified minimum support *(minsup)* and confidence *(minconf)*, the following statements are true: An itemset X is frequent if $\sigma(X/D) \geq$ minsup, and an association rule $\Rightarrow XY$ is strong i $\bigcup XY$ is frequent and $\frac{\sigma(X \bigcup Y/D)}{\sigma(X/Y)}$, minconf. The problem of mining association rules is to find all strong association rules, which can be divided into two subproblems:

1. Find all the frequent itemsets.
2. Generate all strong rules from all frequent itemsets.

Because the second subproblem is relatively straightforward — we can solve it by extracting every subset from an itemset and examining the ratio of its support; most of the previous studies (Agrawal, Imielinski, & Swami, 1993; Agrawal, Mannila, Srikant, Toivonen, & Verkamo, 1996; Park, Chen, & Yu, 1995; Savasere, Omiecinski, & Navathe, 1995) emphasized on developing efficient algorithms for the first subproblem.

This article introduces two important techniques for association rule mining: (a) finding N most frequent itemsets and (b) mining multiple-level association rules.

BACKGROUND

An association rule is called *binary association rule* if all items (attributes) in the rule have only two values: 1 (yes) or 0 (no). Mining binary association rules was the first proposed data mining task and was studied most intensively. Centralized on the *Apriori* approach (Agrawal et al., 1993), various algorithms were proposed (Savasere et al., 1995; Shen, 1999; Shen, Liang, & Ng, 1999; Srikant & Agrawal, 1996). Almost all the algorithms observe the downward property that all the subsets of a frequent itemset must also be frequent, with different pruning strategies to reduce the search space. Apriori works by finding frequent k-itemsets from frequent (k-1)-itemsets iteratively for k=1, 2, …, m-1.

Two alternative approaches, mining on domain partition (Shen, L., Shen, H., & Cheng, 1999) and mining based on knowledge network (Shen, 1999) were proposed. The first approach partitions items suitably into disjoint itemsets, and the second approach maps all records to individual items; both approaches aim to improve the bottleneck of Apriori that requires multiple phases of scans (read) on the database.

Finding all the association rules that satisfy minimal support and confidence is undesirable in many cases for a user's particular requirements. It is therefore necessary to mine association rules more flexibly according to the user's needs. Mining different sets of association rules of a small size for the purpose of predication and classification were proposed (Li, Shen, & Topor, 2001; Li, Shen, & Topor, 2002; Li, Shen, & Topor, 2004; Li, Topor, & Shen, 2002).

MAIN THRUST

Association rule mining can be carried out flexibly to suit different needs. We illustrate this by introducing important techniques to solve two interesting problems.

Finding *N* Most Frequent Itemsets

Give $\subseteq x, yI$, we say that x is greater than y, or y is less than x, if $\sigma(x/D) > \sigma(y/D)$. The largest itemset in D is the itemset that occurs most frequently in D. We want to find the N largest itemsets in D, where N is a user-specified number of interesting itemsets. Because users are usually interested in those itemsets with larger supports, finding N most frequent itemsets is significant, and its solution can be used to generate an appropriate number of interesting itemsets for mining association rules (Shen, L., Shen, H., Pritchard, & Topor, 1998).

We define the rank of itemset x, denoted by $\theta(x)$, as follows: $\theta(x) = |\{\sigma(y/D)>\sigma(x/D), \varnothing\subset y\subseteq I\}|+1$. Call x a winner if $\theta(x)\leq N$ and $\sigma(x/D)\geq 1$, which means that x is one of the N largest itemsets and it occurs in D at least once. We don't regard any itemset with support 0 as a winner, even if it is ranked below N, because we do not need to provide users with an itemset that doesn't occur in D at all.

Use W to denote the set of all winners and call the support of the smallest winner the *critical support*, denoted by *crisup*. Clearly, W exactly contains all itemsets with support exceeding crisup; we also have crisup$\geq$1. It is easy to see that $|W|$ may be different from N: If the number of all itemsets occurring in D is less than N, $|W|$ will be less than N; $|W|$ may also be greater than N, as different itemsets may have the same support. The problem of finding the N largest itemsets is to generate W.

Let x be an itemset. Use $P_k(x)$ to denote the set of all k-subsets (subsets with size k) of x. Use U_k to denote $P_1(I)\cup\ldots\cup P_k(I)$, the set of all itemsets with a size not greater than k. Thus, we introduce the k-rank of x, denoted by $\theta_k(x)$, as follows: $\theta_k(x) = |\{y|\{\sigma(y/D)>x/D), y\in U_k\}|+1$. Call x a k-winner if $\theta_k(x)\leq N$ and $\sigma(x/D)\geq 1$, which means that among all itemsets with a size not greater than k, x is one of the N largest itemsets and also occurs in D at least once. Use W_k to denote the set of all k-winners. We define *k-critical-support*, denoted by *k-crisup*, as follows: If $|W_k|<N$, then k-crisup is 1; otherwise, k-crisup is the support of the smallest k-winner. Clearly, W_k exactly contains all itemsets with a size not greater than k and support not less than k-crisup. We present some useful properties of the preceding concepts as follows.

Property: Let k and i be integers such that $1\leq k\leq k+i \leq |I|$.

(1)Given $x\in U_k$, *we have* $x\in W_k$ iff $\sigma(x/D)\geq k$-crisup.
(2) If $W_{k-1} = W_k$, then $W=W_k$
(3)$W_{k+i}\bigcap U_k\subseteq W_k$.
(4) $1\leq k$-crisup$\leq(k+i)$-crisup.

To find all the winners, the algorithm makes multiple passes over the data. In the first pass, we count the supports of all 1-itemsets, select the N largest ones from them to form W_1, and then use W_1 to generate potential 2-winners with size (2). Each subsequent pass k involves three steps: First, we count the support for potential k-winners with size k (called candidates) during the pass over D; then select the N largest ones from a pool precisely containing supports of all these candidates and all (k-1)-winners to form W_k; finally, use W_k to generate potential (k+1)-winners with size k+1, which will be used in the next pass. This process continues until we can't get any potential (k+1)-winners with size k+1, which implies that $W_k+1 = W_k$. From Property 2, we know that the last W_k exactly contains all winners.

We assume that M_k is the number of itemsets with support equal to k-crisup and a size not greater than k, where $1\leq k\leq |I|$, and M is the maximum of all $M_1\sim M_{|I|}$. Thus, we have $|W_k|=N+M_k-1<N+M$. It was shown that the time complexity of the algorithm is proportional to the number of all the candidates generated in the algorithm, which is $O(\log(N+M)*min\{N+M,|I|\}*(N+M))$ (Shen et al., 1998). Hence, the time complexity of the algorithm is polynomial for bounded N and M.

Mining Multiple-Level Association Rules

Although most previous research emphasized mining association rules at a single concept level (Agrawal et al., 1993; Agrawal et al., 1996; Park et al., 1995; Savasere et al., 1995; Srikant & Agrawal, 1996), some techniques were also proposed to mine rules at generalized abstract (multiple) levels (Han & Fu, 1995). However, they can only find multiple-level rules in a fixed concept hierarchy. Our study in this fold is motivated by the goal of

mining multiple-level rules in all concept hierarchies (Shen, L., & Shen, H., 1998).

A concept hierarchy can be defined on a set of database attribute domains such as $D(a_1),\ldots,D(a_n)$, where for $i \in [1, n]$, a_i denotes an attribute, and $D(a_i)$ denotes the domain of a_i. The concept hierarchy is usually partially ordered according to a general-to-specific ordering. The most general concept is the null description *ANY,* whereas the most specific concepts correspond to the specific attribute values in the database. Given a set of $D(a_1),\ldots,D(a_n)$, we define a concept hierarchy H as follows: $H^n \rightarrow H^{n-1} \rightarrow \ldots \rightarrow H^0$, where $H^i = D(a_1^i) \times \cdots \times D(a_i^i)$ for $i \in [0,n]$, and $\{a_1,..., a_n\} = \{a_1^n,..., a_n^n\} \supset \{a_1^n,..., a_{n-1}^{n-1}\} \supset \ldots \supset \emptyset$. Here, H^n represents the set of concepts at the primitive level, H^{n-1} represents the concepts at one level higher than those at H^n, and so forth; H^0, the highest level hierarchy, may contain solely the most general concept, ANY. We also use $\{a_1^n,..., a_n^n\} \rightarrow \{a_1^n,..., a_{n-1}^{n-1}\} \rightarrow \ldots \rightarrow \{a_1^1\}$ to denote H directly, and H^0 may be omitted here.

We introduce FML items to represent concepts at any level of a hierarchy. Let *, called a *trivial digit,* be a "don't-care" digit. An *FML item* is represented by a sequence of digits, $x = x_1x_2 \ldots x_n$, $x_i \in D(a_i) \cup \{*\}$. The flat-set of x is defined as $S_f(x) = \{(I,x_i) \mid i \in [1; n]$ and $x_i \neq *\}$. Given two items x and y, x is called a generalized item of y if $S_f(x) \subseteq S_f(y)$, which means that x represents a higher-level concept that contains the lower-level concept represented by y. Thus, *5* is a generalized item of 35* due to $S_f(*5*) = \{(2,5)\} \subseteq S_f(35*) = \{(1,3),(2,5)\}$. If $S_f(x) = \emptyset$, then x is called a *trivial item,* which represents the most general concept, ANY.

Let T be an encoded transaction table, t a transaction in T, x an item, and c an itemset. We can say that (a) t supports x if an item y exists in t such that x is a generalized item of y and (b) t supports c if t supports every item in c. The support of an itemset c in T, $\sigma(c/T)$, is the ratio of the number of transactions (in T) that support c to the total number of transactions in T. Given a minsup, an itemset c is large if $\sigma(c/T)e \geq$ minsup; otherwise, it is small.

Given an itemset c, we define its simplest form as $F_s(c) = \{x \in c \mid \forall\, y \in c\ S_f(x) \not\subset S_f(y)\}$ and its complete form as $F_c(c) = \{x \mid S_f(x) \subseteq S_f(y),\ y \in c\}$.

Given an itemset c, we call the number of elements in $F_s(c)$ its *size* and the number of elements in $F_c(c)$ its *weight.* An itemset of size j and weight k is called a *(j)*-itemset, [k]-itemset, or *(j)*[k]-itemset. Let c be a *(j)*[k]-itemset. Use $G_i(c)$ to indicate the set of all [i]-generalized-subsets of c, where $i \leq k$. Thus, the set of all [k-1]-generalized-subsets of c can be generated as follows: $G_{k-1}(c) = \{F_s(F_c(c) - \in x\}) \mid xF_s(c)\}$; the size of $G_{k-1}(c)$ is j. Hence, for $k \geq 1$, c is a (1)-itemset iff $|G_{k-1}(c)| = 1$. With this observation, we call a [k-1]-itemset a self-extensive if a (1)[k]-itemset b exists such that $G_{k-1}(b) = \{a\}$; at the same time, we call b the extension result of a. Thus, all self-extensive itemsets as can be generated from all (1)-itemsets bs as follows: $F_c(a) = F_c(b) - F_s(b)$.

Let b be a (1)-itemset and $F_s(b) = \{x\}$. From $|F_c(b)| = |\{v \mid S_f(y) \subseteq S_f(x)\}| = 2^{|S_f(x)|}$, we know that b is a (1)[$2^{|S_f(x)|}$]-itemset. Let a be the self-extensive itemset generated by b; that is, a is a [$2^{|S_f(x)|}$-1]-itemset such that $F_c(a) = F_c(b) - F_s(b)$. Thus, if $|S_f(x)| > 1$, there exist y, $z \in F_s(a)$ and $y \neq z$ such that $S_f(x) = S_f(y) \cup S_f(z)$. Clearly, this property can be used to generate the corresponding extension result from any self-extensive [2^m-1]-itemset, where $m > 1$. For simplicity, given a self-extensive [2^m-1]-itemset a, where $m > 1$, we directly use $E_r(a)$ to denote its extension result. For example, $E_r(\{12*,1*3,*23\}) = \{123\}$.

The algorithm makes multiple passes over the database. In the first pass, we count the supports of all [2]-itemsets and then select all the large ones. In pass k-1, we start with L_{k-1}, the set of all large [k-1]-itemsets, and use L_{k-1} to generate C_k, a superset of all large [k]-itemsets. Call the elements in C_k *candidate itemsets,* and count the support for these itemsets during the pass over the data. At the end of the pass, we determine which of these itemsets are actually large and obtain L_k for the next pass. This process continues until no new large itemsets are found. Not that $L_1 = \{\{\text{trivial item}\}\}$, because {trivial item} is the unique [1]-itemset and is supported by all transactions.

The computation cost of the preceding algorithm, which finds all frequent FML itemsets is $O(\sum_{c \in C} s(x))$, where C is the set of all candidates, $g(c)$ is the cost for generating c as a candidate, and $s(c)$ is the cost for counting the support of c (Shen, L., & Shen, H., 1998). The algorithm is optimal if the method of support counting is optimal.

After all frequent FML itemsets have been found, we can proceed with the construction of strong FML rules. Use $r(l,a)$ to denote rule $F_s(a) \rightarrow F_s(F_c(l) - F_c(a))$, where l is an itemset and a l. Use $F_o(l,a)$ to denote $F_c(l) - F_c(a)$ and say that $F_o(l,a)$ is an outcome form of l or the outcome form of $r(l,a)$. Note that $F_o(l,a)$ represents only a specific form rather than a meaningful itemset, so it is not equivalent to any other itemset whose simplest

form is $F_s(F_o(l,a))$. Outcome forms are also called *outcomes* directly. Clearly, the corresponding relationship between rules and outcomes is one to one. An outcome is strong if it corresponds to a strong rule. Thus, all strong rules related to a large itemset can be obtained by finding all strong outcomes of this itemset.

Let l be an itemset. Use $O(l)$ to denote the set of all outcomes of l; that is, $O(l) = \{F_o(l,a) | a \quad l\}$. Thus, from $O(l)$, we can output all rules related to l: $F_s(F_c(l)\text{-}o) \Rightarrow F_s(o)$ (denoted by $\hat{r}(l,o)$), where $o O(l)$. Clearly, $r(la)$ and $\hat{r}(l,o)$ denote the same rule if $o=F_o(l,a)$. Let o, $\hat{o} \in O(l)$. We can say two things: (a) o is a $|k|$-outcome of l if o exactly contains k elements and (b) is a sub-outcome of o verus l if. Use $O_k(l)$ to denote the set of all the $|k|$-outcomes of l and use $V_m(o,l)$ to denote the set of all the $|m|$-sub-outcomes of o versus l. Let o be an $|m+1|$-outcome of l and $m e>1$. If $|V_m(o,l)| =1$, then o is called an elementary outcome; otherwise, o is a non-elementary outcome.

Let $r(l,a)$ and $r(l,b)$ be two rules. We can say that $r(l,a)$ is an instantiated rule of $r(lb)$ if $b \quad a$. Clearly, b a implies $\sigma(b/T) \geq \sigma(a/)$ and

$\frac{\sigma(l/T)}{\sigma(a/T)} \geq \frac{\sigma(l/T)}{\sigma(b/T)}$. Hence, all instantiated rules of a strong rule must also be strong. Let l be a large itemset $o_1, o_2 \in O(l)$, $o_1=F_o(l,a)$, and $o_2 = F_o(l,b)$. The three straightforward conclusions are (a) $o_1 \subseteq o_2$ iff $b \quad a$, (b) $\hat{r}(l,o)= r(l,a)$,and (c) $\hat{r}(l,o_2) = r(l,b)$. Therefore $\hat{r}(l,o_1)$,is an instantiated rule of $\hat{r}(l,o_2)$ iff $o_1 \subseteq o_2$, which implies that all the suboutcomes of a strong outcome must also be strong. This characteristic is similar to the property that all generalized subsets of a large itemset must also be large. Hence, the algorithm works as follows. From a large itemset l, we first generate all the strong rules with |1|-outcomes (ignore the |0|-outcome Ø, which only corresponds to all trivial strong rule; $Fs(l) \Rightarrow Ø$ for every large itemset l). We then use all these strong |1|-outcomes to generate all the possible strong |2|-outcomes of l, from which all the strong rules with |2|-outcomes can be produced, and so forth.

The computation cost of the algorithm constructing all the strong FML rules is $O(|C|t + |C|s)$ (Shen, L., & Shen, H., 1998), which is optimal for bounded costs t and s, where C is the set of all the candidate rules, s is the average cost for generating one element in C, and t is the average cost for computing the confidence of one element in C.

FUTURE TRENDS

The discovery of data association is a central topic of data mining. Mining this association flexibly to suit different needs has an increasing significance for applications. Future research trends include mining association rules in data of complex types such as multimedia, time-series, text, and biological databases, in which certain properties (e.g., multidimensionality), constraints (e.g., time variance), and structures (e.g., sequence) of the data must be taken into account during the mining process; mining association rules in databases containing incomplete, missing, and erroneous data, which requires people to produce correct results regardless of the unreliability of data; mining association rules online for streaming data that come from an open-ended data stream and flow away instantaneously at a high rate, which usually adopts techniques such as active learning, concept drift, and online sampling and proceeds in an incremental manner.

CONCLUSION

We have summarized research activities in mining association rules and some recent results of my research in different streams of this topic. We have introduced important techniques to solve two interesting problems of mining N most frequent itemsets and mining multiple-level association rules, respectively. These techniques show that mining association rules can be performed flexibly in user-specified forms to suit different needs. More relevant results can be found in Shen (1999). We hope that this article provides useful insight to researchers for better understanding to more complex problems and their solutions in this research direction.

KEY TERMS

Association Rule: An implicatio⇒ rule *XY* that shows the conditions of co-occurrence of disjoint itemsets (attribute value sets) *X* and *Y* in a given database.

Concept Hierarchy: The organization of a set of database attribute domains into different levels of abstraction according to a general-to-specific ordering.

Confidence o⇒ Rule *XY*: The fraction of the database containing *X* that also contains *Y,* which is the ratio of the supp⋃rt of *XY* to the support of *X*.

Flexible Mining of Association Rules: Mining association rules in user-specified forms to suit different needs, such as on dimension, level of abstraction, and interestingness.

Frequent Itemset: An itemset that has a support greater than user-specified minimum support.

Strong Rule: An association rule whose support (of the union of itemsets) and confidence are greater than user-specified minimum support and confidence, respectively.

Support of Itemset *X*: The fraction of the database that contains *X*, which is the ratio of the number of records containing *X* to the total number of records in the database.

Formal Concept Analysis Based Clustering

Jamil M. Saquer
Southwest Missouri State University, USA

INTRODUCTION

Formal concept analysis (FCA) is a branch of applied mathematics with roots in lattice theory (Wille, 1982; Ganter & Wille, 1999). It deals with the notion of a concept in a given universe, which it calls context. For example, consider the context of transactions at a grocery store where each transaction consists of the items bought together. A concept here is a pair of two sets (A, B). A is the set of transactions that contain all the items in B and B is the set of items common to all the transactions in A. A successful area of application for FCA has been data mining. In particular, techniques from FCA have been successfully used in the association mining problem and in clustering (Kryszkiewicz, 1998; Saquer, 2003; Zaki & Hsiao, 2002). In this article, we review the basic notions of FCA and show how they can be used in clustering.

BACKGROUND

A fundamental notion in FCA is that of a context, which is defined as a triple (G, M, I), where G is a set of objects, M is a set of features (or attributes), and I is a binary relation between G and M. For object g and feature m, gIm if and only if g possesses the feature m. An example of a context is given in *Table 1*, where an "X" is placed in the i^{th} row and j^{th} column to indicate that the object in row i possesses the feature in column j.

The set of features common to a set of objects A is denoted by $\beta(A)$ and is defined as $\{m \in M \mid gIm \ \forall\ g \in A\}$. Similarly, the set of objects possessing all the features in a set of features B is denoted by $\alpha(B)$ and is given by $\{g \in G \mid gIm \ \forall m \in B\}$. The operators α and β satisfy the assertions given in the following lemma.

Lemma 1 (Wille, 1982): Let (G, M, I) be a context. Then the following assertions hold:

1. $A_1 \subseteq A_2$ implies $\beta(A_2) \subseteq \beta(A_1)$ for every $A_1, A_2 \subseteq G$, and $B_1 \subseteq B_2$ implies $\alpha(B_2) \subseteq \alpha(B_1)$ for every $B_1, B_2 \subseteq M$.
2. $A \subseteq \alpha(\beta(A)$ and $A = \beta(\alpha(\beta(A))$ for all $A \subseteq G$, and $B \subseteq \beta(\alpha((B))$ and $B = \alpha(\beta(\alpha\ (B)))$ for all $B \subseteq M$.

Table 1. A context excerpted from (Ganter, and Wille, 1999, p. 18). a = needs water to live; b = lives in water; c = lives on land; d = needs chlorophyll; e = two seeds leaf; f = one seed leaf; g = can move around; h = has limbs; i = suckles its offsprings.

		a	b	c	d	e	f	g	h	i
1	Leech	X	X					X		
2	Bream	X	X					X	X	
3	Frog	X	X	X				X	X	
4	Dog	X		X				X	X	X
5	Spike-weed	X	X		X		X			
6	Reed	X	X	X	X		X			
7	Bean	X		X	X	X				
8	Maize	X		X	X		X			

A formal concept in the context (G, M, I) is defined as a pair (A, B) where $A \subseteq G$, $B \subseteq M$, $\beta(A) = B$, and $\alpha(B) = A$. A is called the extent of the formal concept and B is called its intent. For example, the pair (A, B) where A = {2, 3, 4} and B = {a, g, h} is a formal concept in the context given in *Table 1*. A subconcept/superconcept order relation on concepts is as follows: $(A_1, B_1) \leq (A_2, B_2)$ iff $A_1 \subseteq A_2$ (or equivalently, iff $B_2 \subseteq B_1$). The fundamental theorem of FCA states that the set of all concepts on a given context is a complete lattice, called the concept lattice (Ganter & Wille, 1999). Concept lattices are drawn using Hasse diagrams, where concepts are represented as nodes. An edge is drawn between concepts C_1 and C_2 iff $C_1 \leq C_2$ and there is no concept C_3 such that $C_1 \leq C_3 \leq C_2$. The concept lattice for the context in Table 1 is given in Figure 1.

A less condensed representation of a concept lattice is possible using reduced labeling (Ganter & Wille, 1999). Figure 2 shows the concept lattice in Figure 1 with reduced labeling. It is easier to see the relationships and similarities among objects when reduced labeling is used. The extent of a concept C in *Figure 2* consists of the objects at C and the objects at the concepts that can be reached from C going downward following descending paths towards the bottom concept. Similarly, the intent of C consists of the features at C and the features at the concepts that can be reached from C going upwards following ascending paths to the top concept.

Consider the context presented in *Table 1*. Let B = {a, f}. Then, $\alpha(B) = \{5, 6, 8\}$, and $\beta(\alpha(B)) = b(\{5, 6, 8\}) = \{a, d, f\} \neq \{a, f\}$; therefore, in general, $\beta(\alpha(B)) \neq B$. A set of features B that satisfies the condition $b(\alpha(B)) = B$ is called a closed feature set. Intuitively, a closed feature set is a maximal set of features shared by a set of objects. It is easy to show that intents of the concepts of a concept lattice are all closed feature sets.

The support of a set of features B is defined as the percentage of objects that possess every feature in B. That is, $support(B) = |\alpha(B)|/|G|$, where |B| is the

Figure 1. Concept lattice for the context in Table 1

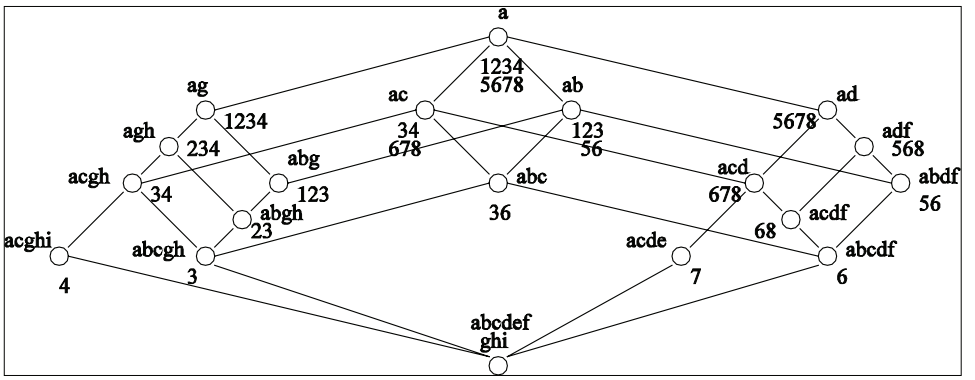

Figure 2. Concept lattice for the context in Table 1 with reduced labeling

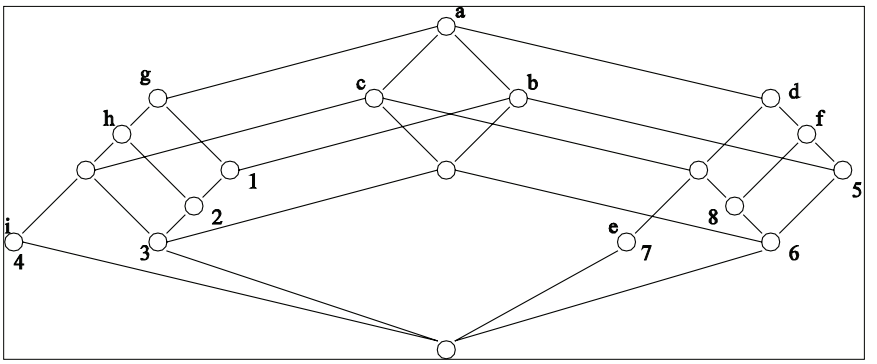

cardinality of B. Let minSupport be a user-specified threshold value for minimum support. A feature set B is frequent iff support(B) ≥ minSupport. A frequent closed feature set is a closed feature set, which is also frequent. For example, for minSupport = 0.3, {a, f} is frequent, {a, d, f} is frequent closed, while {a, c, d, f} is closed but not frequent.

CLUSTERING BASED ON FCA

It is believed that the method described below is the first for using FCA for disjoint clustering. Using FCA for conceptual clustering to gain more information about data is discussed in Carpineto & Romano (1999) and Mineau & Godin (1995). In the remainder of this article we show how FCA can be used for clustering.

Traditionally, most clustering algorithms do not allow clusters to overlap. However, this is not a valid assumption for many applications. For example, in Web documents clustering, many documents have more than one topic and need to reside in more than one cluster (Beil, Ester, & Xu, 2002; Hearst, 1999; Zamir & Etzioni, 1998). Similarly, in the market basket data, items purchased in a transaction may belong to more than one category of items.

The concept lattice structure provides a hierarchical clustering of objects, where the extent of each node could be a cluster and the intent provides a description of that cluster. There are two main problems, though, that make it difficult to recognize the clusters to be used. First, not all objects are present at all levels of the lattice. Second, the presence of overlapping clusters at different levels is not acceptable for disjoint clustering. The techniques described in this chapter solve these problems. For example, for a node to be a cluster candidate, its intent must be frequent (meaning a minimum percentage of objects must possess all the features of the intent). The intuition is that the objects within a cluster must contain many features in common. Overlapping is resolved by using a score function that measures the goodness of a cluster for an object and keeps the object in the cluster where it scores best.

Formalizing the Clustering Problem

Given a set of objects $G = \{g_1, g_2, \ldots, g_n\}$, where each object is described by the set of features it possesses, (i.e., g_i is described by $\beta(g_i)$), $\mathbb{C} = \{C_1, C_2, \ldots, C_k\}$ is a clustering of G if and only if each C_i is a subset of G and $\bigcup C_i = G$, where i ranges from 1 to k. For disjoint clustering, the additional condition $C_i \bigcap C_j = \varnothing$ must be satisfied for all $i \neq j$.

Our method for disjoint clustering consists of two steps. First, assign objects to their initial clusters. Second, make these clusters disjoint. For overlapping clustering, only the first step is needed.

Assigning Objects to Initial Clusters

Each frequent closed feature set (FCFS) is a cluster candidate, with the FCFS serving as a label for that cluster. Each object g is assigned to the cluster candidates described by the maximal frequent closed feature set (MFCFS) contained in $\beta(g)$. These initial clusters may not be disjoint because an object may contain several MFCFS. For example, for minSupport = 0.375, object 2 in *Table 1* contains the MFCFSs agh and abg.

Notice that all of the objects in a cluster must contain all the features in the FCFS describing that cluster (which is also used as the cluster label). This is always true even after any overlapping is removed. This means that this method produces clusters with their descriptions. This is a desirable property. It helps a domain expert to assign labels and descriptions to clusters.

Making Clusters Disjoint

To make the clusters disjoint, we find the best cluster for each overlapping object g and keep g only in that cluster. To achieve this, a score function is used. The function score(g, C_i) measures the goodness of cluster C_i for object g. Intuitively, a cluster is good for an object g if g has many frequent features which are also frequent in C_i. On the other hand, C_i is not good for g if g has frequent features that are not frequent in C_i.

Define global-support(f) as the percentage of objects possessing f in the whole database, and cluster-support(f) as the percentages of objects possessing f in a given cluster C_i. We say f is cluster frequent in C_i if cluster-support(f) is at least a user-specified minimum threshold value q. For cluster C_i, let positive(g, C_i) be the set of features in $\beta(g)$ which are both global-frequent (i.e., frequent in the whole database) and cluster-frequent. Also let negative(g, C_i) be the set of features in $\beta(g)$ which are global-frequent but not cluster-frequent. The function score(g, C_i) is then given by the following formula:

Table 2. Initial cluster assignments and support values. (minSupport = 0.37, θ = 0.7)

C_i	initial clusters	Positive(g,C_i)	negative(g,C_i)
C[agh]	2: abgh 3: abcgh 4: acghi	a (1), g (1), h(1)	b (0.63), c(0.63)
C[abg]	1: abg 2: abgh 3: abcgh	a (1), b (1), g(1)	c(0.63), h(0.38)
C[acd]	6: abcdf 7: acde 8: acdf	a (1), c (1), d(1)	b (0.63), f(0.38)
C[adf]	5: abdf 6: abcdf 8: acdf	a (1), d(1), f(1)	b (0.63), c(0.63)

Table 3. Score calculations and final cluster assignments. (minSupport = 0.37, □ = 0.7)

C_i	Score(g, C_i)	Final clusters
C[agh]	2: 1 - .63 + 1 + 1 = 2.37 3: 1 - .63 - .63 + 1 + 1 = 1.74 4: does not overlap	 4
C[abg]	1: does not overlap 2: 1 + 1 + 1 - .38 = 2.62 3: 1 + 1 - .63 + 1 - .38 = 1.99	1 2 3
C[acd]	6: 1 - .63 + 1 +1 - .38 = 2.62 5: does not overlap 8: 1 + 1 + 1 -.38 = 2.62	6 7 8
C[adf]	5: does not overlap 6: 1 - .63 - .63 + 1 + 1 = 1.74 8: 1 - .63 + 1 + 1 = 2.37	 5

$$score(g, C_i) = \sum_{f \in positive(g, Ci)} cluster\text{-}support(f) - \sum_{f \in negative(g, Ci)} global\text{-}support(f).$$

The first term in score(g, C_i) favors C_i for every feature in positive(g, C_i) because these features contribute to intra-cluster similarity. The second term penalizes C_i for every feature in negative(g, C_i) because these features contribute to inter-cluster similarities.

An overlapping object will be deleted from all initial clusters except for the cluster where it scores highest. Ties are broken by assigning the object to the cluster with the longest label. If this does not resolve ties, then one of the clusters is chosen randomly.

An Illustrating Example

Consider the objects in *Table* 1. The closed feature sets are the intents of the concept lattice in *Figure 1*. For minSupport = 0.35, a feature set must appear in at least 3 objects to be frequent. The frequent closed feature

sets are a, ag, ac, ab, ad, agh, abg, acd, and adf. These are the candidate clusters. Using the notation C[x] to indicate the cluster with label x, and assigning objects to MFCFS results in the following initial clusters: C[agh] = {2, 3, 4}, C[abg] = {1, 2, 3}, C[acd] = {6, 7, 8}, and C[adf] = {5, 6, 8}. To find the most suitable cluster for object 6, we need to calculate its score in each cluster containing it. For cluster-support threshold value θ of 0.7, it is found that, score(6,C[acd]) = 1 - 0.63 + 1 + 1 - 0.38 = 1.99 and score[6,C[adf]) = 1 - 0.63 - 0.63 + 1 + 1 = 1.74.

We will use score(6,C[acd]) to explain the calculation. All features in $\beta(6)$ are global-frequent. They are a, b, c, d, and f, with global frequencies 1, 0.63, 0.63, 0.5, and 0.38, respectively. Their respective cluster-support values are 1, 0.33, 1, 1, and 0.67. For a feature to be cluster-frequent in C[acd], it must appear in at least [θ x |C[acd]|] = 3 of its objects. Therefore, a, c, d ∈ positive(6,C[acd]), and b, f ∈ negative(6,C[acd]). Substituting these values into the formula for the score function, it is found that the score(6,C[acd]) = 1.99. Since score(6,C[acd]) > score[6,C[adf]), object 6 is assigned to C[acd].

Tables 2 and *3* show the score calculations for all overlapping objects. *Table 2* shows initial cluster assignments. Features that are both global-frequent and cluster-frequent are shown in the column labeled positive(g,C_i), and features that are only global-frequent are in the column labeled negative(g,C_i). For elements in the column labeled positive(g,C_i), the cluster-support values are listed between parentheses after each feature name. The same format is used for global-support values for features in the column labeled negative(g,C_i). It is only a coincidence that in this example all cluster-support values are 1 (try θ = 0.5 for different values). Table 3 shows score calculations, and final cluster assignments.

Notice that, different threshold values may result in different clusters. The value of minSupport affects cluster labels and initial clusters while that of θ affects final elements in clusters. For example, for minSupport = 0.375 and θ = 0.5, we get the following final clusters C[agh] = {3, 4}, C[abg] = {1, 2}, C[acd] = {7, 8}, and C[adf] = {5, 6}.

FUTURE TRENDS

We have shown how FCA can be used for clustering. Researchers have also used the techniques of FCA and frequent itemsets in the association mining problem (Fung, Wang, & Ester, 2003; Wang, Xu, & Liu, 1999; Yun, Chuang, & Chen, 2001). We anticipate this framework to be suitable for other problems in data mining such as classification. Latest developments in efficient algorithms for generating frequent closed itemsets make this approach efficient for handling large amounts of data (Gouda & Zaki, 2001; Pei, Han, & Mao, 2000; Zaki & Hsiao, 2002).

CONCLUSION

This chapter introduces formal concept analysis (FCA); a useful framework for many applications in computer science. We also showed how the techniques of FCA can be used for clustering. A global support value is used to specify which concepts can be candidate clusters. A score function is then used to determine the best cluster for each object. This approach is appropriate for clustering categorical data, transaction data, text data, Web documents, and library documents. These data usually suffer from the problem of high dimensionality with only few items or keywords being available in each transaction or document. FCA contexts are suitable for representing this kind of data.

KEY TERMS

Cluster-Support of Feature F In Cluster C_i: Percentage of objects in C_i possessing f.

Concept: A pair (A, B) of a set A of objects and a set B of features such that B is the maximal set of features possessed by all the objects in A and A is the maximal set of objects that possess every feature in B.

Context: A triple (G, M, I) where G is a set of objects, M is a set of features and I is a binary relation between G and M such that gIm if and only if object g possesses the feature m.

Formal Concept Analysis: A mathematical framework that provides formal and mathematical treatment of the notion of a concept in a given universe.

Negative(g, Ci): Set of features possessed by g which are global-frequent but not cluster-frequent.

Positive(g, Ci): Set of features possessed by g which are both global-frequent and cluster-frequent.

Support or Global-Support of Feature F: Percentage of object "transactions" in the whole context (or whole database) that possess f.

INTRODUCTION

In recent years, data streams have emerged as a new data type that has attracted much attention from the data mining community. They arise naturally in a number of applications (Brian et al., 2002), including financial service (stock ticker, financial monitoring), sensor networks (earth sensing satellites, astronomic observations), web tracking and personalization (web-click streams). These stream applications share three distinguishing characteristics that limit the applicability of most traditional mining algorithms (Minos et al., 2002; Pedro and Geoff, 2001): (1) the continuous arrival rate of the stream is high and unpredictable; (2) the volume of data is unbounded, making it impractical to store the entire content of the stream; (3) in terms of practical applicability, stream mining results are often expected to be closely approximated the exact results as well as to be available at any time. Consequently, the main challenge in mining data streams is to develop effective algorithms that support the processing of stream data in one-pass manner (preferably on-line) whilst operating under system resources limitations (e.g., memory space, CPU cycles or bandwidth).

This chapter discusses the above challenge in the context of finding frequent sets from transactional data streams. The problems will be presented and some effective methods, both from deterministic and probabilistic approaches, are reviewed in details. The trade-offs between memory space and accuracy of mining results are also discussed. Furthermore, the problems will be considered in three fundamental mining models for stream environments: landmark window, forgetful window and sliding window models.

BACKGROUND

Generally, the problem of finding frequent sets from a data stream can be stated as follows. Let $I = \{a_1, a_2,... a_m\}$ be a set of items (or objects) and let X be an itemset such as $X \subseteq I$. Given a transactional data stream, DS, which is a sequence of incoming transactions, $(t_1, t_2,...,t_n)$, where $t_i \subseteq I$, the frequency of X is defined as the number of transactions in DS that contain X and its support is defined as the ratio between its frequency and the number of transactions in the stream. Then, the problem of mining frequent sets from data stream DS is to find all itemsets whose support is greater than a given threshold $s \in (0,1)$ called minimum support.

However, due to the unlimited size of streaming data, all transactions appearing in the stream DS are not always of equal importance. Rather, their usefulness is dependent upon applications. For example, some applications focus only on a fixed portion (most recently arriving) of the stream, while other applications consider all transactions seen so far; yet the transaction weight (or importance) is reduced gradually with time. This gives rise to different mining models: Landmark window model, Forgetful window model and Sliding window model. In the following section, most typical algorithms classified in these models will be discussed in details.

MAIN FOCUS

This section presents and discusses some typical algorithms addressing the problem of finding frequent sets from data streams. The mining model is first described, following it are the algorithm analysis and discussion.

Landmark Window Model

In this model, frequent sets are computed from a set of contiguous transactions in the stream identified between a specific transaction in the past, called landmark, and the current transaction. Accordingly, one endpoint (landmark) is fixed, while the other gradually increases with the arrival of new transactions. This model is often suitable for off-line data streams where transactions usually arrive in batches (Gurmeet and Rajeev, 2002), for example, with warehouse applications where new batches of records are updated at regular time intervals. However, there are also many other online streaming applications employing this model (Johannes et al., 2001). For example, in a telecom transaction stream, the scope of the stream is captured on a daily basic. Accordingly, a set of landmarks is given to the mining system and the results are computed from the current point back to the immediately-preceding landmark. We discuss some typical algorithms in this mining model.

Lossy Counting (Gurmeet and Rajeev, 2002) is one of the first algorithms to find all frequent sets from entire transactional streams. It is a deterministic approach since the mining results are guaranteed within some error. Given an error threshold ε and a minimum support threshold s, Lossy Counting guarantees that all itemsets whose true frequency exceeds sN are included in the mining results (where N is the number of transactions seen so far in the stream). Furthermore, the estimated frequency for each output itemset is guaranteed to be no more than its true frequency by an amount of εN. In Lossy Counting, the stream is divided into buckets, each has the same size of $w = 1/\varepsilon$ transactions and labeled with bucket ids, starting from 1. At transaction N, the bucket id is $b = \lceil N/w \rceil$. During the mining process, Lossy Counting maintains a synopsis S which is a set of entries (X, f, Δ), where X is an itemset, f is its estimated frequency, and Δ is the maximal possible error in f. For each X found in the stream, its frequency will be incremented by 1 if it is found in S; otherwise a new entry is created with the value $(X, f, b - 1)$, where $b = \lceil N/w \rceil$. At each bucket boundary (i.e., $N \equiv 0 \bmod w$), S is pruned by deleting all itemsets that have $f + \Delta \leq b$. The frequent itemsets are those having $f \geq (s - \varepsilon)N$.

To see how Lossy Counting approximates frequency errors, it is important to note that the stream is divided into equally sized buckets, and each itemset X will have its frequency tracked only if it appears frequently enough; i.e., on average, at least once on every bucket sized $1/\varepsilon$. Accordingly, the deletion rule ensures that whenever $f \leq b - \Delta$, X will be deleted. Note that, $(b - \Delta)$ is the number of buckets since the last time X occurs frequently enough to be counted. This value is always no more than N/w which is the number of buckets so far in the stream. Consequently, the pruning condition always makes sure that $f \leq b - \Delta \leq N/w$ or $f \leq \varepsilon N$. This is also the maximal lost on counting frequency of every itemset.

It is important to note that when Lossy Counting is applied to mining frequent itemsets, it needs to mine the stream in batch mode in order to avoid explicitly enumerating all subsets of every transaction. Consequently, this approach may limit its applicability in some online streaming environments (Johannes et al., 2001). Recently, this drawback has been addressed by EStream algorithm (Xuan Hong et al., 2006). In this algorithm, the error on the mining results is strictly guaranteed within a given threshold whilst the data stream is processed online. The basic idea of EStream is still based on the bucketing technique. However, it has been observed that when the transaction flow is processed online and the downward closure property is employed to find frequent sets, a longer itemset is usually being delayed counting until all its subsets are found potentially frequent. Accordingly, there will be a bigger error margin on frequent sets of larger sizes. Therefore, in EStream, the error (also frequency) of each itemset is identified precisely based on their length. This algorithm has been theoretically proven and guarantees that: (i) there is no error on frequency counting of 1-itemsets; (ii) for 2-itemsets, the maximal error on frequency counting is no more than εN; (iii) and for itemsets of length $k > 2$, the error is no more than $2\varepsilon N$ (where k is the maximal length of frequent itemsets).

The advantage of a deterministic approach is that it is able to produce all truly frequent itemsets and limit the maximal error on frequency counting. However, in order to provide this guarantee, a large amount of

memory space is needed to maintain itemsets whose support is greater than ε (meanwhile we only need to find those whose support is greater than s). Furthermore, since all itemsets having frequency $f \geq (s - \varepsilon)N$ are reported as frequent, this might include some itemsets whose frequency is between $(s - \varepsilon)N \leq f \leq sN$, and are not truly frequent. This gives the motivation to develop methods based on a probabilistic approach and FDPM (Jeffrey et al., 2004) is one of such algorithms.

FDPM (Frequent Data stream Pattern Mining): In FDPM, the Chernoff bound has been applied to mine frequent sets from entire data streams. Generally, the Chernoff bound can give us certain probability guarantees on the estimation of statistics of the underlying data when given a certain number of observations (transactions) regarding the data. In FDPM, the Chernoff bound is used to reduce the error of mining results when more and more transactions have been processed. For this reason, ε is a running value instead of a parameter specified by users. Its value will approach 0 when the number of observed transactions is very large.

In frequent set mining problems, an itemset X appearing in a transaction t_i can be viewed as a Bernoulli trial and thus one can denote a random variable $A_i=1$ if X occurs in t_i and $A_i=0$ if not. Now considering a sequence of transactions $t_1, t_2,...,t_n$, as n independent Bernoulli trials such that $\Pr(A_i = 1) = p$ and $\Pr(A_i = 0) = 1 - p$ for a probability p. Then, let r be the number of times that $A_i=1$ in these n transactions, with its expectation being np. The Chernoff bound states that, for any $\gamma > 0$:

$$\Pr\{| r - np | \geq np\gamma\} \leq 2e^{-np\gamma^2/2}$$

By dividing the left hand size by n and replacing p by s, $p\gamma$ by ε, and r/n by $\bar{r}$:

$$\Pr\{| \bar{r} - s | \geq \varepsilon\} \leq 2e^{-n\varepsilon^2/(2s)}$$

Let the right hand size be equal to δ, then:

$$\varepsilon = \sqrt{\frac{2s\ln(2/\delta)}{n}}$$

Now, given a sequence of transactions arriving in the stream $t_1, t_2,...,t_n, t_{n+1},...,t_N$, and assume that n first transactions have been observed ($n < N$). For an itemset X, we call *sup(X,n)* its running support in n transactions, and *sup(X,N)* its true support in N transactions. By replacing $\bar{r}$ by *sup(X,n)* and s by *sup(X,N)*, then when n transactions have been processed, *sup(X,n)* is beyond $\pm\varepsilon$ of *sup(X,N)* with probability no more than δ. In FDPM design, this observation is used to prune itemsets that may not potentially be frequent. A set of entries P is used to maintain frequent itemsets found in the stream. In case where each transaction in the stream is only one item, P's size is bounded by at most $1/(s - \varepsilon)$ entries. However, when each transaction is a set of items, P's size is identified via experiments (due to the nature of the exponential explosion of itemsets). Whenever P is full, those itemsets whose frequency is smaller than $(s - \varepsilon)n$ will be deleted from P. Recall that, since ε is reduced with time, this deletion condition makes P always keep all potential frequent itemsets. The advantage of FDPM is that the memory space used to maintain potentially frequent item(set)s is much smaller than those in the above deterministic algorithms. FDPM prunes itemsets whose support is smaller than $(s - \varepsilon)$ while the deterministic algorithms prune those smaller than ε. However, FDPM's drawback is that it assumes data arriving in the stream are independent (in order to apply the Chernoff bound). In reality, the characteristics of data streams may often change with time and the data is highly possible to be dependent. In these cases, the quality of FDPM may not be able to be guaranteed. Furthermore, this algorithm is false-negative oriented due to the basic of a probabilistic approach.

Forgetful Window Model

Different from the landmark window model, where all transactions appearing in the stream are equally important, in the forgetful window model, the old transactions will have less effect on the mining results comparing to the new arrival ones in the stream. Therefore, in this model, a fading function is often used to reduce the weight (or importance) of transactions as time goes by. Also, note that when transactions are reduced their weight, the importance of the frequent itemsets in which they appear is also reduced.

FP-Streaming (Giannella et al., 2003) is a typical algorithm addressing this model. In this work, the stream is physically divided into batches and frequent itemsets are discovered separately from each other. Their frequencies are reduced gradually by using a fading factor $\Phi<1$. For instance, let X be an itemset that has been found frequent in a set of consecutive batches

$B_i,\ldots,B_j$, where i, j are batch indices and $i<j$, then its frequency will be faded gradually by the formula

$$\sum_{k=i}^{j} \Phi^{j-k} f_X(B_k).$$

Note that since Φ is always smaller than 1, the older the B_k, the smaller the Φ^{j-k} value. Furthermore, in FP-Streaming, the frequency of an itemset will be maintained for every batch as long as it is still frequent; meanwhile the number of batches is increased with time. Therefore, in order to address the memory space constraint, a logarithm tilted-time window is utilized for each itemset in FP-Stream. It stores the itemset's frequency with fine granularity for recent batches and coarser granularity for older ones. Consequently, this approach not only requires less memory space but also allows to find changes or trends in the stream (by comparing itemsets' frequencies between different periods of time frame). This algorithm is also a deterministic approach since the error on frequency counting is guaranteed within a given threshold.

Sliding Window Model

Compared to the two above models, this model further considers the elimination of transactions. When new transactions come, the oldest ones will be eliminated from the mining model. Accordingly, the mining results are only discovered within a fixed portion of the stream which is pre-specified by a number of transactions (count-based sliding window) or by a time period (time-based sliding window). The sliding window model is quite suitable for various online data stream applications such as stock markets, financial analysis or network monitoring where the most valuable information is that discovered from the recently arriving portion of the stream. In the following, we review two typical algorithms proposed in this mining model.

Time Sensitive Sliding window: this algorithm is proposed to mine frequent sets from a time-based sliding window. The window is defined as a set of time intervals during which the rate of arrival transaction flow can change with time. Accordingly, the number of transactions arriving in each time interval (thus the sliding window) may not be fixed. Potentially frequent itemsets are then uncovered from each time interval. Their local frequencies are stored in a counting frequency table. Unlike the methods presented above (e.g., Lossy Counting, EStream, FDPM) where the memory space is affected by the error threshold, this method directly fixes the memory space for the counting frequency table. Consequently, whenever this table is full, there is a need to adjust it in order to get space for newly generated itemsets. The adjustment can be achieved by merging two adjacent entries, which have frequency counting found in the same time interval, into one entry. This new entry may select either the smaller or the larger value (between two original entries) for its frequency counting. Due to this procedure, the mining results can only be either false-positive oriented or false-negative oriented. Furthermore, in this algorithm, the error on frequency counting of each output itemset cannot be precisely estimated and bounded.

FTP-DS (Frequent Temporal Patterns of Data Streams) is another typical algorithm to mine frequent sets from a time-based sliding window (Wei-Guang et al., 2003). However, in this approach, the stream is divided into several disjoint sub-streams where each one represents the transaction flow of one customer. Accordingly, an itemset's frequency is defined as the ratio between the number of customers that subscribe to it and the total number of customers in the sliding window. When the window slides, the frequency of each itemset is then tracked for each time period. In order to address the issue of memory space constraint, the least mean square (LMS) method is applied. Therefore, a linear function $f = a + b \times t$ is used as a summary form to represent each itemset's frequency history. Given time period t, the itemset's frequency in this period can be derived. The interesting point of this approach is that both coefficients a and b can be updated incrementally. For example, given $\{(t_s, f_s),\ldots,(t_c, f_c)\}$ to be a set of time period and frequency count pairs for an itemset X from t_s to t_c, according to the LMS method, the sum of squared error (SSE) needs to be minimized:

$$SSE = \sum e_i^2 = \sum (f_i - a - b \times t_i)^2$$

(where i =s,…,c)

By differentiating SSE with respect to a and b, the formulas to compute two coefficients are:

$$b = (\sum f_i t_i - q^{-1} \sum f_i \sum t_i) \times (\sum t_i^2 - q^{-1} (\sum w_i)^2)^{-1}$$

and

$$a = q^{-1}(\sum f_i - b \times \sum t_i),$$

where $q = t_c - t_s + 1$. Note that two summations $\sum f_i t_i, \sum f_{i,}$ are easily updated incrementally at each time period t_i; meanwhile $\sum t_i, (\sum t_i)^2$ can be simply interpolated from t_s and t_c. Therefore, only 3 numbers $(t_s, \sum f_i t_i, \sum f_{i,})$ need to be maintained for each itemset, making the memory space independent from the data stream size. However, it is still an open problem to provide an error bound on the mining results when the LMS method is used in this algorithm.

FUTURE TRENDS

From the above discussion, it can be seen that most algorithms reported so far only focus on the problem of maintaining frequent itemsets within limited memory space. Some of them can provide error guarantees on the mining results. However, they all ignore the fact that CPU is also a bounded resource. In reality, for many stream applications such as stock monitoring or telecom fraud detection, the data arrival rate is rapid and mostly unpredictable (due to the dynamic changing behavior of data sources). Meanwhile, the mining results of these streams usually require delivery under time constraints to enable optimal decisions. Therefore, it is necessary to address the problem of controlling CPU workload in the context of finding frequent sets from online streaming environments (Xuan Hong et al., 2007). A natural approach is to drop some fraction of data streams in order to reduce workload (Nesime et al., 2007). However, it is necessary to address the following questions: How to determine overload situations? How much load needs to be shed? How to approximate frequent sets under the introduction of load shedding? More theories and techniques of load shedding certainly should be developed in the near future.

CONCLUSION

Data streams disseminate data in the form of continuous, rapid, unbound and fast changing behavior. Accordingly, algorithms designed in stream environments usually face the challenge of supporting one-pass data processing whilst working under the limitation of system resources. This chapter discussed this challenge in the context of mining frequent sets from streaming data. Most typical approaches, together with their mining models, have been presented and analyzed. However, these works are still in an early stage of studying data streams. Many issues remain open and new techniques must be developed to address them. Furthermore, finding frequent sets is also the core step in many data mining tasks including association rule mining, correlation analysis, clustering, and classification. It is believed that, when more effective algorithms are developed to find frequent sets in stream environments, their applicability will play a key role in various real-time making decision systems.

KEY TERMS

Bernoulli Trial: In probability and statistics, an experiment is called a Bernoulli trial if its outcome is random and can take one of two values "true" or "false".

Binomial Distribution: A discrete probability distribution of the number of "true" outcomes in a sequence of n independent true/false experiments (Bernoulli trials), each of which yields "true" with probability p.

Deterministic Algorithm: In stream mining for frequent sets, an algorithm is deterministic if it can provide the mining results with *a priori* error guarantees.

False-Negative Oriented Approach: In stream mining for frequent sets, if an algorithm misses some truly frequent itemsets in the final results then it is called a false-negative oriented approach.

False-Positive Oriented Approach: In stream mining for frequent sets, if an algorithm outputs some infrequent itemsets in the final results then it is called a false-positive oriented approach.

Immediate Subset: Given an itemset X of length m, itemset Y is called its immediate subset if $Y \subseteq X$ and Y has length m-1.

Load Shedding: The process of dropping excess load from a mining system in order to guarantee the timely delivery of mining results.

Fuzzy Methods in Data Mining

Eyke Hüllermeier
Philipps-Universität Marburg, Germany

INTRODUCTION

Tools and techniques that have been developed during the last 40 years in the field of fuzzy set theory (FST) have been applied quite successfully in a variety of application areas. A prominent example of the practical usefulness of corresponding techniques is *fuzzy control*, where the idea is to represent the input-output behaviour of a controller (of a technical system) in terms of fuzzy rules. A concrete control function is derived from such rules by means of suitable inference techniques.

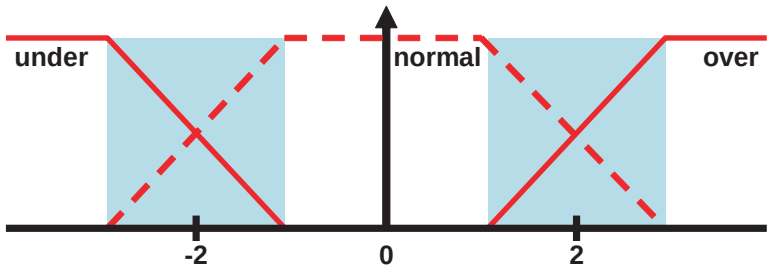
While aspects of knowledge representation and reasoning have dominated research in FST for a long time, problems of *automated learning and knowledge acquisition* have more and more come to the fore in recent years. There are several reasons for this development, notably the following: Firstly, there has been an internal shift within fuzzy systems research from "modelling" to "learning", which can be attributed to the awareness that the well-known "knowledge acquisition bottleneck" seems to remain one of the key problems in the design of intelligent and knowledge-based systems. Secondly, this trend has been further amplified by the great interest that the fields of *knowledge discovery in databases* (KDD) and its core methodical component, *data mining*, have attracted in recent years.

It is hence hardly surprising that data mining has received a great deal of attention in the FST community in recent years (Hüllermeier, 2005). The aim of this chapter is to give an idea of the usefulness of FST for data mining. To this end, we shall briefly highlight, in the next but one section, some potential advantages of fuzzy approaches. In preparation, the next section briefly recalls some basic ideas and concepts from FST. The style of presentation is purely non-technical throughout; for technical details we shall give pointers to the literature.

BACKGROUND ON FUZZY SETS

A fuzzy subset F of a reference set X is identified by a so-called *membership function* (often denoted $\mu_F(\bullet)$), which is a generalization of the characteristic function of an ordinary set $A \subseteq X$ (Zadeh, 1965). For each element $x \in X$, this function specifies the *degree of membership* of x in the fuzzy set. Usually, membership degrees $\mu_F(x)$ are taken from the unit interval $[0,1]$, i.e., a membership function is an $X \rightarrow [0,1]$ mapping, even though more general membership scales (such as ordinal scales or complete lattices) are conceivable.

Figure 1. Fuzzy partition of the gene expression level with a "smooth" transition (grey regions) between underexpression, normal expression, and overexpression



Fuzzy sets formalize the idea of *graded membership* according to which an element can belong "more or less" to a set. Consequently, a fuzzy set can have "non-sharp" boundaries. Many sets or concepts associated with natural language terms have boundaries that are non-sharp in the sense of FST. Consider the concept of "forest" as an example. For many collections of trees and plants it will be quite difficult to decide in an unequivocal way whether or not one should call them a forest.

In a data mining context, the idea of "non-sharp" boundaries is especially useful for discretizing numerical attributes, a common preprocessing step in data analysis. For example, in gene expression analysis, one typically distinguishes between *normally expressed*, *underexpressed*, and *overexpressed* genes. This classification is made on the basis of the expression level of the gene (a normalized numerical value), as measured by so-called DNA-chips, by using corresponding thresholds. For example, a gene is often called overexpressed if its expression level is at least twofold increased. Needless to say, corresponding thresholds (such as 2) are more or less arbitrary. Figure 1 shows a *fuzzy partition* of the expression level with a "smooth" transition between under-, normal, and overexpression. For instance, according to this formalization, a gene with an expression level of at least 3 is definitely considered overexpressed, below 1 it is definitely not overexpressed, but in-between, it is considered overexpressed to a certain degree (Ortoloani et al., 2004).

Fuzzy sets or, more specifically, membership degrees can have different semantic interpretations. Particularly, a fuzzy set can express three types of cognitive concepts which are of major importance in artificial intelligence, namely *uncertainty*, *similarity*, and *preference* (Dubois, 1997). To operate with fuzzy sets in a formal way, FST offers generalized set-theoretical respectively logical connectives and operators (as in the classical case, there is a close correspondence between set-theory and logic) such as triangular norms (t-norms, generalized logical conjunctions), t-conorms (generalized disjunctions), and generalized implication operators. For example, a t-norm $\otimes$ is a $[0,1]\times[0,1]\rightarrow[0,1]$ mapping which is associative, commutative, monotone increasing (in both arguments) and which satisfies the boundary conditions $\alpha \otimes 0 = 0$ and $\alpha \otimes 1 = \alpha$ for all $0 \leq \alpha \leq 1$ (Klement et al., 2002). Well-known examples of t-norms include the minimum $(\alpha, \beta) \mapsto \min(\alpha, \beta)$ and the product $(\alpha, \beta) \mapsto \alpha\beta$.

BENEFITS OF FUZZY DATA MINING

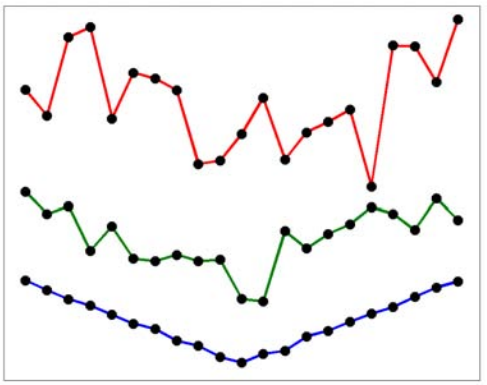
This section briefly highlights some potential contributions that FST can make to data mining; see (Hüllermeier, 2005) for a more detailed (technical) exposition.

Graduality

The ability to represent gradual concepts and fuzzy properties in a thorough way is one of the key features of fuzzy sets. This aspect is also of primary importance in the context of data mining. In fact, patterns that are of interest in data mining are often inherently vague and do have boundaries that are non-sharp in the sense of FST. To illustrate, consider the concept of a "peak": It is usually not possible to decide in an unequivocal way whether a timely ordered sequence of measurements, such as the expression profile of a gene, has a "peak" (a particular kind of pattern) or not. Rather, there is a gradual transition between having a peak and not having a peak. Likewise, the spatial extension of patterns like a "cluster of points" or a "region of high density" in a data space will usually have soft rather than sharp boundaries.

Many data mining methods proceed from a representation of the entities under consideration in terms of *feature vectors*, i.e., a fixed number of features or attributes, each of which represents a certain property

Figure 2. Three exemplary time series that are more or less "decreasing at the beginning"



of an entity (e.g., the age of a person). Having defined a suitable feature set, a common goal is to analyze relationships and dependencies between the attributes. In this regard, the possibility to model graded properties in an adequate way is useful for both feature extraction and subsequent dependency analysis.

To illustrate, consider again a (discrete) time series of the form $x = (x(1), x(2)...x(n))$, e.g., a gene expression profile where $x(t)$ is the expression level at time point t. For a profile of that kind, it might be of interest whether or not it is "decreasing at the beginning". This property is inherently fuzzy: First, it is unclear which time points belong to the "beginning", and defining these points in a non-fuzzy way by a "crisp" subset $B = \{1,2...k\}$ comes along with a certain arbitrariness (the choice of threshold $k \in \{1...n\}$) and does not appear fully convincing. Second, the intended meaning of "decreasing at the beginning" will not be captured well by the standard mathematical definition, which requires

$$\forall t \in B : x(t) \geq x(t+1), \quad (1)$$

In fact, the human perception of "decreasing" will usually be tolerant toward small violations of Eqn. 1, especially if such violations may be caused by noise in the data; see Figure 2 for an illustration, where the second profile is still considered as "decreasing at the beginning", at least to some extent. FST offers a large repertoire of techniques and concepts for generalizing the description of a property at a formal (logical) level, including generalized logical connectives such as the aforementioned t-norms and t-conorms, fuzzy GREATER-THAN relations (which generalize the above $\geq$ relation), and fuzzy FOR-MOST quantifiers (which generalize the universal quantifier in Eqn. 1). This way, it becomes possible to specify the degree to which a profile is "decreasing at the beginning", i.e., to characterize a profile in terms of a fuzzy feature which assumes a value in the unit interval [0,1] instead of a binary feature which is either present (1) or absent (0). See (Lee et al., 2006) for an interesting application, where corresponding modeling techniques have been used in order to formalize so-called candlestick patterns which are of interest in stock market analysis.

The increased expressiveness offered by fuzzy methods is also advantageous for the modeling of patterns in the form of relationships and dependencies between different features. As a prominent example of a (local) pattern, consider the concept of an association rule $A \rightarrow B$ suggesting that, if the antecedent A holds, then typically the consequent B holds as well (Agrawal & Srikant, 1994). In the non-fuzzy case, a rule is either satisfied (supported) by a concrete example (data entity) or not. In the fuzzy case, a rule can again be satisfied (supported) to a certain degree (Chen et al., 2003). At a formal level, the modeling of a rule makes use of generalized logical operators such as t-norms (for combining the conditions in the antecedent part) and implication operators (for combining the antecedent and the consequent part). Depending on the concrete operators employed, a fuzzy rule can have different semantic interpretations. For example, the meaning of gradual THE MORE—THE MORE dependencies such as "the more a profile is decreasing at the beginning, the more it increases at the end" can be captured in an adequate way by means of so called residuated implication operators; we refer to (Dubois et al., 2006) for a technical discussion of these issues.

In a data mining context, taking graduality into account can be very important in order to decide whether a certain pattern is "interesting" or not. For example, one important criterion in this regard is *frequency*, i.e., the number of occurrences of a pattern in a data set. If a pattern is specified in an overly restrictive (non-fuzzy) manner, it can easily happen that none of the entities matches the specification, even though many of them can be seen as approximate matches. In such cases, the pattern might still be considered as "well-supported" by the data (Dubois et al., 2005).

Regarding computational aspects, one may wonder whether the problem to extract interesting fuzzy patterns from large data sets, i.e., patterns that fulfil a number of generalized (fuzzy) criteria, can still be solved by efficient algorithms that guarantee scalability. Fortunately, efficient algorithmic solutions can be assured in most cases, mainly because fuzzy extensions can usually resort to the same algorithmic principles as non-fuzzy methods. Consequently, standard algorithms can most often be used in a modified form, even though there are of course exceptions to this rule.

Linguistic Representation and Interpretability

A primary motivation for the development of fuzzy sets was to provide an interface between a numerical scale and a symbolic scale which is usually composed

of linguistic terms. Thus, fuzzy sets have the capability to interface quantitative patterns with qualitative knowledge structures expressed in terms of natural language. This makes the application of fuzzy technology very appealing from a knowledge representational point of view, as it allows patterns discovered in a database to be presented in a linguistic and hence comprehensible way. For example, given a meaningful formalization of the concepts "multilinguality" and "high income" in terms of fuzzy sets, it becomes possible to discover an association rule in an employee database which expresses a dependency between these properties and can be presented to a user in the form "multilinguality usually implies high income" (Kacprzyk and Zadrozny, 2005).

Without any doubt, the user-friendly representation of models and patterns is often rightly emphasized as one of the key features of fuzzy methods (Mencar et al., 2005). Still, this potential advantage should be considered with caution in the context of data mining. A main problem in this regard concerns the high subjectivity and context-dependency of fuzzy patterns: A rule such as "multilinguality usually implies high income" may have different meanings to different users of a data mining system, depending on the concrete interpretation of the fuzzy concepts involved (multilinguality, high income). It is of course possible to disambiguate a model by complementing it with the semantics of these concepts (including the specification of membership functions). Then, however, the complete model, consisting of a qualitative (linguistic) and a quantitative part, becomes more cumbersome.

To summarize on this score, the close connection between a numerical and a linguistic level for representing patterns, as established by fuzzy sets, can indeed help a lot to improve interpretability of patterns, though linguistic representations also involve some complications and should therefore not be considered as preferable per se.

Robustness

Robustness is often emphasized as another advantage of fuzzy methods. In a data mining context, the term "robustness" can of course refer to many things. Generally, a data mining method is considered robust if a small variation of the observed data does hardly alter the induced model or the evaluation of a pattern. Another desirable form of robustness of a data mining method is robustness toward variations of its parameterization: Changing the parameters (e.g., the interval-boundaries of a histogram, Viertl & Trutschnig, 2006) slightly should not have a dramatic effect on the output of the method.

Even though the topic of robustness is still lacking a thorough theoretical foundation in the fuzzy set literature, it is true that fuzzy methods can avoid some obvious drawbacks of conventional interval-based approaches for dealing with numerical attributes. For example, the latter can produce quite undesirable "threshold effects": A slight variation of an interval boundary can have a very strong effect on the evaluation of patterns such as association rules (Sudkamp, 2005). Consequently, the set of "interesting" patterns can be very sensitive toward the discretization of numerical attributes.

Representation of Uncertainty

Data mining is inseparably connected with uncertainty (Vazirgiannis et al., 2003). For example, the data to be analyzed is imprecise, incomplete, or noisy most of the time, a problem that can badly deteriorate a mining algorithm and lead to unwarranted or questionable results. But even if observations are perfect, the alleged "discoveries" made in that data are of course afflicted with uncertainty. In fact, this point is especially relevant for data mining, where the systematic search for interesting patterns comes along with the (statistical) problem of multiple hypothesis testing, and therefore with a high danger of making false discoveries.

Fuzzy sets and the related uncertainty calculus of *possibility theory* have made important contributions to the representation and processing of uncertainty. In data mining, like in other fields, related uncertainty formalisms can complement probability theory in a reasonable way, because not all types of uncertainty relevant to data mining are of a probabilistic nature, and because other formalisms are in some situations more expressive than probability. For example, probability is not very suitable for representing ignorance, which might be useful for modeling incomplete or missing data.

FUTURE TRENDS

Looking at the current research trends in data mining, which go beyond analyzing simple, homogeneous, and

static data sets, fuzzy methods are likely to become even more important in the near future. For example, fuzzy set-based modeling techniques may provide a unifying framework for modeling complex, uncertain, and heterogeneous data originating from different sources, such as text, hypertext, and multimedia data. Moreover, fuzzy methods have already proved to be especially useful for mining data and maintaining patterns in dynamic environments where patterns "smoothly" evolve in the course of time (Beringer & Hüllermeier, 2007).

Finally, FST seems to be especially qualified for data pre- and post-processing, e.g., for data summarization and reduction, approximation of complex models and patterns in terms of "information granules" (Hüllermeier, 2007), or the (linguistic) presentation of data mining results. Even though current research is still more focused on the mining process itself, this research direction is likely to become increasingly important against the background of the aforementioned trend to analyze complex and heterogeneous information sources.

CONCLUSIONS

Many features and patterns of interest in data mining are inherently fuzzy, and modeling them in a non-fuzzy way will inevitably produce results which are unsatisfactory in one way or the other. For example, corresponding patterns may not appear meaningful from a semantic point of view or lack transparency. Moreover, non-fuzzy methods are often not very robust and tend to overlook patterns which are only approximately preserved in the data. Fuzzy methods can help to alleviate these problems, especially due to their increased expressiveness that allows one to represent features and patterns in a more adequate and flexible way.

KEY TERMS

Fuzzy Feature: A fuzzy feature is a property of an object (data entity) that can be present to a certain degree. Formally, a fuzzy feature is modelled in terms of a fuzzy set and can be considered as a generalization of a binary feature.

Fuzzy Partition: A fuzzy partition of a set X is a (finite) collection of fuzzy subsets which cover X in the sense that every $x \in X$ belongs to at least one fuzzy set with a non-zero degree of membership. Fuzzy partitions are often used instead of interval-partitions in order to discretize the domain of numerical attributes.

Fuzzy Pattern: A fuzzy pattern is a pattern the representation of which involves concepts from fuzzy set theory, i.e., membership functions or generalized logical operators. A typical example is a fuzzy association rule, which connects two fuzzy features by means of a generalized logical connective such as an implication operator.

Fuzzy Set: A fuzzy set is a set that allows for a partial belonging of elements. Formally, a fuzzy set of a given reference X set is defined by a membership function that assigns a membership degree (from an ordered scale, usually the unit interval) to every element of X.

Generalized Logical Operators: Generalizations of Boolean connectives (negation, conjunction, disjunction, implication) which operate on a fuzzy membership scale (usually the unit interval). In particular, the class of so-called triangular norms (with associated triangular co-norms) generalizes the logical conjunction (disjunction).

Interpretability: In a data mining context, interpretability refers to the request that the results produced by a mining algorithm should be transparent and understandable by a (human) user of the data mining system. Amongst others, this requires a low complexity of models and patterns shown to the user and a representation in terms of cognitively comprehensible concepts.

Robustness: In a data mining context, robustness of methods and algorithms is a desirable property that can refer to different aspects. Most importantly, a method should be robust in the sense that the results it produces are not excessively sensitive toward slight variations of its parameterization or small changes of the (input) data.

A General Model for Data Warehouses

Michel Schneider
Blaise Pascal University, France

INTRODUCTION

Basically, the schema of a data warehouse lies on two kinds of elements: facts and dimensions. Facts are used to memorize measures about situations or events. Dimensions are used to analyse these measures, particularly through aggregation operations (counting, summation, average, etc.). To fix the ideas let us consider the analysis of the sales in a shop according to the product type and to the month in the year. Each sale of a product is a fact. One can characterize it by a quantity. One can calculate an aggregation function on the quantities of several facts. For example, one can make the sum of quantities sold for the product type "mineral water" during January in 2001, 2002 and 2003. Product type is a criterion of the dimension Product. Month and Year are criteria of the dimension Time. A quantity is so connected both with a type of product and with a month of one year. This type of connection concerns the organization of facts with regard to dimensions. On the other hand a month is connected to one year. This type of connection concerns the organization of criteria within a dimension. The possibilities of fact analysis depend on these two forms of connection and on the schema of the warehouse. This schema is chosen by the designer in accordance with the users needs.

Determining the schema of a data warehouse cannot be achieved without adequate modelling of dimensions and facts. In this article we present a general model for dimensions and facts and their relationships. This model will facilitate greatly the choice of the schema and its manipulation by the users.

BACKGROUND

Concerning the modelling of dimensions, the objective is to find an organization which corresponds to the analysis operations and which provides strict control over the aggregation operations. In particular it is important to avoid double-counting or summation of non-additive data. Many studies have been devoted to this problem. Most recommend organizing the criteria (we said also members) of a given dimension into hierarchies with which the aggregation paths can be explicitly defined. In (Pourabbas, 1999), hierarchies are defined by means of a containment function. In (Lehner, 1998), the organization of a dimension results from the functional dependences which exist between its members, and a multi-dimensional normal form is defined. In (Hùsemann, 2000), the functional dependences are also used to design the dimensions and to relate facts to dimensions. In (Abello, 2001), relationships between levels in a hierarchy are apprehended through the Part-Whole semantics. In (Tsois, 2001), dimensions are organized around the notion of a dimension path which is a set of drilling relationships. The model is centered on a parent-child (one to many) relationship type. A drilling relationship describes how the members of a children level can be grouped into sets that correspond to members of the parent level. In (Vassiliadis, 2000), a dimension is viewed as a lattice and two functions "anc" and "desc" are used to perform the roll up and the drill down operations. Pedersen (1999) proposes an extended multidimensional data model which is also based on a lattice structure, and which provides non-strict hierarchies (i.e. too many relationships between the different levels in a dimension).

Modelling of facts and their relationships has not received so much attention. Facts are generally considered in a simple fashion which consists in relating a fact with the roots of the dimensions. However, there is a need for considering more sophisticated structures where the same set of dimensions are connected to different fact types and where several fact types are inter-connected. The model described in (Pedersen, 1999) permits some possibilities in this direction but is not able to represent all the situations.

Apart from these studies it is important to note various propositions (Agrawal, 1997; Datta, 1999; Gyssens, 1997; Nguyen, 2000) for cubic models where the primary objective is the definition of an algebra for multidimensional analysis. Other works must also be mentioned. In (Golfarelli, 1998), a solution is proposed to

derive multidimensional structures from E/R shemas. In (Hurtado, 2001) are established conditions for reasoning about summarizability in multidimensional structures.

MAIN THRUST

Our objective in this article is to propose a generic model based on our personal research work and which integrates existing models. This model can be used to apprehend the sharing of dimensions in various ways and to describe different relationships between fact types. Using this model, we will also define the notion of well-formed warehouse structures. Such structures have desirable properties for applications. We suggest a graph representation for such structures which can help the users in designing and requesting a data warehouse.

Modelling Facts

A fact is used to record measures or states concerning an event or a situation. Measures and states can be analysed through different criteria organized in dimensions.

A fact type is a structure

fact_name[(fact_key),
(list_of_reference_attributes), (list_of_fact_attributes)]

where

- fact_name is the name of the type;
- fact_key is a list of attribute names; the concatenation of these attributes identifies each instance of the type;
- list_of_reference_attributes is a list of attribute names; each attribute references a member in a dimension or another fact instance;
- list_of_fact_attributes is a list of attribute names; each attribute is a measure for the fact.

The set of referenced dimensions comprises the dimensions which are directly referenced through the list_of_reference_attributes, but also the dimensions which are indirectly referenced through other facts.

Each fact attribute can be analysed along each of the referenced dimensions. Analysis is achieved through the computing of aggregate functions on the values of this attribute.

As an example let us consider the following fact type for memorizing the sales in a set of stores.

Sales[(ticket_number, product_key), (time_key, product_key, store_key),
(price_per_unit, quantity)]

The key is (ticket_number, product_key). This means that there is an instance of Sales for each different product of a ticket. There are three dimension references: time_key, product_key, store_key. There are two fact attributes: price_per_unit, quantity. The fact attributes can be analysed through aggregate operations by using the three dimensions.

There may be no fact attribute; in this case a fact records the occurrence of an event or a situation. In such cases, analysis consists in counting occurrences satisfying a certain number of conditions.

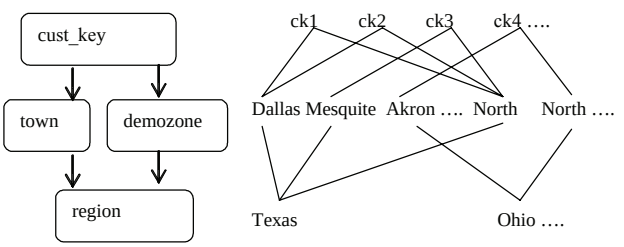
For the needs of an application, it is possible to introduce different fact types sharing certain dimensions and having references between them.

Modelling Dimensions

The different criteria which are needed to conduct analysis along a dimension are introduced through members. A member is a specific attribute (or a group of attributes) taking its values on a well defined domain. For example, the dimension TIME can include members such as DAY, MONTH, YEAR, etc. Analysing a fact attribute A along a member M means that we are interested in computing aggregate functions on the values of A for any grouping defined by the values of M. In the article we will also use the notation Mij for the j-th member of i-th dimension.

Members of a dimension are generally organized

Figure 1. A typical hierarchy in a dimension



in a hierarchy which is a conceptual representation of the hierarchies of their occurrences. Hierarchy in dimensions is a very useful concept that can be used to impose constraints on member values and to guide the analysis. Hierarchies of occurrences result from various relationships which can exist in the real world: categorization, membership of a subset, mereology. Figure 1 illustrates a typical situation which can occur. Note that a hierarchy is not necessarily a tree.

We will model a dimension according to a hierarchical relationship (HR) which links a child member Mij (i.e. town) to a parent member Mik (i.e. region) and we will use the notation Mij–Mik. For the following we consider only situations where a child occurrence is linked to a unique parent occurrence in a type. However, a child occurrence, as in case (b) or (c), can have several parent occurrences but each of different types. We will also suppose that HR is reflexive, antisymmetric and transitive. This kind of relationship covers the great majority of real situations. Existence of this HR is very important since it means that the members of a dimension can be organized into levels and correct aggregation of fact attribute values along levels can be guaranteed.

Each member of a dimension can be an entry for this dimension i.e. can be referenced from a fact type. This possibility is very important since it means that dimensions between several fact types can be shared in various ways. In particular, it is possible to reference a dimension at different levels of granularity. A dimension root represents a standard entry. For the three dimensions in Figure 1, there is a single root. However, definition 3 authorizes several roots.

As in other models (Hùsemann, 2000), we consider property attributes which are used to describe the members. A property attribute is linked to its member through a functional dependence, but does not introduce a new member and a new level of aggregation. For example the member *town* in the *customer* dimension may have property attributes such as population, administrative position, etc. Such attributes can be used in the selection predicates of requests to filter certain groups.

We now define the notion of member type, which incorporates the different features presented above.

A member type is a structure:

member_name[(member_key),
dimension_name,
(list_of_reference_attributes)]

where

- member_name is the name of the type;
- member_key is a list of attribute names; the concatenation of these attributes identifies each instance of the type;
- list_of_reference_attributes is a list of attribute names where each attribute is a reference to the successors of the member instance in the cover graph of the dimension.

Only the member_key is mandatory.

Using this model, the representations of the members of dimension *customer* in Figure 1 are the following:

cust_root[(cust_key), customer, (town_name, zone_name)]
town[(town_name), customer,(region_name)]
demozone[(zone_name), customer, (region_name)]
region[(region_name), customer, ()]

Well-Formed Structures

In this section we explain how the fact types and the member types can be interconnected in order to model various warehouse structures.

First, a fact can directly reference any member of a dimension. Usually a dimension is referenced through one of its roots (as we saw above, a dimension can have several roots). But it is also interesting and useful to have references to members other than the roots. This means that a dimension can be used by different facts with different granularities. For example, a fact can directly reference *town* in the *customer* dimension and another can directly reference *region* in the same

Figure 2. Typical warehouse structures

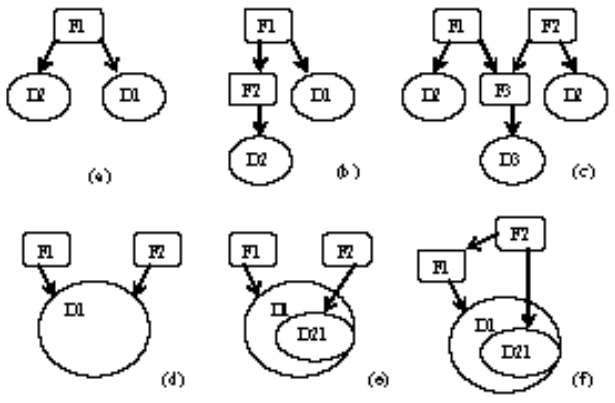


Figure 3. The DWG of a star-snowflake structure

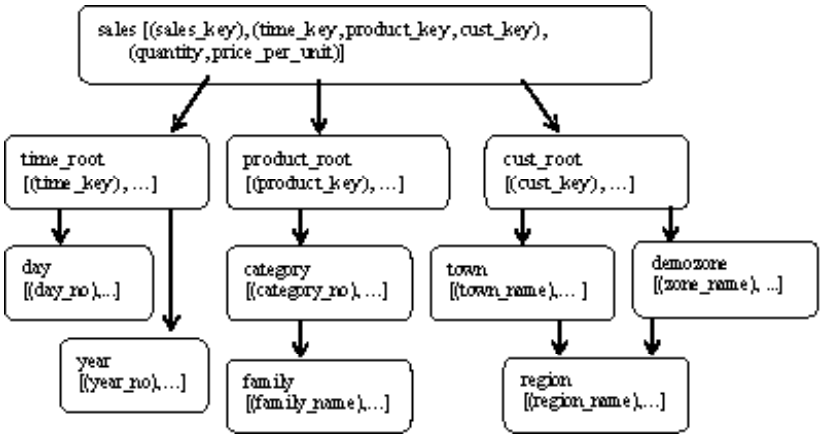

dimension. This second reference corresponds to a coarser granule of analysis than the first.

Moreover, a fact F1 can reference any other fact F2. This type of reference is necessary to model real situations. This means that a fact attribute of F1 can be analysed by using the key of F2 (acting as the grouping attribute of a normal member) and also by using the dimensions referenced by F2.

To formalise the interconnection between facts and dimensions, we thus suggest extending the HR relationship of section 3 to the representation of the associations between fact types and the associations between fact types and member types. We impose the same properties (reflexivity, anti-symmetry, transitivity). We also forbid cyclic interconnections. This gives a very uniform model since fact types and member types are considered equally. To maintain a traditional vision of the data warehouses, we also ensure that the members of a dimension cannot reference facts.

Figure 2 illustrates the typical structures we want to model. Case (a) corresponds to the simple case, also known as star structure, where there is a unique fact type F1 and several separate dimensions D1, D2, etc. Cases (b) and (c) correspond to the notion of facts of fact. Cases (d), (e) and (f) correspond to the sharing of the same dimension. In case (f) there can be two different paths starting at F2 and reaching the same member M of the sub-dimension D21. So analysis using these two paths cannot give the same results when reaching M. To pose this problem we introduce the DWG and the path coherence constraint.

To represent data warehouse structures, we suggest using a graph representation called DWG (data warehouse graph). It consists in representing each type (fact type or member type) by a node containing the main information about this type, and representing each reference by a directed edge.

Suppose that in the DWG graph, there are two different paths P1 and P2 starting from the same fact type F, and reaching the same member type M. We can analyse instances of F by using P1 or P2. The path coherence constraint is satisfied if we obtain the same results when reaching M.

For example in case of figure 1 this constraint means the following: for a given occurrence of cust_key, whether the town path or the demozone path is used, one always obtains the same occurrence of region.

We are now able to introduce the notion of well-formed structures.

Definition of a Well-Formed Warehouse Structure

A warehouse structure is well-formed when the DWG is acyclic and the path coherence constraint is satisfied for any couple of paths having the same starting node and the same ending node.

A well-formed warehouse structure can thus have several roots. The different paths from the roots can be always divided into two sub-paths: the first one with only fact nodes and the second one with only member nodes. So, roots are fact types.

Since the DWG is acyclic, it is possible to distribute its nodes into levels. Each level represents a level of aggregation. Each time we follow a directed edge, the level increases (by one or more depending on the used path). When using aggregate operations, this action corresponds to a ROLLUP operation (corresponding to the semantics of the HR) and the opposite operation to a DRILLDOWN. Starting from the reference to a dimension D in a fact type F, we can then roll up in the hierarchies of dimensions by following a path of the DWG.

Illustrating the Modelling of a Typical Case with Well-Formed Structures

Well-formed structures are able to model correctly and completely the different cases of Figure 2. We illustrate in this section the modelling for the star-snowflake structure.

We have a star-snowflake structure when:

- there is a unique root (which corresponds to the unique fact type);
- each reference in the root points towards a separate subgraph in the DWG (this subgraph corresponds to a dimension).

Our model does not differentiate star structures from snowflake structures. The difference will appear with the mapping towards an operational model (relational model for example). The DWG of a star-snowflake structure is represented in Figure 3. This representation is well-formed. Such a representation can be very useful to a user for formulating requests.

FUTURE TRENDS

A first opened problem is that concerning the property of summarizability between the levels of the different dimensions. For example, the total of the sales of a product for 2001 must be equal to the sum of the totals for the sales of this product for all months of 2001. Any model of data warehouse has to respect this property. In our presentation we supposed that function HR verified this property. In practice, various functions were proposed and used. It would be interesting and useful to begin a general formalization which would regroup all these propositions.

Another opened problem concerns the elaboration of a design method for the schema of a data warehouse. A data warehouse is a data base and one can think that its design does not differ from that of a data base. In fact a data warehouse presents specificities which it is necessary to take into account, notably the data loading and the performance optimization. Data loading can be complex since sources schemas can differ from the data warehouse schema. Performance optimization arises particularly when using relational DBMS for implementing the data warehouse.

CONCLUSION

In this paper we propose a model which can describe various data warehouse structures. It integrates and extends existing models for sharing dimensions and for representing relationships between facts. It allows for different entries in a dimension corresponding to different granularities. A dimension can also have several roots corresponding to different views and uses. Thanks to this model, we have also suggested the concept of Data Warehouse Graph (DWG) to represent a data warehouse schema. Using the DWG, we define the notion of well-formed warehouse structures which guarantees desirable properties.

We have illustrated how typical structures such as star-snowflake structures can be advantageously represented with this model. Other useful structures like those depicted in Figure 2 can also be represented.

The DWG gathers the main information from the warehouse and it can be very useful to users for formulating requests. We believe that the DWG can be used as an efficient support for a graphical interface to manipulate multidimensional structures through a graphical language.

The schema of a data warehouse represented with our model can be easily mapped into an operational model. Since our model is object-oriented a mapping towards an object model is straightforward. But it is possible also to map the schema towards a relational model or an object relational model. It appears that our model has a natural place between the conceptual schema of the application and an object relational implementation of the warehouse. It can thus serve as a helping support for the design of relational data warehouses.

KEY TERMS

Data Warehouse: A data base which is specifically elaborated to allow different analysis on data. Analysis consists generally to make aggregation operations (count, sum, average, etc.). A data warehouse is different from a transactional data base since it accumulates data along time and other dimensions. Data of a warehouse are loaded and updated at regular intervals from the transactional data bases of the company.

Dimension: Set of members (criteria) allowing to drive the analysis (example for the Product dimension: product type, manufacturer type). Members are used to drive the aggregation operations.

Drilldown: Opposite operation of the previous one.

Fact: Element recorded in a warehouse (example: each product sold in a shop) and whose characteristics (i.e. measures) are the object of the analysis (example: quantity of a product sold in a shop).

Galaxy Structure: Structure of a warehouse for which two different types of facts share a same dimension.

Hierarchy: The members of a dimension are generally organized along levels into a hierarchy.

Member: Every criterion in a dimension is materialized through a member.

Rollup: Operation consisting in going in a hierarchy at a more aggregated level.

Star Structure: Structure of a warehouse for which a fact is directly connected to several dimensions and can be so analyzed according to these dimensions. It is the most simple and the most used structure.

A Genetic Algorithm for Selecting Horizontal Fragments

Ladjel Bellatreche
Poitiers University, France

INTRODUCTION

Decision support applications require complex queries, e.g., multi way joins defining on huge warehouses usually modelled using star schemas, i.e., a fact table and a set of data dimensions (Papadomanolakis & Ailamaki, 2004). Star schemas have an important property in terms of join operations between dimensions tables and the fact table (i.e., the fact table contains foreign keys for each dimension). None join operations between dimension tables. Joins in data warehouses (called star join queries) are particularly expensive because the fact table (the largest table in the warehouse by far) participates in every join and multiple dimensions are likely to participate in each join.

To speed up star join queries, many optimization structures were proposed: redundant structures (materialized views and advanced index schemes) and non redundant structures (data partitioning and parallel processing). Recently, data partitioning is known as an important aspect of physical database design (Sanjay, Narasayya & Yang, 2004; Papadomanolakis & Ailamaki, 2004). Two types of data partitioning are available (Özsu & Valduriez, 1999): vertical and horizontal partitioning. Vertical partitioning allows tables to be decomposed into disjoint sets of columns. Horizontal partitioning allows tables, materialized views and indexes to be partitioned into disjoint sets of rows that are physically stored and usually accessed separately. Contrary to redundant structures, data partitioning does not replicate data, thereby reducing storage requirement and minimizing maintenance overhead. In this paper, we concentrate only on horizontal data partitioning (HP).

HP may affect positively (1) query performance, by performing *partition elimination*: if a query includes a partition key as a predicate in the WHERE clause, the query optimizer will automatically route the query to only relevant partitions and (2) database manageability: for instance, by allocating partitions in different machines or by splitting any access paths: tables, materialized views, indexes, etc. Most of database systems allow three methods to perform the HP using PARTITION statement: RANGE, HASH and LIST (Sanjay, Narasayya & Yang, 2004). In the range partitioning, an access path (table, view, and index) is split according to a range of values of a given set of columns. The hash mode decomposes the data according to a hash function (provided by the system) applied to the values of the partitioning columns. The list partitioning splits a table according to the listed values of a column. These methods can be combined to generate composite partitioning. Oracle currently supports range-hash and range-list composite partitioning using PARTITION - SUBPARTITION statement. The following SQL statement shows an example of fragmenting a table Student using range partitioning.

CREATE TABLE student (Student_ID Number(6), Student_FName VARCHAR(25), Student-LName VARCHAR(25), PRIMARY KEY (Student_ID) PARTITION BY *RANGE* (student_LN) (PARTITION student_ae VALUES LESS THAN ('F%') TABLESPACE part1, PARTITION student_fl VALUES LESS THAN ('M%') TABLESPACE part2, PARTITION student_mr VALUES LESS THAN ('S%') TABLESPACE part3, PARTITION student_sz VALUES LESS THAN (MAXVALUE) TABLESPACE part4);

HP can also be combined with others optimization structures like indexes, materialized views, and parallel processing. Several work and commercial systems show its utility and impact in optimizing OLAP queries (Noaman & Barker, 1999, Sanjay, Narasayya & Yang, 2004; Stöhr, Märtens & Rahm, 2000). But none of these studies has formalized the problem of selecting a horizontal partitioning schema to speed up a set of queries as optimization problem with constraint and proposed selection algorithms.

Logically, two types of HP are distinguished (Ceri, Negri & Pelagatti, 1982; Özsu & Valduriez, 1999): (1) *primary HP* and (2) *derived HP*. The primary HP consists in fragmenting a table T based only on its attribute(s). The derived HP consists in splitting a table S (e.g., the fact table of a given star schema) based on fragmentation schemas of other tables (e.g., dimension tables). This type has been used in (Stöhr, Märtens & Rahm, 2000). The primary HP may be used in optimizing selection operations, while the second in optimizing join and selection operations since it pre-computes them.

BACKGROUND

The HP in relational data warehouses is more challenging compared to that in relational and object databases. Several work and commercial systems show its utility and impact in optimizing OLAP queries (Sanjay, Narasayya & Yang, 2004; Stöhr, Märtens & Rahm,2000). But none study has formalized the problem of selecting a horizontal partitioning schema to speed up a set of queries as an optimization problem and proposed selection algorithms.

This challenge is due to the several choices of partitioning schema (a fragmentation schema is the result of the data partitioning process) of a star or snowflake schemas:

1. Partition only the dimension tables using simple predicates defined on these tables (a simple predicate p is defined by: p: A_i θ Value; where A_i is an attribute, θ ∈{=, <, >, ≥, ≤}, and Value ∈ Domain(A_i)). This scenario is not suitable for OLAP queries, because the sizes of dimension tables are generally small compare to the fact table. Most of OLAP queries access the fact table, which is huge Therefore, any partitioning that does not take into account the fact table is discarded.
2. Partition only the fact table using simple predicates defined on this table because it normally contains millions of rows and is highly normalized. The fact relation stores time-series factual data. The fact table is composed of foreign keys and raw data. Each foreign key references a primary key on one of the dimension relations. These dimension relations could be time, product, customer, etc. The raw data represent the numerical measurement of the organization such as sales amount, number of units sold, prices and so forth. The raw data usually never contain descriptive (textual) attributes because the fact relation is designed to perform arithmetic operations such as summarization, aggregation, average and so forth on such data. In a data warehouse modelled by a star schema, most of OLAP queries access dimension tables first and after that to the fact table. This choice is also discarded.
3. Partition some/all dimension tables using their predicates, and then partition the fact table based on the fragmentation schemas of dimension tables. This approach is best in applying partitioning in data warehouses. Because it takes into consideration the star join queries requirements and the relationship between the fact table and dimension tables. In our study, we recommend the use of this scenario.

Horizontal Partitioning Selection Problem

Suppose a relational warehouse modelled by a star schema with d dimension tables and a fact table F. Among these dimension tables, we consider that g tables are fragmented (g ≤ d), where each table D_i (1 ≤ i ≤ g) is partitioned into m_i fragments: {D_{i1}, D_{i2}, …, D_{imi}}, such as: $D_{ij} = \sigma_{cl_{ji}}(D_i)$, where cl_{ji} and σ represent a conjunction of simple predicates and the selection predicate, respectively. Thus, the fragmentation schema of the fact table F is defined as follows:

$F_i = F \lceil D_{1i} \lceil D_{2i} \lceil \ldots \lceil D_{gi}$, $(1 \le i \le m_i)$, where $\lceil$ represents the semi join operation.

Example

To illustrate the procedure of fragmenting the fact table based on the fragmentation schemas of dimension tables, let's consider a star schema with three dimension tables: Customer, Time and Product and one fact table Sales. Suppose that the dimension table Customer is fragmented into two fragments *CustFemale* and *CustMale* defined by the following clauses:

CustFemale = $\sigma_{(Sex = `F')}$ (Customer) and CustMale = $\sigma_{(Sex = `M')}$ (Customer).

Therefore, the fact table *Sales* is fragmented based on the partitioning of Customer into two fragments $Sales_1$ and $Sales_2$ such as: $Sales_1$ = Sales $\ltimes$ CustFemale and $Sales_2$ = Sales $\ltimes$ CustMale. The initial star schema (Sales, Customer, Product, Time) is represented as the juxtaposition of two sub star schemas S_1 and S_2 such as: S_1: ($Sales_1$, CustFemale, Product, Time) (sales activities for only female customers) and S_2: ($Sales_2$, CustMale, Product, Time) (sales activities for only male customers). Note that the attributes used for partitioning are called fragmentation attributes (Sex attribute).

The number of horizontal fragments of the fact table generated by the partitioning procedure is given by the following equation:

$$N = \prod_{i=1}^{g} m_i ,$$

where m_i represents the number of fragments of the dimension table D_i. This number may be very large. For example, suppose we have: Customer dimension table partitioned into 50 fragments using the State attribute (case of 50 states in the U.S.A.), Time into 36 fragments using the Month attribute (if the sale analysis is done based on the three last years), and Product into 80 fragments using Package_type attribute, therefore the fact table will be fragmented into **144 000** fragments (50 * 36 * 80). Consequently, instead to manage one star schema, the data warehouse administrator (DWA) will manage 144 000 sub star schemas. It will be very hard for him to maintain all these sub-star schemas.

A formulation of the horizontal partitioning problem is the following:

Given a set of dimension tables D = {D_1, D_2, ..., D_d} and a set of OLAP queries Q = {Q_1, Q_2, ..., Q_m}, where each query Q_i ($1 \leq i \leq m$) has an access frequency. The HP problem consists in determining a set of dimension tables $D' \subseteq D$ to be partitioned and generating a set of fragments that can be used to partition the fact table F into a set of horizontal fragments (called fact fragments) {F_1, F_2, ..., F_N} such that: **(1)** The sum of the query cost when executed on top of the partitioned star schema is minimized; and **(2)** $N \leq W$, where W is a threshold fixed by the DWA representing the maximal number of fragments that he can maintain. This threshold is chosen based on the nature of the most frequently queries that contain selection conditions. Each The respect of this constraint avoids an explosion of the number of the fact fragments.

To deal with the HP selection problem, we use a genetic algorithm (Bellatreche, Boukhalfa & Abdalla, 2006).

MAIN FOCUS

We use a genetic algorithm (GA) to select a HP schema. The motivation to use GAs in solving horizontal partitioning problem was based on the observations that data warehouse can have a large number of fragmentation schemas. GAs has been largely used in databases. For instance, in optimizing query joins (Ioannidis & Kang, 1990) and selecting materialized views (**Zhang & Yang,**1999). GAs (Holland, 1975) are search methods based on the evolutionary concept of natural mutation and the survival of the fittest individuals. Given a well-defined search space they apply three different genetic search operations, namely, selection, crossover, and mutation, to transform an initial population of chromosomes, with the objective to improve their quality.

Fundamental to the GA structure is the notion of chromosome, which is an encoded representation of a feasible solution. Before the search process starts, a set of chromosomes is initialized to form the first generation. Then the three genetic search operations are repeatedly applied, in order to obtain a population with better characteristics. An outline of a GA is as follows: (see Box 1.).

Different steps of the GA: encoding mechanism, selection, crossover and mutation operators are presented in the following sections.

The most difficult part of applying GA is the representation of the solutions that represent fragmentation schemas. Traditionally, GAs used binary strings

Box 1.

```
Generate initial population;
Perform selection step;
While (stopping criterion not met) do
        Perform Crossover step;
        Perform mutation step;
        Perform Selection step;
End while
Report the best chromosome as the final solution.
```

to represent their chromosomes. In this study, another representation is proposed.

Coding Mechanism

Note that any horizontal fragment is defined by a clause of conjunctive predicates (minterm) defined on fragmentation attributes (Bellatreche & Boukhalfa, 2005). Before presenting our coding mechanism of dimension fragment, we should identify which dimension tables will participate in fragmenting the fact table. To do so, we propose the following procedure: (1) extract all simple predicates used by the m queries, (2) assign to each dimension table D_i ($1 \leq i \leq d$) its set of simple predicates, denoted by $SSPD_i$, (3) dimension tables having an empty SSPD will not be considered in the partitioning process.

Note that each fragmentation attribute has a domain of values. The clauses of horizontal fragments partition each attribute domain into sub domains. Consider two fragmentation attributes[1] Age and Gender of dimension table CUSTOMER and one attribute Season of dimension table TIME. The domains of these attributes are defined as follows: Dom(Age) =]0, 120], Dom(Gender) = {'M', 'F'}, and Dom(Season) = {"Summer", "Spring", "Autumn", "Winter"}. Suppose that on the attribute Age, three simple predicates are defined as follows: P_1 : (Age $\leq$ 18), P_2 : (Age $\geq$ 60), et P_3 : (18 < Age < 60). The domain of this attribute is then partitioned into three sub domains (see Figure 1 (a)): Dom(Age) = $d_{11} \cup d_{12} \cup d_{13}$, with d_{11} =]0, 18], d_{12} =]18, 60[, d_{13} = [60, 120]. Similarly, the domain of Gender attribute is decomposed into two sub domains: Dom(Gender) = $d_{21} \cup d_{22}$, with d_{21} = {'M'}, d_{22} = {'F'}. Finally, domain of Season is partitioned into four sub domains: Dom(Season) = $d_{31} \cup d_{32} \cup d_{33} \cup d_{34}$, where d_{31} = {"Summer"}, d_{32} = {"Spring"}, d_{33} = {"Autumn"}, and d_{34} = {"Winter"}.

The decomposition of each fragmentation attribute domain can be represented by an array with n_i cells, where n_i corresponds to number of its sub domains. The values of these cells are between 1 and n_i. Consequently, each chromosome (fragmentation schema) can be represented by a multi-dimensional array. From this representation, the obtainment of horizontal fragments is straightforward. It consists in generating all conjunctive clauses. If two cells of the same array have a same value, then they will be merged (or-ed).

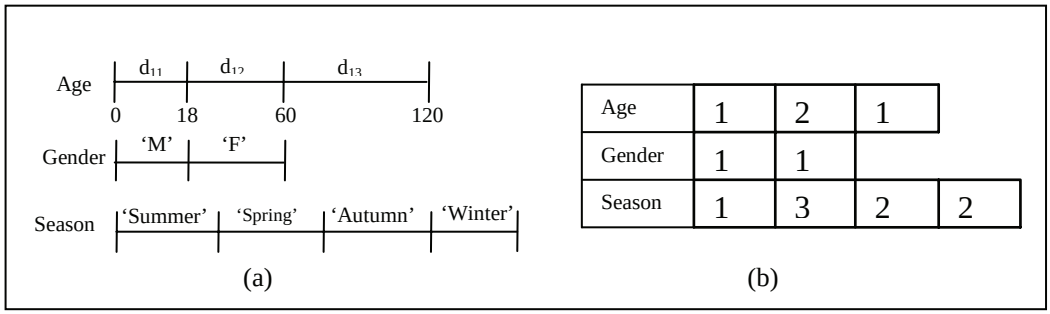
For example, in Figure 1(b), we can deduce that the fragmentation of the data warehouse is not performed using the attribute Gender, because all its sub domains have the same value. Consequently, the warehouse will be fragmented using only Season and Age. For Season attribute, three simple predicates are possible: P_1 : Season = "Summer", P_2 : Season = "Spring", and P_3 : (Season = "Autumn") OR (Season = "Winter"). For Age attribute, two predicates are possible: P_4 : (Age $\leq$ 18) OR (Age $\geq$ 60) and P_5 : (18 < Age < 60) Therefore, the data warehouse can be fragmented into six fragments defined by the following clauses: Cl_1 : ($P_1 \wedge P_4$); Cl_2 : ($P_1 \wedge P_5$); Cl_3 : ($P_2 \wedge P_4$); Cl_4 : ($P_2 \wedge P_5$); Cl_5 : ($P_3 \wedge P_4$); and Cl_6 : ($P_3 \wedge P_5$).

The coding that we proposed satisfies the correctness rules (completeness, reconstruction and disjointness (Özsu & Valduriez, 1999). It is used to represent fragments of dimension tables and fact table. This multidimensional array representation may be used to generate all possible fragmentation schemas (an exhaustive search). This number is calculated as:

$$2^{\sum_{i=1}^{K} n_i},$$

where K represents the number of fragmentation attributes. This number is equal to the number of minterms

Figure 1. Sub Domains of fragmentation attributes



generated by the horizontal fragmentation algorithm proposed by (Özsu & Valduriez, 1999).

The selection operation of GAs gives the probability of chromosomes being selected for reproduction. The principle is to assign higher probabilities to filter chromosomes. The roulette wheel method is used in our algorithm. The roulette wheel selection scheme allocates a sector on a roulette wheel to each chromosome. The ratio of angles of two adjacent sectors is a constant. The basic idea of rank based roulette wheel selection is to allocate larger sector angle to better chromosomes so that better solutions will be included in the next generation with higher probability. A new chromosome for the next generation is cloned after a chromosome as an offspring if a randomly generated number falls in the sector corresponding to the chromosome. Alternatively, the proportionate selection scheme generates chromosomes for the next generation only from a predefined percentage of the previous population.

The goodness of each each chromosome is evaluated using the cost model defined in (Bellatreche, Boukhalfa & Abdalla, 2006).

We use a two-point crossover mechanism for the following reason (note that fragments are represented by arrays): The chromosomes are crossed over once for each fragmentation attribute. If the crossover is done over one chromosome, an attribute with high number of sub domains (example of attribute Season that has 4 sub domains) will have a probability greater than attribute with low number of sub domains, like gender (with two sub domains). This operation is applied until none reduction of the number fact fragments fixed by the DBA.

The mutation operation is needed to create new chromosomes that may not be present in any member of a population and enables GA to explore all possible solutions (in theory) in the search space. The experimental details of our GA are given in (Bellatreche, Boukhalfa & Abdalla, 2006).

FUTURE TRENDS

Selecting horizontal data partitioning schema will become a challenging problem in physical database design. Other types of algorithms, like simulated annealing, ant colony, etc. may be used. Since in the data warehouse environment, changes are very frequently, it will be interesting to develop dynamic algorithms that take into account different changes (query changes, access frequency of a query, selectivity factor of predicates, size of tables, etc.). The horizontal partitioning can be also combined with other optimization structures like materialized views and indexes.

CONCLUSION

Data warehouse is usually modelled using relational database schema with huge fact table and dimension tables. On the top of this schema, complex queries are executed. To speed up these queries and facilitate the manageability of the huge warehouse, we propose the use of horizontal partitioning. It consists in decomposing different tables of the warehouse into fragments. First, we propose a methodology for fragmenting the fact table based on the fragmentation schemas of dimension tables. Second we formalize the problem of selecting an optimal horizontal partitioning schema as an optimization problem with constraint representing the number of horizontal fragments that the data warehouse administrator can manage. Finally, we propose a genetic algorithm to deal with problem.

KEY TERMS

Data Partitioning: Distributing the rows of a table into several separate fragments.

Dimension Table: A table containing the data for one dimension within a star schema. The primary key is used to link to the fact table, and each level in the dimension has a corresponding field in the dimension table.

Derived Horizontal Fragmentation: Is the partitioning of a relation that results from simple predicates being defined on another relation.

Fact Table: The central table in a star schema, containing the basic facts or measures of interest. Dimension fields are also included (as foreign keys) to link to each dimension table.

Fitness Function: Is defined over the genetic representation and measures the quality of the represented solution.

Genetic Algorithm: Is search methods based on the evolutionary concept of natural mutation and the survival of the fittest individuals.

Minterm Predicate: Is the conjunction of simple predicates.

Primary Horizontal Partitioning: Primary horizontal fragmentation of a table is performed using predicates of queries accessing this table.

Selection Predicate: Selection predicate is the parameter of the selection operator of the relational algebra. It has the following form: Attribute θ Value; where Attribute is an attribute of a given table, $\theta \in \{=, <, >, \geq, \leq\}$, and Value $\in$ Domain(A_i)).

Selectivity of a Simple Predicate: Estimates the number of tuples from a relation that satisfy the simple predicate within a query.

Genetic Programming

William H. Hsu
Kansas State University, USA

INTRODUCTION

Genetic programming (**GP**) is a sub-area of evolutionary computation first explored by John Koza (1992) and independently developed by Nichael Lynn Cramer (1985). It is a method for producing computer programs through adaptation according to a user-defined fitness criterion, or objective function.

Like genetic algorithms, GP uses a representation related to some computational model, but in GP, fitness is tied to task performance by specific program semantics. Instead of strings or permutations, genetic programs are most commonly represented as variable-sized expression trees in imperative or functional programming languages, as grammars (O'Neill & Ryan, 2001), or as circuits (Koza et al., 1999). GP uses patterns from biological evolution to evolve programs:

- **Crossover:** Exchange of genetic material such as program subtrees or grammatical rules
- **Selection:** The application of the fitness criterion to choose which individuals from a population will go on to reproduce
- **Replication:** The propagation of individuals from one generation to the next
- **Mutation:** The structural modification of individuals

To work effectively, GP requires an appropriate set of program operators, variables, and constants. Fitness in GP is typically evaluated over fitness cases. In data mining, this usually means training and validation data, but cases can also be generated dynamically using a simulator or directly sampled from a real-world problem solving environment. GP uses evaluation over these cases to measure performance over the required task, according to the given fitness criterion.

BACKGROUND

Although Cramer (1985) first described the use of crossover, selection, and mutation and tree representations for using genetic algorithms to generate programs, Koza is indisputably the field's most prolific and persuasive author. (Wikipedia, 2007) In four books since 1992, Koza et al. have described GP-based solutions to numerous toy problems and several important real-world problems.

> **State of the field:** To date, GPs have been successfully applied to a few significant problems in machine learning and data mining, most notably symbolic regression and feature construction. The method is very computationally intensive, however, and it is still an open question in current research whether simpler methods can be used instead. These include supervised inductive learning, deterministic optimization, randomized approximation using non-evolutionary algorithms (such as Markov chain Monte Carlo approaches), or genetic algorithms and evolutionary algorithms. It is postulated by GP researchers that the adaptability of GPs to structural, functional, and structure-generating solutions of unknown form makes them more amenable to solving complex problems. Specifically, Koza et al. demonstrate (1999, 2003) that in many domains, GP is capable of "human-competitive" automated discovery of concepts deemed to be innovative through technical review such as patent evaluation.

MAIN THRUST OF THE CHAPTER

The general strengths of genetic programs lie in their ability to produce solutions of variable functional form, reuse partial solutions, solve multi-criterion optimization problems, and explore a large search space of solutions in parallel. Modern GP systems are also able to produce structured, object-oriented, and functional

programming solutions involving recursion or iteration, subtyping, and higher-order functions.

A more specific advantage of GPs are their ability to represent procedural, generative solutions to pattern recognition and machine learning problems. Examples of this include image compression and reconstruction (Koza, 1992) and several of the recent applications surveyed below.

GP Methodology

GP in pattern classification departs from traditional supervised inductive learning in that it evolves solutions whose functional form is not determined in advance, and in some cases can be theoretically arbitrary. Koza (1992, 1994) developed GPs for several pattern reproduction problems such as the multiplexer and symbolic regression problems.

Since then, there has been continuing work on inductive GP for pattern classification (Kishore et al., 2000), prediction (Brameier & Banzhaf, 2001), and numerical curve-fitting (Nikolaev & Iba, 2001, IEEE Trans. Evol. Comp.). GP has been used to boost performance in learning polynomial functions (Nikolaev & Iba, 2001, GP & Evol. Machines). More recent work on tree-based multi-crossover schemes has produced positive results in GP-based design of classification functions (Muni et al., 2004).

While early work in GP for data mining and knowledge discovery in databases (KDD) focused on specific fitness measures related to classification and prediction (Eggermont *et al.*, 1999), more recent work has sought to use GP to implement search behaviors and procedural solutions. Among the methodologies related to GP are swarm intelligence approaches such as ant colony optimization (ACO) and particle swarm optimization (PSO), which seek to evolve solutions through fine-grained simulation of many simple agents. (Azzag *et al.*, 2007; Holden & Freitas, 2007; Tsang & Kwong, 2007)

Applications in Data Mining and Warehousing

The domains within data mining and warehousing where GP has been most successfully applied in recent research include classification (Raymer et al., 1996; Connolly, 2004a; Langdon & Buxton, 2004; Langdon & Barrett, 2005; Holden & Freitas, 2007), prediction (Kaboudan, 2000), and search (Burke & Kendall, 2005). Higher-level tasks such as decision support are often reduced to classification or prediction, while the symbolic representation (S-expressions) used by GP admits query optimization.

GP for Control of Inductive Bias, Feature Construction, and Feature Extraction

GP approaches to inductive learning face the general problem of optimizing inductive bias: the preference for groups of hypotheses over others on bases other than pure consistency with training data or other fitness cases. Krawiec (2002) approaches this problem by using GP to preserve useful components of representation (features) during an evolutionary run, validating them using the classification data, and reusing them in subsequent generations. This technique is related to the wrapper approach to KDD, where validation data is held out and used to select examples for supervised learning, or to construct or select variables given as input to the learning system. Because GP is a generative problem solving approach, feature construction in GP tends to involve production of new variable definitions rather than merely selecting a subset.

Evolving dimensionally-correct equations on the basis of data is another area where GP has been applied. Keijzer & Babovic (2002) provide a study of how GP formulates its declarative bias and preferential (search-based) bias. In this and related work, it is shown that proper units of measurement (strong typing) approach can capture declarative bias towards correct equations, whereas type coercion can implement even better preferential bias.

Grammar-Based GP for Data Mining

Not all GP-based approaches use expression tree-based representations, nor functional program interpretation as the computational model. Wong and Leung (2000) survey data mining using grammars and formal languages. This general approach has been shown effective for some natural language learning problems, and extension of the approach to procedural informa-

tion extraction is a topic of current research in the GP community.

GP Implementations: Functionality and Research Features

A number of GP software packages are publicly and commercially available. General features common to most GP systems for research and development include: a very high-period random number generator such as the Mersenne Twister for random constant generation and GP operations; a variety of selection, crossover, and mutation operations; and trivial parallelism (e.g., through multithreading).

One of the most popular packages for experimentation with GP is *Evolutionary Computation in Java*, or *ECJ* (Luke *et al.*, 2007). *ECJ* implements the above features as well as parsimony, "strongly-typed" GP, migration strategies for exchanging individual subpopulations in island mode or multi-deme GP, vector representations, and reconfigurabity using parameter files.

In addition to standalone software packages, some systems used for industral-grade applications provide an interface between a GP module and a relational database server. These include SQL (Connolly, 2004a; Ishida & Pozo, 2002) and Microsoft form-based (Connolly, 2004b) interfaces.

Other Applications: Optimization, Policy Learning

Like other genetic and evolutionary computation methodologies, GP is driven by fitness and suited to optimization approaches to machine learning and data mining. Its program-based representation makes it good for acquiring policies by reinforcement learning. Many GP problems are "error-driven" or "payoff-driven" (Koza, 1992), including the ant trail problems and foraging problems now explored more heavily by the swarm intelligence and ant colony optimization communities. A few problems use specific information-theoretic criteria such as maximum entropy or sequence randomization.

FUTURE TRENDS

Limitations: Scalability and Solution Comprehensibility

Genetic programming remains a controversial approach due to its high computational cost, scalability issues, and current gaps in fundamental theory for relating its performance to traditional search methods, such as hill climbing. While GP has achieved results in design, optimization, and intelligent control that are as good as and sometimes better than those produced by human engineers, it is not yet widely used as a technique due to these limitations in theory. An additional controversy in the intelligent systems community is the role of knowledge in search-driven approaches such as GP. Some proponents of GP view it as a way to generate innovative solutions with little or no domain knowledge, while critics have expressed skepticism over original results due to the lower human-comprehensibility of some results. The crux of this debate is a tradeoff between innovation and originality versus comprehensibility, robustness, and ease of validation. Successes in replicating previously-patented engineering designs such as analog circuits using GP (Koza et al., 2003) have increased its credibility in this regard.

Open Issues: Code Growth, Diversity, Reuse, and Incremental Learning

Some of the most important open problems in GP deal with the proliferation of solution code (called code growth or code bloat), the reuse of previously-evolved partial solutions, and incremental learning. Code growth is an increase in solution size across generations, and generally refers to one that is not matched by a proportionate increase in fitness. It has been studied extensively in the field of GP by many researchers. Luke (2000) provides a survey of known and hypothesized causes of code growth, along with methods for monitoring and controlling growth. Recently Burke et al. (2004) explored the relationship between diversity (variation among solutions) and code growth and fitness. Some techniques for controlling

code growth include reuse of partial solutions through such mechanisms as automatically-defined functions, or ADFs (Koza, 1994) and incremental learning – that is, learning in stages. One incremental approach in GP is to specify criteria for a simplified problem and then transfer the solutions to a new GP population (Hsu & Gustafson, 2002).

CONCLUSION

Genetic programming (GP) is a search methodology that provides a flexible and complete mechanism for machine learning, automated discovery, and cost-driven optimization. It has been shown to work well in many optimization and policy learning problems, but scaling GP up to most real-world data mining domains is a challenge due to its high computational complexity. More often, GP is used to evolve data transformations by constructing features, or to control the declarative and preferential inductive bias of the machine learning component. Making GP practical poses several key questions dealing with how to scale up; make solutions comprehensible to humans and statistically validate them; control the growth of solutions; reuse partial solutions efficiently; and learn incrementally.

Looking ahead to future opportunities and challenges in data mining, genetic programming provides one of the more general frameworks for machine learning and adaptive problem solving. In data mining, they are likely to be most useful where a generative or procedural solution is desired, or where the exact functional form of the solution – whether a mathematical formula, grammar, or circuit – is not known in advance.

KEY TERMS

Automatically-Defined Function (ADF): Parametric functions that are learned and assigned names for reuse as subroutines. ADFs are related to the concept of macro-operators or macros in speedup learning.

Code Growth (Code Bloat): The proliferation of solution elements (e.g., nodes in a tree-based GP representation) that do not contribute towards the objective function.

Crossover: In biology, a process of sexual recombination, by which two chromosomes are paired up

and exchange some portion of their genetic sequence. Crossover in GP is highly stylized and involves structural exchange, typically using subexpressions (subtrees) or production rules in a grammar.

Evolutionary Computation: A solution approach based on simulation models of natural selection, which begins with a set of potential solutions, then iteratively applies algorithms to generate new candidates and select the fittest from this set. The process leads toward a model that has a high proportion of fit individuals.

Generation: The basic unit of progress in genetic and evolutionary computation, a step in which selection is applied over a population. Usually, crossover and mutation are applied once per generation, in strict order.

Individual: A single candidate solution in genetic and evolutionary computation, typically represented using strings (often of fixed length) and permutations in genetic algorithms, or using "problem solver" representations – programs, generative grammars, or circuits – in genetic programming.

Island mode GP: A type of parallel GP where multiple subpopulations (demes) are maintained and evolve independently except during scheduled exchanges of individuals.

Mutation: In biology, a permanent, heritable change to the genetic material of an organism. Mutation in GP involves structural modifications to the elements of a candidate solution. These include changes, insertion, duplication, or deletion of elements (subexpressions, parameters passed to a function, components of a resistor-capacitor-inducer circuit, nonterminals on the right-hand side of a production rule).

Parsimony: An approach in genetic and evolutionary computation, related to "minimum description length", which rewards compact representations by imposing a penalty for individuals in direct proportion to their size (e.g., number of nodes in a GP tree). The rationale for parsimony is that it promotes generalization in supervised inductive learning and produces solutions with less code, which can be more efficient to apply.

Selection: In biology, a mechanism in by which the fittest individuals survive to reproduce, and the basis of speciation according to the Darwinian theory of evolution. Selection in GP involves evaluation of a quantitative criterion over a finite set of fitness cases, with the combined evaluation measures being compared in order to choose individuals.

Genetic Programming for Automatically Constructing Data Mining Algorithms

Alex A. Freitas
University of Kent, UK

Gisele L. Pappa
Federal University of Minas Geras, Brazil

INTRODUCTION

At present there is a wide range of data mining algorithms available to researchers and practitioners (Witten & Frank, 2005; Tan et al., 2006). Despite the great diversity of these algorithms, virtually all of them share one feature: they have been *manually* designed. As a result, current data mining algorithms in general incorporate human biases and preconceptions in their designs.

This article proposes an alternative approach to the design of data mining algorithms, namely the automatic creation of data mining algorithms by means of Genetic Programming (GP) (Pappa & Freitas, 2006). In essence, GP is a type of Evolutionary Algorithm – i.e., a search algorithm inspired by the Darwinian process of natural selection – that evolves computer programs or executable structures.

This approach opens new avenues for research, providing the means to design novel data mining algorithms that are less limited by human biases and preconceptions, and so offer the potential to discover new kinds of patterns (or knowledge) to the user. It also offers an interesting opportunity for the automatic creation of data mining algorithms tailored to the data being mined.

BACKGROUND

An Evolutionary Algorithm (EA) is a computational problem-solving method inspired by the process of natural selection. In essence, an EA maintains a population of "individuals", where each individual represents a candidate solution to the target problem. EAs are iterative generate-and-test procedures, where at each "generation" (iteration) a population of individuals is generated and each individual has its "fitness" computed. The fitness of an individual is a measure of the quality of its corresponding candidate solution. The higher the fitness of an individual, the higher the probability that the individual will be selected to be a "parent" individual. Certain operations (often "crossover" and/or "mutation" operations inspired by their natural counterparts) are applied to the selected parent individuals in order to produce "children" individuals. The important point is that, since the children are in general produced from parents selected based on fitness, the children (new candidate solutions) tend to inherit parts of the good solutions of the previous generation, and the population as a whole gradually evolves to fitter and fitter individuals (better and better solutions to the target problem). For a comprehensive review of EAs in general the reader is referred to (De Jong, 2006; Eiben & Smith, 2003), and a comprehensive review of EAs for data mining can be found in (Freitas, 2002).

The basic principle of EAs – i.e., artificial evolution of candidate solutions, where parent solutions are selected based on their fitness in order to create new children solutions – still holds in Genetic Programming (GP). The main distinguishing feature of GP – by comparison with other types of EA – is that the candidate solutions represented by GP individuals are (or at least should be) computer programs or executable structures. GP has been an active research field for about 15 years (Koza, 1992; Banzhaf et al., 1998; Langdon & Poli, 2002; Koza, 2003), and Koza (2006) reports 36 instances where GP discovered a solution infringing or duplicating some patent, which led Koza to claim that GP is an automated invention machine that routinely produces human-competitive results. However, the creation of a GP system for automatically evolving a full data mining algorithm, as proposed in this article, is a new research topic which is just now

starting to be systematically explored, as discussed in the next section.

MAIN FOCUS

The problem of automatically evolving a data mining algorithm to solve a given data mining task is very challenging, because the evolved algorithm should be generic enough to be applicable to virtually any data set that can be used as input to that task. For instance, an evolved algorithm for the classification task should be able to mine any classification data set (i.e., a data set having a set of records, each of them containing a class attribute and a set of predictor attributes – which can have different data types); an evolved clustering algorithm should be able to mine any clustering data set, etc.

In addition, the automatic evolution of a fully-fledged data mining algorithm requires a GP method that not only is aware of the basic structure of the type of data mining algorithm to be evolved, but also is capable of avoiding fatal programming errors – e.g. avoiding infinite loops when coping with "while" or "repeat" statements. Note that most GP systems in the literature do not have difficulties with the latter problem because they cope only with relatively simple operations (typically mathematical and logical operations), rather than more sophisticated programming statement such as "while" or "repeat" loops. To cope with the two aforementioned problems, a promising approach is to use a grammar-based GP system, as discussed next.

Grammar-Based Genetic Programming

Grammar-Based Genetic Programming (GGP) is a particular type of GP where a grammar is used to create individuals (candidate solutions). There are several types of GGP (Wong & Leung, 2000; O'Neill & Ryan, 2003). A type of GGP particularly relevant for this article consists of individuals that directly encode a candidate program in the form of a tree, namely a derivation tree produced by applying a set of derivation steps of the grammar. A derivation step is simply the application of a production rule to some non-terminal symbol in the left-handed side of the rule, producing the (non-terminal or terminal) symbol in the right-handed side of the rule. Hence, each individual is represented by a derivation tree where the leaf nodes are terminal symbols of the grammar and the internal nodes are the non-terminal symbols of the grammar.

The use of such a grammar is important because it not only helps to constrain the search space to valid algorithms but also guides the GP to exploit valuable background knowledge about the basic structure of the type of data mining algorithm being evolved (Pappa & Freitas, 2006; Wong & Leung, 2000).

In the context of the problem of evolving data mining algorithms the grammar incorporates background knowledge about the type of data mining algorithm being evolved by the GP. Hence, broadly speaking, the non-terminal symbols of the grammar represent high-level descriptions of the major steps in the pseudo-code of a data mining algorithm, whilst the terminal symbols represent a lower-level implementation of those steps.

A New Grammar-Based GP System for Automatically Evolving Rule Induction Algorithms

The previously discussed ideas about Grammar-Based Genetic Programming (GGP) were used to create a GGP system that automatically evolves a rule induction algorithm, guided by a grammar representing background knowledge about the basic structure of rule induction algorithms (Pappa & Freitas, 2006), (Pappa 2007). More precisely, the grammar contains two types of elements, namely:

a. general programming instructions – e.g. *if-then* statements, *for/while* loops; and
b. procedures specifying major operations of rule induction algorithms – e.g., procedures for initializing a classification rule, refining a rule by adding or removing conditions to/from it, selecting a (set of) rule(s) from a number of candidate rules, pruning a rule, etc.

Hence, in this GGP each individual represents a candidate rule induction algorithm, obtained by applying a set of derivation steps from the rule induction grammar. The terminals of the grammar correspond to modular blocks of Java programming code, so each individual is actually a Java program implementing a full rule induction algorithm.

This work can be considered a major "case study" or "proof of concept" for the ambitious idea of automati-

cally evolving a data mining algorithm with genetic programming, and it is further described below. In any case, it should be noted that the proposed idea is generic enough to be applicable to other types of data mining algorithms – i.e., not only rule induction algorithms – with proper modifications in the GGP. The authors' motivation for focusing on rule induction algorithms was that this type of algorithm usually has the advantage of discovering comprehensible knowledge, represented by IF-THEN classification rules (i.e., rules of the form IF (conditions) THEN (predicted class)) that are intuitively interpretable by the user (Witten & Frank, 2005). This is in contrast to some "black box" approaches such as support vector machines or neural networks. Note that the comprehensibility of discovered knowledge is usually recognized as an important criterion in evaluating that knowledge, in the context of data mining (Fayyad et al., 1996; Freitas, 2006).

In order to train the GGP for evolving rule induction algorithms, the authors used a "meta-training set" consisting of six different data sets. The term meta-training set here refers to a set of data sets, all of which are using simultaneously for the training of the GGP – since the goal is to evolve a generic rule induction algorithm. This is in contrast with the normal use of a GP system for rule induction, where the GP is trained with a single data set – since the goal is to evolve just a rule set (rather than algorithm) specific to the given data set. The fitness of each individual – i.e., each candidate rule induction algorithm – is, broadly speaking, an aggregated measure of the classification accuracy of the rule induction algorithm over all the six data sets in the meta-training set. After the evolution is over, the best rule induction algorithm generated by the GGP was then evaluated on a "meta-test set" consisting of five data sets, none of which were used during the training of the GGP. The term meta-test set here refers to a set of data sets, all of which are used to evaluate the generalization ability of a rule induction algorithm evolved by the GGP. Overall, cross-validation results showed that the rule induction algorithms evolved by the GGP system were competitive with several well-known rule induction algorithms – more precisely, CN2, Ripper and C4.5Rules (Witten & Frank, 2005) – which were manually designed and refined over decades of research.

Related Work on GP Systems for Evolving Rule Induction Algorithms

The authors are aware of only two directly relevant related works, as follows. Suyama et al. (1998) proposed a GP system to evolve a classification algorithm. However, the GP system used an ontology consisting of coarse-grained building blocks, where a leaf node of the ontology is a full classification algorithm, and most nodes in the ontology refer to changes in the dataset being mined. Hence, this work can be considered as evolving a good combination of a modified dataset and a classification algorithm selected (out of predefined algorithms) for that modified dataset. By contrast, the methods proposed in (Pappa & Freitas, 2006) are based on a grammar combining finer-grained components of classification algorithms, i.e., the building blocks include programming constructs such as "while" and "if" statements, search strategies, evaluation procedures, etc., which were not used in (Suyama et al., 1998).

In addition, Wong (1998) proposed a grammar-based GP to evolve a classification algorithm adapted to the data being mined. However, that work focused on just one existing rule induction algorithm (viz. FOIL) of which the GP evolved only one component, namely its evaluation function. By contrast, the method proposed in (Pappa & Freitas, 2006) had access to virtually all the components of a classification algorithm, which led to the construction of new rule induction algorithms quite different from existing ones in some runs of the GP.

FUTURE TRENDS

The discussion on the previous section focused on the automatic evolution of rule induction algorithms for classification, but of course this is by no means the only possibility. In principle other types of data mining algorithms can also be automatically evolved by using the previously described approach, as long as a suitable grammar is created to guide the search of the Genetic Programming system. Since this kind of research can be considered pioneering, there are innumerous possibilities for further research varying the type of data mining algorithm to be evolved – i.e., one could evolve other types of classification algorithms, clustering algorithms, etc.

CONCLUSION

This article proposed the idea of designing a Grammar-based Genetic Programming (GGP) system to automatically evolve a data mining algorithm, and briefly discussed, as a practical example of the effectiveness of this approach, a new GGP system that automatically creates rule induction algorithms. In this GGP system the evaluation of candidate rule induction algorithms was performed by using a "meta-training set" consisting of six datasets, in order to generate rule induction algorithms robust across a number of different datasets. This robustness was indeed obtained, since the automatically-evolved rule induction algorithms were competitive with several well-known manually-designed rule induction algorithms in five datasets used in the "meta-test set", representing datasets unseen during the evolution of the GGP.

An alternative research direction, whose experiments are ongoing, is to use a meta-training and a meta-test set having just one dataset. In this approach a subset of the single data set being mined is used in the meta-training set during the GGP evolution, and the remaining subset of the data (i.e., the set of records or data instances not used in the meta-training set) is used in the meta-test set, to evaluate the generalization ability of the rule induction algorithm output by the GGP. In this case the GGP works in a way that actually evolves a rule induction algorithm tailored to the data being mined, which offers the potential to automatically construct data mining algorithms customized to any dataset provided by the user. Note that this represents a new level of automation in data mining. The potentially significant benefit of this automation is clear because the number of datasets to be mined (as well as the number of users) is much greater than the number of (human) data mining algorithm designers, and so one can hardly expect that human designers would have time to manually design algorithms customized to the data being mined.

KEY TERMS

Classification: A type of data mining task where the goal is essentially to predict the class of a record (data instance) based on the values of the predictor attributes for that example. The algorithm builds a classifier from the training set, and its performance is evaluated on a test set (see the definition of training set and test set below).

Classification Rule: A rule of the form IF (conditions) THEN (predicted class), with the meaning that, if a record (data instance) satisfies the conditions in the antecedent of the rule, the rule assigns to that record the class in the consequent of the rule.

Evolutionary Algorithm: An iterative computational problem-solving method that evolves good solutions to a well-defined problem, inspired by the process of natural selection.

Genetic Programming: A type of evolutionary algorithm where the solutions being evolved by the algorithm represent computer programs or executable structures.

Rule Induction Algorithm: A type of data mining algorithm that discovers rules in data.

Test Set: A set of records whose class is unknown by a classification algorithm, used to measure the predictive accuracy of the algorithm after it is trained with records in the training set.

Training Set: A set of records whose class is known, used to train a classification algorithm.

Global Induction of Decision Trees

INTRODUCTION

Decision trees are, besides decision rules, one of the most popular forms of knowledge representation in Knowledge Discovery in Databases process (Fayyad, Piatetsky-Shapiro, Smyth & Uthurusamy, 1996) and implementations of the classical decision tree induction algorithms are included in the majority of data mining systems. A hierarchical structure of a tree-based classifier, where appropriate tests from consecutive nodes are subsequently applied, closely resembles a human way of decision making. This makes decision trees natural and easy to understand even for an inexperienced analyst. The popularity of the decision tree approach can also be explained by their ease of application, fast classification and what may be the most important, their effectiveness.

Two main types of decision trees can be distinguished by the type of tests in non-terminal nodes: *univariate* and *multivariate* decision trees. In the first group, a single attribute is used in each test. For a continuous-valued feature usually an inequality test with binary outcomes is applied and for a nominal attribute mutually exclusive groups of attribute values are associated with outcomes. As a good representative of univariate inducers, the well-known C4.5 system developed by Quinlan (1993) should be mentioned.

In univariate trees a split is equivalent to partitioning the feature space with an axis-parallel hyper-plane. If decision boundaries of a particular dataset are not axis-parallel, using such tests may lead to an over-complicated classifier. This situation is known as the "staircase effect". The problem can be mitigated by applying more sophisticated multivariate tests, where more than one feature can be taken into account. The most common form of such tests is an oblique split, which is based on a linear combination of features (hyper-plane). The decision tree which applies only oblique tests is often called *oblique* or *linear*, whereas heterogeneous trees with univariate, linear and other multivariate (e.g., instance-based) tests can be called *mixed decision trees* (Llora & Wilson, 2004). It should be emphasized that computational complexity of the multivariate induction is generally significantly higher than the univariate induction. CART (Breiman, Friedman, Olshen & Stone, 1984) and OC1 (Murthy, Kasif & Salzberg, 1994) are well known examples of multivariate systems.

BACKGROUND

The issue of finding an optimal decision tree for a given classification problem is known to be a difficult optimization task. Naumov (1991) proved that optimal decision tree construction from data is NP-complete under a variety of measures. In this situation it is obvious that a computationally tractable induction algorithm has to be heuristically enhanced. The most popular strategy is based on the top-down approach (Rokach & Maimon, 2005), where a locally optimal search for tests (based, e.g., on a Gini, towing or entropy rule) and data splitting are recursively applied to consecutive subsets of the training data until the stopping condition is met. Usually, the growing phase is followed by post-pruning (Esposito, Malerba & Semeraro, 1997) aimed at increasing generalization power of the obtained classifier and mitigating the risk of the over-fitting to the learning data.

There are problems where the greedy search fails (e.g., the classical chess board problem) and more sophisticated methods are necessary. In this chapter, we present a global approach, where the whole tree (i.e., its structure and all splits) is constructed at the same time. The motivation for this is the fact that top-down induction with, e.g., entropy minimization, makes locally optimal decisions and at least more compact tree can be obtained when it is constructed and assessed in a global way.

As a first step toward global induction, limited look-ahead algorithms were proposed (e.g., Alopex Perceptron Decision Tree of Shah & Sastry (1999) evaluates quality of a split based on the degree of linear separability of sub-nodes). Another approach consists in a two-stage induction, where a greedy algorithm is applied in the first stage and then the tree is refined to be as close to optimal as possible (GTO (Bennett, 1994) is an example of a linear programming based method for optimizing trees with fixed structures).

In the field of evolutionary computations, the global approach to decision tree induction was initially investigated in genetic programming (GP) community. The tree-based representation of solutions in a population makes this approach especially well-suited and easy for adaptation to decision tree generation. The first attempt was made by Koza (1991), where he presented GP-method for evolving LISP S-expressions corresponding to decision trees. Next, univariate trees were evolved by Nikolaev and Slavov (1998) and Tanigawa and Zhao (2000), whereas Bot and Langdon (2000) proposed a method for induction of classification trees with limited oblique splits.

Among genetic approaches for univariate decision tree induction two systems are particularly interesting here: GATree proposed by Papagelis and Kalles (2001) and GAIT developed by Fu, Golden, Lele, Raghavan and Wasil (2003). Another related global system is named GALE (Llora & Garrell, 2001). It is a fine-grained parallel evolutionary algorithm for evolving both axis-parallel and oblique decision trees.

MAIN FOCUS

We now discuss how evolutionary computation can be applied to induction of decision trees. General concept of a standard evolutionary algorithm is first presented and then we will discuss how it can be applied to build a decision tree classifier.

Evolutionary Algorithms

Evolutionary algorithms (Michalewicz, 1996) belong to a family of metaheuristic methods which represent techniques for solving a general class of difficult computational problems. They provide a general framework (see Figure 1) which is inspired by biological mechanisms of evolution. A biological terminology is used here. The algorithm operates on individuals which compose a current population. Individuals are assessed using a measure named the fitness function and those with higher fitness have usually bigger probability of being selected for reproduction. Genetic operators such as mutation and crossover influence new generations of individuals. This guided random search (offspring usually inherits some traits from its ancestors) is stopped when some convergence criteria is satisfied.

Figure 1. A general framework of evlutionary algorithms

```
(1) Initialize the population
(2) Evaluate initial population
(3) Repeat
    (3.1) Perform competitive selection
    (3.2) Apply genetic operators to generate new solutions
    (3.3) Evaluate solutions in the population
  Until some convergence criteria is satisfied
```

A user defined adaptation of such a general evolutionary algorithm can in itself have heuristic bias (Aguilar-Ruiz, Giráldez, & Riquelme, 2007). It can prune the search space of the particular evolutionary application. The next section shows how this framework was adapted to the problem of decision tree induction.

Decision Tree Induction with Evolutionary Algorithms

In this section the synergy of evolutionary algorithms which are designed to solve difficult computational problems and decision trees which have an NP-complete solution space is introduced. To apply a general algorithm presented in Figure 1 to decision tree induction, the following factors need to be considered:

- Representation of individuals,
- Genetic operators: mutation and crossover,
- Fitness function.

Representation

An evolutionary algorithm operates on individuals. In the evolutionary approach to decision tree induction which is presented in this chapter, individuals are represented as actual trees, which can have different structure and different content. Each individual encoded

as a decision tree represents a potential solution to the problem. Genetic operators operate on such structures and additional post-evolutionary operators ensure that obtained descendant represents a "rational" solution. The problem is that the results of a crossover operator can contain a significant part (sub-tree) which does not have any observations. By pruning or improving those useless parts of obtained individuals the search space can be reduced significantly. In this way such improving actions together with direct representation of individuals in a natural tree like structure bring a user defined heuristic to the evolutionary algorithm.

There are three possible test types which can be used in internal nodes of decision trees discussed in this chapter: two univariate and one multivariate (Kretowski & Grzes, 2007b). In case of univariate tests, a test representation depends on the considered attribute type. For nominal attributes at least one attribute value is associated with each branch. It means that an inner disjunction is implemented. For continuous-valued features typical inequality tests with two outcomes are used. In order to speed up the search process only boundary thresholds (a boundary threshold for the given attribute is defined as a midpoint between such a successive pair of examples in the sequence sorted by the increasing value of the attribute, in which the examples belong to two different classes) are considered as potential splits and they are calculated before starting the evolutionary computation. Finally, an oblique test with a binary outcome can also be applied as a multivariate test (Kretowski & Grzes, 2006).

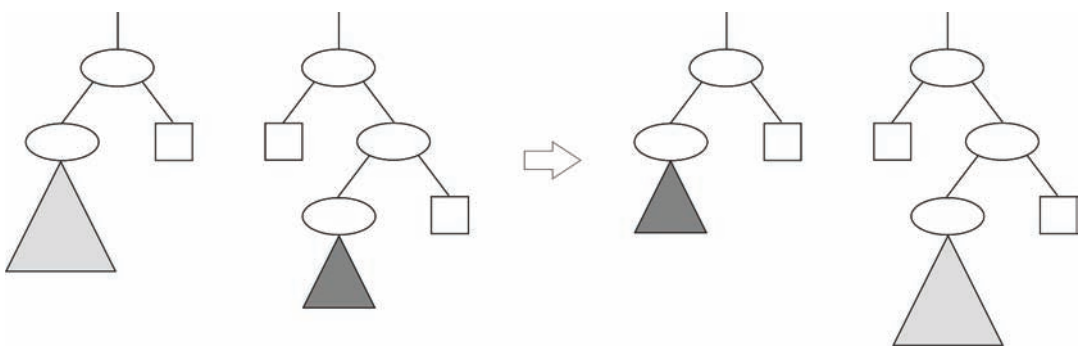
Genetic Operators

Genetic operators are the two main forces that form the basis of evolutionary systems and provide a necessary diversity and novelty. There are two specialized genetic operators corresponding to the classical mutation and crossover. The application of these operators can result in changes of both the tree structure and tests in non-terminal nodes.

Crossover in evolutionary algorithms has its analogy in nature. It is inspired by sexual reproduction of living organisms. The crossover operator attempts to combine elements of two existing individuals (parents) in order to create a new (novel) solution but with some features of its "parents". Because the algorithm is supposed to look for both the structure of the tree and type and parameters of tests, several variants of crossover operators can be applied (Kretowski & Grzes, 2007b). All of them start with selecting the crossover positions – nodes – in two affected individuals. In the most straightforward variant, the subtrees starting in the selected nodes are exchanged. This corresponds to the classical crossover from genetic programming (Koza, 1991). In the second variant, which can be applied only when non-internal nodes have been randomly chosen and the numbers of their outcomes are equal, tests associated with these nodes are exchanged (see Figure 2). The last variant is applicable when non-internal nodes have been drawn and numbers of their descendants are equal. In this case branches which start from the selected nodes are exchanged in random order.

Mutation is also inspired by nature that is by mutation of an organism's DNA. This operator makes periodically random changes in some places of some members of the population. In presented approach, the problem specific representation requires specialized operators. Hence modifications performed by the mutation operator depend for example on the node type (i.e., if the considered node is a leaf node or an internal node). For a non-terminal node a few possibilities exist:

Figure 2. The crossover operator: exchanging sub-trees



- A completely new test of the same or different type can be selected,
- The existing test can be modified,
- An oblique test can be simplified to the corresponding inequality test by eliminating (zeroing) the smallest coefficients or an axis-parallel test can be transformed into oblique one,
- One sub-tree can be replaced by another sub-tree from the same node,
- A node can be transformed (pruned) into a leaf.

Modifying a leaf makes sense only if it contains objects from different classes. The leaf is transformed into an internal node and a new test is randomly chosen. The search for effective tests can be recursively repeated for all newly created descendants (leaves). As a result the mutated leaf can be replaced by a sub-tree, which potentially accelerates the evolution.

Fitness Function

The two forces of evolutionary systems which bring diversity and novelty are crossover and mutation. Selection acts as a force which increases the quality of the population. For this reason the mechanism of selection usually requires a quantitative measure to assess individuals in the population. Such an objective function is called a fitness function and in practice is a very important and sensitive element of the evolutionary system. It drives the learning process in a particular direction. In case of decision trees we need for example to balance the reclassification quality and the complexity (at least size) of the tree. This comes directly from a 14th century principle called Occam's razor which states that an explanation for any phenomenon should take as few assumptions as possible. This has straightforward implications in classification methods, and is particularly noticeable in decision trees. The decision tree which is too big becomes over-fitted to learning data leading to a poor performance on unseen, testing observations.

In a typical top-down induction of decision trees over-fitting is mitigated by defining a stopping condition or by applying a post-pruning. In the discussed approach, the search for an optimal structure is embedded into the evolutionary algorithm by incorporating a complexity term in the fitness function. A similar idea is used in cost complexity pruning in the CART system (Breiman *et al.*, 1984). The fitness function is maximized and has the following form:

$$Fitness(T) = Q_{\mathrm{Re}class}(T) - \alpha(Comp(T) - 1.0)$$

where $Q_{Reclass}(T)$ is the training accuracy (reclassification quality) of the tree T and α is the relative importance of the classifier complexity. In the simplest form the tree complexity $Comp(T)$ can be defined as the classifier size which is usually equal to the number of nodes. The penalty associated with the classifier complexity increases proportionally with the tree size and prevents over-fitting. Subtracting 1.0 eliminates the penalty when the tree is composed of only one leaf (in majority voting). This general form of the fitness function can be adjusted to different requirements like for example induction of mixed decision trees (Kretowski & Grzes, 2007b) which can contain all tree types of tests or put emphasis on the feature selection (Kretowski & Grzes, 2006).

Algorithm Properties

Because the algorithm presented here is built on top of a general metaheuristic concept, it gains flexibility from it. Metaheuristic is a method for solving a general class of problems and because of that it is relatively easy to adjust the algorithm to different goals and demands. Especially the fitness function allows modifying the algorithm in a simple and straightforward way. As it was mentioned in the previous section, the complexity term can take into account the structure of tests in internal nodes and provide feature selection (Kretowski & Grzes, 2006b) when less complicated tests are rewarded.

Our discussion has focused so far on the most popular criterion of classification systems: the prediction error. In many fields, like for example medicine or finance, this approach may not be sufficient when costs of features (due to costly measurements) or misclassification-cost (due to costs of wrong decision) should be taken into account. The term cost-sensitive classification is used in the field (Turney, 1995). The algorithm was adjusted to meet also these criteria. The modification of the fitness function allowed selecting features in accordance to their cost and optimizing the misclassification cost instead of the prediction error (Kretowski & Grzes, 2007a).

FUTURE TRENDS

While investigating evolutionary algorithms there is always a strong motivation for speeding them up. It is also a well-known fact that evolutionary approaches are well suited for parallel architecture (Alba, 2005) and an implementation based on Message Passing Interface (MPI) is available. This is especially important in the context of modern data mining applications, where huge learning sets need to be analyzed.

Another possibility of speeding up and focusing the evolutionary search is embedding the local search operators into the algorithm (so called *memetic algorithms*). Applications of such hybrid solutions to the global induction are currently investigated (Kretowski, 2008).

CONCLUSION

In this chapter, the global induction of univariate, oblique and mixed decision trees is presented. In contrast to the classical top-down approaches, both the structure of the classifier and all tests in internal nodes are searched during one run of the evolutionary algorithm. Specialized genetic operators applied in informed way and suitably defined fitness function allow us to focus the search process and efficiently generate competitive classifiers also for cost-sensitive problems. Globally induced trees are generally less complex and in certain situations more accurate.

KEY TERMS

Cost-Sensitive Classifier: A classifier, which can optimize at least one type of cost: misclassification cost (assigning different costs to different types of misclassifications) or cost of features (values of features usually come from measurements of different costs).

Decision Tree Pruning: The approach to avoiding over-fitting the input data. Firstly, the tree which over-fits the data is constructed and then pruning simplifies this tree by pruning its lower parts. This process generally aims at obtaining the simplest tree with the highest classification of input data that is at improving the generalization power of the decision tree.

Global Induction: A method of decision tree generation, where both the tree structure and all tests are searched at the same time; usually based on evolutionary approach in contrast to top-down induction.

Mixed Decision Trees: A decision tree in which different types of tests are permitted: univariate (e.g., nominal and inequality tests) and multivariate (e.g., oblique or instance-based tests).

Oblique Decision Tree: A binary decision tree with tests based on hyper-planes (linear combinations of features).

Over-Fitting: The problem existing in supervised learning when a classifier perfectly classifies the training data but performs much worse on unseen data; the problem can emerge when machine learning algorithm fits noise or insufficient data, i.e., when it learns on irrelevant facts or generalizes from specific cases.

Top-Down Induction: A recursive method of decision tree generation; starts with the entire input dataset in the root node; an optimal test for data splitting is searched and branches corresponding to the test outcomes are created; different measures for test evaluation have been used, e.g., Gini, entropy and towing rules; test searches and data splitting are repeated in the created nodes unless the stopping condition is met.

Graph-Based Data Mining

Lawrence B. Holder
University of Texas at Arlington, USA

Diane J. Cook
University of Texas at Arlington, USA

INTRODUCTION

Graph-based data mining represents a collection of techniques for mining the relational aspects of data represented as a graph. Two major approaches to graph-based data mining are *frequent subgraph mining* and *graph-based relational learning*. This chapter will focus on one particular approach embodied in the Subdue system, along with recent advances in graph-based supervised learning, graph-based hierarchical conceptual clustering, and graph-grammar induction.

Most approaches to data mining look for associations among an entity's attributes, but relationships between entities represent a rich source of information, and ultimately knowledge. The field of *multi-relational data mining*, of which graph-based data mining is a part, is a new area investigating approaches to mining this relational information by finding associations involving multiple tables in a relational database. Two main approaches have been developed for mining relational information: logic-based approaches and graph-based approaches.

Logic-based approaches fall under the area of *inductive logic programming* (ILP). ILP embodies a number of techniques for inducing a logical theory to describe the data, and many techniques have been adapted to multi-relational data mining (Dzeroski & Lavrac, 2001; Dzeroski, 2003). Graph-based approaches differ from logic-based approaches to relational mining in several ways, the most obvious of which is the underlying representation. Furthermore, logic-based approaches rely on the prior identification of the predicate or predicates to be mined, while graph-based approaches are more data-driven, identifying any portion of the graph that has high support. However, logic-based approaches allow the expression of more complicated patterns involving, e.g., recursion, variables, and constraints among variables. These representational limitations of graphs can be overcome, but at a computational cost.

BACKGROUND

Graph-based data mining (GDM) is the task of finding novel, useful, and understandable graph-theoretic patterns in a graph representation of data. Several approaches to GDM exist based on the task of identifying frequently occurring subgraphs in graph transactions, i.e., those subgraphs meeting a minimum level of support. Washio and Motoda (2003) provide an excellent survey of these approaches. We here describe four representative GDM methods.

Kuramochi and Karypis (2001) developed the FSG system for finding all frequent subgraphs in large graph databases. FSG starts by finding all frequent single and double edge subgraphs. Then, in each iteration, it generates candidate subgraphs by expanding the subgraphs found in the previous iteration by one edge. In each iteration the algorithm checks how many times the candidate subgraph occurs within an entire graph. The candidates, whose frequency is below a user-defined level, are pruned. The algorithm returns all subgraphs occurring more frequently than the given level.

Yan and Han (2002) introduced gSpan, which combines depth-first search and lexicographic ordering to find frequent subgraphs. Their algorithm starts from all frequent one-edge graphs. The labels on these edges together with labels on incident vertices define a code for every such graph. Expansion of these one-edge graphs maps them to longer codes. Since every graph

can map to many codes, all but the smallest code are pruned. Code ordering and pruning reduces the cost of matching frequent subgraphs in gSpan. Yan and Han (2003) describe a refinement to gSpan, called CloseGraph, which identifies only subgraphs satisfying the minimum support, such that no supergraph exists with the same level of support.

Inokuchi et al. (2003) developed the Apriori-based Graph Mining (AGM) system, which searches the space of frequent subgraphs in a bottom-up fashion, beginning with a single vertex, and then continually expanding by a single vertex and one or more edges. AGM also employs a canonical coding of graphs in order to support fast subgraph matching. AGM returns association rules satisfying user-specified levels of support and confidence.

The last approach to GDM, and the one discussed in the remainder of this chapter, is embodied in the Subdue system (Cook & Holder, 2000). Unlike the above systems, Subdue seeks a subgraph pattern that not only occurs frequently in the input graph, but also significantly compresses the input graph when each instance of the pattern is replaced by a single vertex. Subdue performs a greedy search through the space of subgraphs, beginning with a single vertex and expanding by one edge. Subdue returns the pattern that maximally compresses the input graph. Holder and Cook (2003) describe current and future directions in this graph-based relational learning variant of GDM.

MAIN THRUST OF THE CHAPTER

As a representative of GDM methods, this section will focus on the Subdue graph-based data mining system. The input data is a directed graph with labels on vertices and edges. Subdue searches for a substructure that best compresses the input graph. A *substructure* consists of a subgraph definition and all its occurrences throughout the graph. The initial state of the search is the set of substructures consisting of all uniquely labeled vertices. The only operator of the search is the *Extend Substructure* operator. As its name suggests, it extends a substructure in all possible ways by a single edge and a vertex, or by only a single edge if both vertices are already in the subgraph.

Subdue's search is guided by the *minimum description length* (MDL) principle, which seeks to minimize the description length of the entire data set. The evaluation heuristic based on the MDL principle assumes that the best substructure is the one that minimizes the description length of the input graph when compressed by the substructure. The description length of the substructure *S* given the input graph *G* is calculated as $DL(G,S) = DL(S)+DL(G|S)$, where $DL(S)$ is the description length of the substructure, and $DL(G|S)$ is the description length of the input graph compressed by the substructure. Subdue seeks a substructure S that minimizes $DL(G,S)$.

The search progresses by applying the *Extend Substructure* operator to each substructure in the current state. The resulting state, however, does not contain all the substructures generated by the *Extend Substructure* operator. The substructures are kept on a queue and are ordered based on their description length (or sometimes referred to as *value*) as calculated using the MDL principle. The queue's length is bounded by a user-defined constant.

The search terminates upon reaching a user-specified limit on the number of substructures extended, or upon exhaustion of the search space. Once the search terminates and Subdue returns the list of best substructures found, the graph can be compressed using the best substructure. The compression procedure replaces all instances of the substructure in the input graph by single vertices, which represent the substructure's instances. Incoming and outgoing edges to and from the replaced instances will point to, or originate from the new vertex that represents the instance. The Subdue algorithm can be invoked again on this compressed graph.

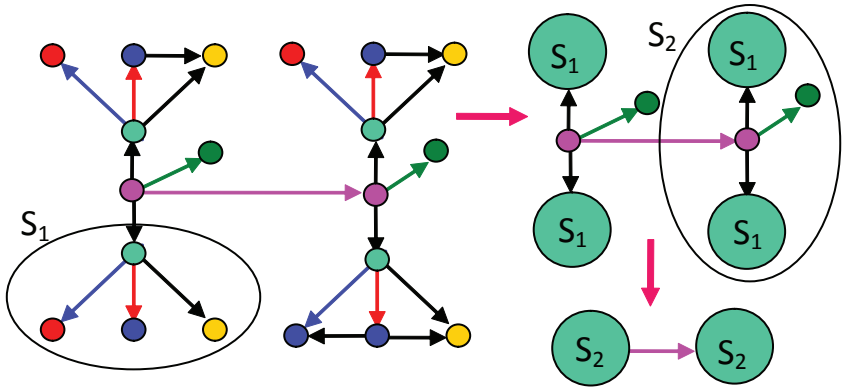
Figure 1 illustrates the GDM process on a simple example. Subdue discovers substructure S_1, which is used to compress the data. Subdue can then run for a second iteration on the compressed graph, discovering substructure S_2. Because instances of a substructure can appear in slightly different forms throughout the data, an inexact graph match, based on graph edit distance, is used to identify substructure instances.

Most GDM methods follow a similar process. Variations involve different heuristics (e.g., frequency vs. MDL) and different search operators (e.g., merge vs. extend).

Graph-Based Hierarchical Conceptual Clustering

Given the ability to find a prevalent subgraph pattern in a larger graph and then compress the graph with this

Figure 1. Graph-based data mining: A simple example.



pattern, iterating over this process until the graph can no longer be compressed will produce a hierarchical, conceptual clustering of the input data. On the i^{th} iteration, the best subgraph S_i is used to compress the input graph, introducing new vertices labeled S_i in the graph input to the next iteration. Therefore, any subsequently-discovered subgraph S_j can be defined in terms of one or more of S_is, where $i < j$. The result is a *lattice*, where each cluster can be defined in terms of more than one parent subgraph. For example, Figure 2 shows such a clustering done on a DNA molecule. Note that the ordering of pattern discovery can affect the parents of a pattern. For instance, the lower-left pattern in Figure 2 could have used the C-C-O pattern, rather than the C-C pattern, but in fact, the lower-left pattern is discovered before the C-C-O pattern. For more information on graph-based clustering, see (Jonyer et al., 2001).

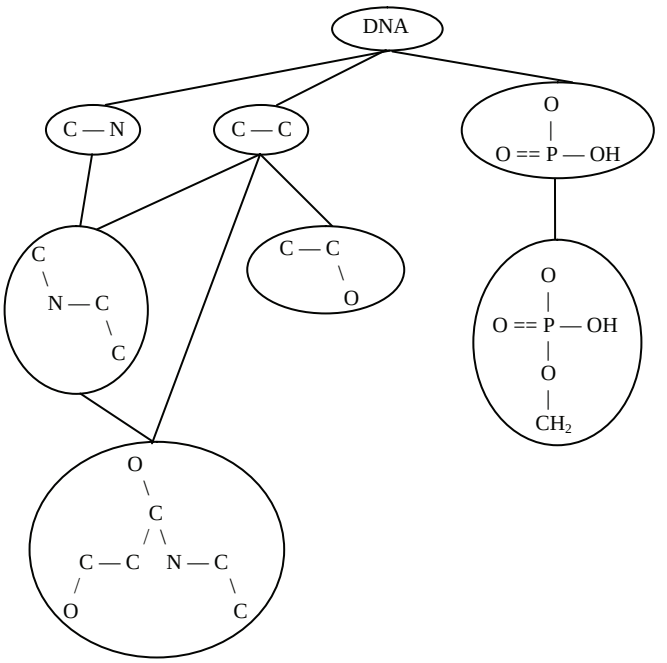
Graph-Based Supervised Learning

Extending a graph-based data mining approach to perform supervised learning involves the need to handle negative examples (focusing on the two-class scenario). In the case of a graph the negative information can come in three forms. First, the data may be in the form of numerous smaller graphs, or graph transactions, each labeled either positive or negative. Second, data may be composed of two large graphs: one positive and one negative. Third, the data may be one large graph in which the positive and negative labeling occurs throughout. We will talk about the third scenario in the section on future directions. The first scenario is closest to the standard supervised learning problem in that we have a set of clearly defined examples. Let G^+ represent the set of positive graphs, and G^- represent the set of negative graphs. Then, one approach to supervised learning is to find a subgraph that appears often in the positive graphs, but not in the negative graphs. This amounts to replacing the information-theoretic measure with simply an *error-based measure*. This approach will lead the search toward a small subgraph that discriminates well. However, such a subgraph does not necessarily compress well, nor represent a characteristic description of the target concept.

We can bias the search toward a more characteristic description by using the information-theoretic measure to look for a subgraph that compresses the positive examples, but not the negative examples. If $I(G)$ represents the description length (in bits) of the graph G, and $I(G|S)$ represents the description length of graph G compressed by subgraph S, then we can look for an S that minimizes $I(G^+|S) + I(S) + I(G^-) - I(G^-|S)$, where the last two terms represent the portion of the negative graph incorrectly compressed by the subgraph. This approach will lead the search toward a larger subgraph that characterizes the positive examples, but not the negative examples.

Finally, this process can be iterated in a set-covering approach to learn a disjunctive hypothesis. If using the error measure, then any positive example containing the learned subgraph would be removed from subsequent iterations. If using the information-theoretic measure, then instances of the learned subgraph in both the positive and negative examples (even multiple instances

Figure 2. Graph-based hierarchical, conceptual clustering of a DNA molecule.



per example) are compressed to a single vertex. Note that the compression is a lossy one, i.e, we do not keep enough information in the compressed graph to know how the instance was connected to the rest of the graph. This approach is consistent with our goal of learning general patterns, rather than mere compression. For more information on graph-based supervised learning, see (Gonzalez et al., 2002).

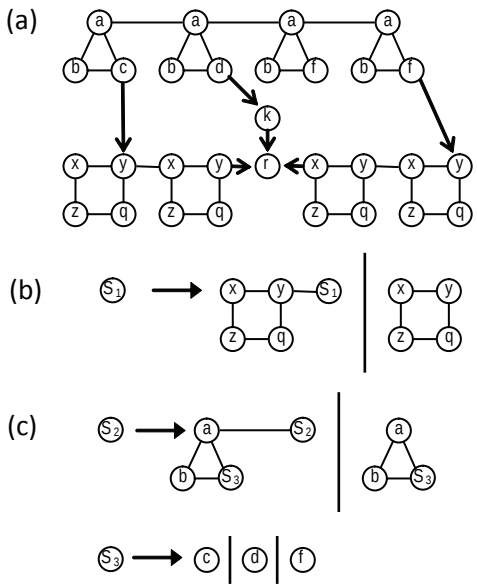
Graph Grammar Induction

As mentioned earlier, two of the advantages of logic-based approach to relational learning are the ability to learn recursive hypotheses and constraints among variables. However, there has been much work in the area of graph grammars, which overcome this limitation. Graph grammars are similar to string grammars except that terminals can be arbitrary graphs rather than symbols from an alphabet. While much of the work on graph grammars involves the analysis of various classes of graph grammars, recent research has begun to develop techniques for learning graph grammars (Doshi et al., 2002; Jonyer et al., 2002).

Figure 3b shows an example of a *recursive graph grammar* production rule learned from the graph in Figure 3a. A GDM approach can be extended to consider graph grammar productions by analyzing the instances of a subgraph to see how they are related to each other. If two or more instances are connected to each other by one or more edges, then a recursive production rule generating an infinite sequence of such connected subgraphs can be constructed. A slight modification to the information-theoretic measure taking into account the extra information needed to describe the recursive component of the production is all that is needed to allow such a hypothesis to compete along side simple subgraphs (i.e., terminal productions) for maximizing compression.

These graph grammar productions can include non-terminals on the right-hand side. These productions can be disjunctive, as in Figure 3c, which represents the final production learned from Figure 3a using this approach. The disjunction rule is learned by looking for similar, but not identical, extensions to the instances of a subgraph. A new rule can be constructed that captures the disjunctive nature of this extension, and included in the pool of production rules competing based on their ability to compress the input graph. With a proper encoding of this disjunction information, the MDL criterion will tradeoff the complexity of the rule with the

Figure 3. Graph grammar learning example with (a) the input graph, (b) the first grammar rule learned, and (c) the second and third grammar rules learned.



amount of compression it affords in the input graph. An alternative to defining these disjunction non-terminals is to instead construct a variable whose range consists of the different disjunctive values of the production. In this way we can introduce constraints among variables contained in a subgraph by adding a constraint edge to the subgraph. For example, if the four instances of the triangle structure in Figure 3a each had another edge to a *c*, *d*, *f* and *f* vertex respectively, then we could propose a new subgraph, where these two vertices are represented by variables, and an equality constraint is introduced between them. If the range of the variable is numeric, then we can also consider inequality constraints between variables and other vertices or variables in the subgraph pattern.

Jonyer (2003) has developed a graph grammar learning approach with the above capabilities. The approach has shown promise both in handling noise and learning recursive hypotheses in many different domains including learning the building blocks of proteins and communication chains in organized crime.

FUTURE TRENDS

The field of graph-based relational learning is still young, but the need for practical algorithms is growing fast. Therefore, we need to address several challenging scalability issues, including incremental learning in dynamic graphs. Another issue regarding practical applications involves the blurring of positive and negative examples in a supervised learning task, that is, the graph has many positive and negative parts, not easily separated, and with varying degrees of class membership.

Partitioning and Incremental Mining for Scalability

Scaling GDM approaches to very large graphs, graphs too big to fit in main memory, is an ever-growing challenge. Two approaches to address this challenge are being investigated. One approach involves *partitioning* the graph into smaller graphs that can be processed in a distributed fashion (Cook et al., 2001). A second

approach involves implementing GDM within a relational database management system, taking advantage of user-defined functions and the optimized storage capabilities of the RDBMS.

A newer issue regarding scalability involves *dynamic graphs*. With the advent of real-time streaming data, many data mining systems must mine incrementally, rather than off-line from scratch. Many of the domains we wish to mine in graph form are dynamic domains. We do not have the time to periodically rebuild graphs of all the data to date and run a GDM system from scratch. We must develop methods to incrementally update the graph and the patterns currently prevalent in the graph. One approach is similar to the graph partitioning approach for distributed processing. New data can be stored in an increasing number of partitions. Information within partitions can be exchanged, or a repartitioning can be performed if the information loss exceeds some threshold. GDM can be used to search the new partitions, suggesting new subgraph patterns as they evaluate highly in new and old partitions.

Supervised Learning with Blurred Graphs

In a highly relational domain the positive and negative examples of a concept are not easily separated. Such a graph is called a *blurred graph*, in that the graph as a whole contains class information, but perhaps not individual components of the graph. This scenario presents a challenge to any data mining system, but especially to a GDM system, where clearly classified data may be tightly related to less classified data. Two approaches to this task are being investigated. The first involves modifying the MDL encoding to take into account the amount of information necessary to describe the class membership of compressed portions of the graph. The second approach involves treating the class membership of a vertex or edge as a cost and weighting the information-theoretic value of the subgraph patterns by the costs of the instances of the pattern. The ability to learn from blurred graphs will allow the user more flexibility in indicating class membership where known, and to varying degrees, without having to clearly separate the graph into disjoint examples.

CONCLUSION

Graph-based data mining (GDM) is a fast-growing field due to the increasing interest in mining the relational aspects of data. We have described several approaches to GDM including logic-based approaches in ILP systems, graph-based frequent subgraph mining approaches in AGM, FSG and gSpan, and a graph-based relational learning approach in Subdue. We described the Subdue approach in detail along with recent advances in supervised learning, clustering, and graph-grammar induction.

However, much work remains to be done. Because many of the graph-theoretic operations inherent in GDM are NP-complete or definitely not in P, scalability is a constant challenge. With the increased need for mining streaming data, the development of new methods for incremental learning from dynamic graphs is important. Also, the blurring of example boundaries in a supervised learning scenario gives rise to graphs, where the class membership of even nearby vertices and edges can vary considerably. We need to develop better methods for learning in these blurred graphs.

Finally, we discussed several domains throughout this paper that benefit from a graphical representation and the use of GDM to extract novel and useful patterns. As more and more domains realize the increased predictive power of patterns in relationships between entities, rather than just attributes of entities, graph-based data mining will become foundational to our ability to better understand the ever-increasing amount of data in our world.

KEY TERMS

Blurred Graph: Graph in which each vertex and edge can belong to multiple categories to varying degrees. Such a graph complicates the ability to clearly define transactions on which to perform data mining.

Conceptual Graph: Graph representation described by a precise semantics based on first-order logic.

Dynamic Graph: Graph representing a constantly-changing stream of data.

Frequent Subgraph Mining: Finding all subgraphs within a set of graph transactions whose frequency satisfies a user-specified level of minimum support.

Graph-based Data Mining: Finding novel, useful, and understandable graph-theoretic patterns in a graph representation of data.

Graph Grammar: Grammar describing the construction of a set of graphs, where terminals and non-terminals represent vertices, edges or entire subgraphs.

Inductive Logic Programming: Techniques for learning a first-order logic theory to describe a set of relational data.

Minimum Description Length (MDL) Principle: Principle stating that the best theory describing a set of data is the one minimizing the description length of the theory plus the description length of the data described (or compressed) by the theory.

Multi-Relational Data Mining: Mining patterns that involve multiple tables in a relational database.

Graphical Data Mining

Carol J. Romanowski
Rochester Institute of Technology, USA

INTRODUCTION

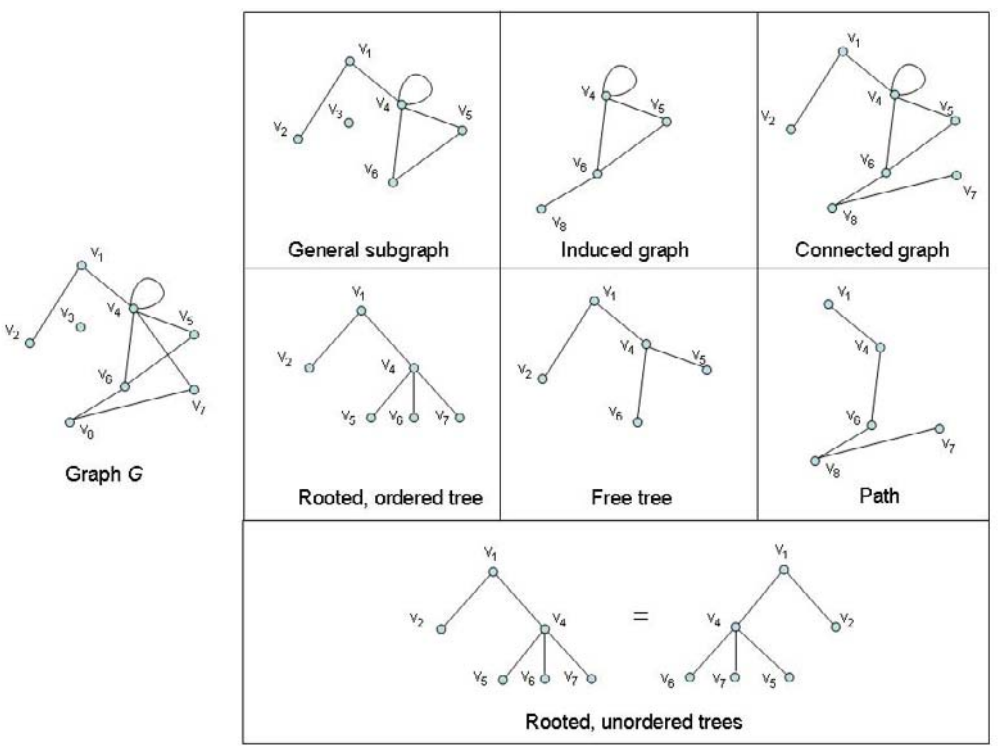
Data mining has grown to include many more data types than the "traditional" flat files with numeric or categorical attributes. Images, text, video, and the internet are now areas of burgeoning data mining research. Graphical data is also an area of interest, since data in many domains—such as engineering design, network intrusion detection, fraud detection, criminology, document analysis, pharmacology, and biochemistry—can be represented in this form.

Graph mining algorithms and methods are fewer and less mature than those designed for numerical or categorical data. In addition, the distinction between graph matching and graph mining is not always clear. In graph mining, we often want to find all possible frequent subgraphs of all possible sizes that occur a specified minimum number of times. That goal involves iteratively matching incrementally larger subgraphs, while classical graph matching is a single search for a static subgraph. Also, graph mining is an unsupervised learning task. Instead of searching for a single match to a specific graph, we are looking for known or unknown graphs embedded in the data.

BACKGROUND

A graph *G* is a structure that contains a set of vertices *V* and their incident edges *E* and comprises many

Figure 1. Graph structures



substructures (see Figure 1). A *general subgraph* is a subset of any vertices and edges in the parent graph. An *induced subgraph* contains a subset of the vertices and all edges between those vertices that exist in the parent graph. A *connected subgraph* is a subset of vertices that are connected with edges; no isolated vertices are allowed. *Trees* are acyclic, directed, branched subgraphs that can be ordered (the order of branch nodes is fixed) or unordered (the order of branch nodes is of no concern). Rooted trees have one vertex with no edges coming into it; all other vertices are reachable from the root, while free trees have no root. A *path* is a subgraph that has no branches.

The most common graph mining task is finding frequent subgraph structures within either a large, single graph or a database of smaller graphs (Washio & Motoda, 2003). Most methods for finding frequent subgraphs are based on the Apriori algorithm (Agrawal & Srikant, 1994) and involve four steps:

1. Starting with a defined smallest unit, generate increasingly larger subgraphs.
2. Check that the generated subgraphs appear in the database or graph.
3. Count the number of times each subgraph appears.
4. Discard subgraphs that are less frequent than the user-specified minimum, or *support*, thus avoiding investigation of their supergraphs. Also discard isomorphisms (subgraphs with identical vertices and edges).

Subgraph matching, or isomorphism testing, is thought to have no polynomial time algorithm for general graphs (Skiena, 1998). Graph mining algorithms attempt to reduce the computational load of this problem in many ways, all of which rely on the downward closure property (see step 4). This property states that a subgraph of a larger graph is more frequent than the larger graph; therefore, if a particular subgraph is infrequent, it is removed from the search space because further expansion would not yield a viable candidate. Another way to reduce search space is to restrict candidates to subgraphs with no common edges (Washio & Motoda, 2003).

MAIN FOCUS

The most basic difference among graph mining algorithms is whether the input data is a single graph or a database of smaller graphs. Algorithms written for a single graph input can be used on a database of smaller graphs, but the reverse is not true (Goethels et al., 2005). Most general graph and tree mining algorithms are frequent subgraph methods focused on a database of graphs, although the single graph approach is more versatile.

Within the main categories of single vs. database of graphs, these frequent subgraph methods are often very similar, and are mostly distinguished by the strategies for generating candidate subgraphs and reducing the support computation cost, by the method of graph matching employed, and by the basic substructure unit. Complete algorithms generate every possible candidate subgraph, while heuristic algorithms truncate the candidate generation stage.

Many of the complete methods such as AGM and AcGM (Inokuchi et al., 2000, 2003), FSG (Kuramochi & Karypis, 2004), GASTON (Nijssen & Kok, 2004) and algorithms proposed by Vanetik et al. (2004) and Inokuchi (2004) use the join method of Apriori to generate new candidate subgraphs. In this method, two graphs of size k with identical subgraphs of size k-1are joined together to form a graph of size k+1. For example, consider two connected graphs, each with k = 3 nodes. Graph A contains nodes {B, E, and K} while Graph B contains nodes {C, E, and K}. The new candidate graph would contain nodes {B, C, E, and K} and their incident edges.

Each of these algorithms uses a different substructure unit (either a vertex, edge, or combination of vertex and edge called a *leg*) to generate larger subgraphs. All take a database of graphs as input. GASTON is particularly notable because it can find frequent paths and free trees in addition to general subgraphs.

Some complete algorithms use pattern extension instead of join operations to generate candidate subgraphs. In this method, the new candidate graph is formed by extending a vertex or edge. Examples of these non-Apriori methods include gSpan (Yan et al., 2002) and its variants, CloseGraph (Yan et al., 2003) LCGMiner (Xu & Lei, 2004), ADI-Mine (Wang et al., 2004), and GraphMiner (Wang et al., 2005). Basically, these algorithms build spanning trees for each

graph, using a depth-first search, and order the trees lexicographically into a set of DFS codes. This process results in a hierarchical ordered search tree, over which the algorithm performs a depth first search for subgraph isomorphisms.

FFSM (Huan et al., 2003) is a non-Apriori-like algorithm that allows either the extension or join operations, attempting to increase the efficiency of candidate generation. SPIN (Huan et al., 2004) builds on FFSM, mining maximal frequent subgraphs by finding frequent trees in the graph, and constructing frequent subgraphs from the trees. The algorithm classifies the trees by using a canonical spanning tree as the template for an equivalence class. Pruning mechanisms remove all but the maximally frequent subgraphs. SPIN was designed for applications such as chemical compound analysis, in which frequent patterns are usually tree structures.

MoFa (Borgelt & Berthold, 2002) is a hybrid method that finds connected molecular fragments in a chemical compound database. In this algorithm, atoms are represented as vertices and bonds as edges. MoFa is based on the association mining algorithm *Eclat* rather than Apriori; this algorithm performs a depth first search, and extends the substructure by either a bond or an atom at each iteration.

Heuristic methods include the classic algorithm SUBDUE (Cook & Holder, 1994; Chakravarthy, et al., 2004), a system that uses minimum description length (MDL) to find common patterns that efficiently describe the graph. SUBDUE starts with unique vertex labels and incrementally builds substructures, calculating the MDL heuristic to determine if a substructure is a candidate for compression, and constraining the search space with a beam search. Subgraphs that efficiently compress the graph are replaced with a single vertex, and the discovery process is repeated. This procedure generates a hierarchy of substructures within the complete graph, and is capable of compressing the graph to a single vertex.

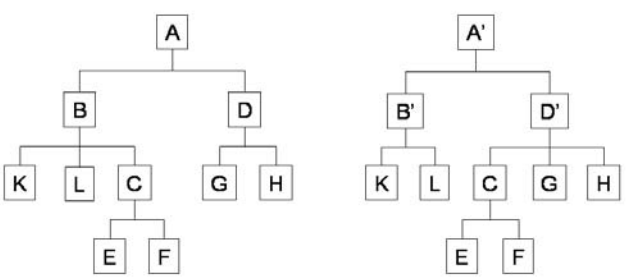
Meinl and Berthold (2004) combined MoFa and the Apriori-based approach FSG (Kuramochi & Karypis, 2003) to mine molecular fragments. The authors exploit the characteristics of the two algorithms; MoFa requires large amounts of memory in the beginning stages, while FSG's memory usage increases in the latter stages of the mining task. The search process begins with FSG and seeds MoFa with frequent subgraphs that reach a specified size. This approach requires a subgraph isomorphism test on new candidates to avoid reusing seeds.

The major mining task for tree-structured data is also frequent subgraph mining, using the same basic four steps as for general graphs. However, unlike the general graph case, polynomial-time subgraph isomorphism algorithms are possible for trees (Horvath et al., 2005; Valiente, 2002). Domains that benefit from frequent subtree mining include web usage (Cooley et al., 1997), bioinformatics (Zhang & Wang, 2006), XML document mining (Zaki & Aggarwal, 2003), and network routing (Cui et al., 2003).

Clustering Methods

Clustering methods find groups of similar subgraphs in a single graph, or similar graphs in a database of several graphs. These algorithms require a similarity

Figure 2. Two bills of materials



or distance table to determine cluster membership. Distance values can be calculated using Euclidean distance, the inner product of graph vectors, unit cost edit distance, or single-level subtree matching. Unit cost edit distance sums the number of unit cost operations needed to insert, delete, or substitute vertices, or change labels until two trees are isomorphic. This measure views the graph as a collection of paths and can also be applied to ordered or unordered trees. Single-level subtree matching (Romanowski & Nagi, 2005) decomposes a tree into subtrees consisting of a parent vertex and its immediate children. In Figure 2, single level subtrees are those rooted at B, D, C for the leftmost tree, and B', C, and D' for the rightmost tree. The algorithm finds the least cost weighted bipartite matchings between the subtrees and sums them to find the total distance between trees A and A'.

This distance measure can be used to cluster tree-based data in any domain where the path-based representation is not applicable, and where otherwise similar trees may have different topologies. Examples include documents, XML files, bills of material, or web pages.

Examples of graph or spatial clustering algorithms are CLARANS (Ng & Han, 1994), ANF (Palmer et al., 2002) and extensions of SUBDUE (Jonyer et al., 2000). Extensive work has been done on clustering in social networks; for an extensive survey, see (Chakrabarti & Faloutsos, 2006).

FUTURE TRENDS

Graph mining research continues to focus on reducing the search space for candidate subgraph generation, and on developing hybrid methods that exploit efficient operations at each stage of the frequent subgraph search. Approximate graph mining is another growing area of inquiry (Zhang et al., 2007).

Web and hypertext mining are also new areas of focus, using mainly visualization methods (e.g., Chen et al., 2004; Yousefi et al., 2004). Other interesting and related areas are link mining (Getoor, 2003), viral marketing (Richardson & Domingos, 2002), and multi-relational data mining (MRDM), which is mining from more than one data table at a time (Domingos, 2003; Dzeroski & DeRaedt, 2002, 2003; Holder & Cook, 2003; Pei et al, 2004).

Graph theory methods will increasingly be applied to non-graph data types, such as categorical datasets (Zaki et al., 2005), object oriented design systems (Zhang et al., 2004), and data matrices (Kuusik et al., 2004). Since tree isomorphism testing appears to be faster and more tractable than general graph isomorphism testing, researchers are transforming general graphs into tree structures to exploit the gain in computational efficiency.

Subgraph frequency calculations and graph matching methods, such as the tree similarity measure, will continue to be investigated and refined to reflect the needs of graph-based data (Vanetik et al., 2006; Romanowski et al., 2006). An additional area of study is how graphs change over time (Faloutsos et al., 2007).

CONCLUSION

Graph research has proliferated as more and more applications for graphically-based data are recognized. However, few current algorithms have been compared using identical datasets and test platforms (Wörlein et al., 2005). This omission makes it difficult to quantitatively evaluate algorithmic approaches to efficient subgraph isomorphism detection, candidate generation, and duplicate subgraph pruning.

Graph mining is an attractive and promising methodology for analyzing and learning from graphical data. The advantages of data mining—the ability to find patterns human eyes might miss, rapidly search through large amounts of data, discover new and unexpected knowledge—can generate major contributions to many different communities.

KEY TERMS

Acyclic Graph: A graph that does not contain a cycle, or a path from one vertex that ends up back at the same vertex.

Directed Graph: A graph in which pairs of vertices are connected with edges that have a single direction. Hence, if Vertex 1 is connected to Vertex 2 by a directed edge, then Vertex 1 is considered the parent of Vertex 2 and cannot be reached from Vertex 2 via that edge.

Lexicographic Order: Also called "dictionary order"; subgraphs can have many isomorphs, and ordering them allows the algorithm to choose the minimum lexicographic subgraph to represent all of a particular subgraph's isomorphs. Thus, the search space is reduced since an algorithm will not need to test multiple copies of the same subgraph.

Supergraph: A graph that contains one or more subgraphs. If subgraph *G'* is contained in graph *G*, then *G* is a supergraph of *G'*.

Support: In frequent subgraph mining, *support* is the number of times a particular subgraph pattern appears in a database of graphs. Users designate a minimum support value; subgraphs that occur fewer times than the minimum support are infrequent, and would not be used for further candidate subgraph generation.

Topology: The number and arrangement of vertices and edges in a graph.

Weighted Bipartite Matching: A method of pairwise matching of two sets of nodes or vertices, where edges between them carry weights. An example is the marriage problem, where one set represents the women and one set represents the men; the edges between them represent how much each person is attracted to the other, and the goal is to generate a set of pairs with the highest possible sum of the matched weights.

Guide Manifold Alignment by Relative Comparisons

INTRODUCTION

When we are faced with data, one common task is to learn the correspondence relationship between different data sets. More concretely, by learning data correspondence, samples that share similar intrinsic parameters, which are often hard to estimate directly, can be discovered. For example, given some face image data, an alignment algorithm is able to find images of two different persons with similar poses or expressions. We call this technique the alignment of data. Besides its usage in data analysis and visualization, this problem also has wide potential applications in various fields. For instance, in *facial expression recognition*, one may have a set of standard labeled images with known expressions, such as *happiness*, *sadness*, *surprise*, *anger and fear*, of a particular person. Then we can recognize the expressions of another person just by aligning his/her facial images to the standard image set. Its application can also be found directly in pose estimation. One can refer to (Ham, Lee & Saul, 2005) for more details.

Although intuitive, without any premise this alignment problem can be very difficult. Usually, the samples are distributed in high-dimensional observation spaces, and the relation between features and samples' intrinsic parameters can be too complex to be modeled explicitly. Therefore, some hypotheses about the data distribution are made. In the recent years, the manifold assumption of data distribution has been very popular in the field of data mining and machine learning. Researchers have realized that in many applications the samples of interest are actually confined to particular subspaces embedded in the high-dimensional feature space (Seung & Lee, 2000; Roweis & Saul, 2000). Intuitively, the manifold assumption means that certain groups of samples are lying in a non-linear low-dimensional subspace embedded in the observation space. This assumption has been verified to play an important role in human perception (Seung & Lee, 2000), and many effective algorithms are developed under it in the recent years. Under the manifold assumption, structural information of data can be utilized to facilitate the alignment. Figure 1 illustrates two 1-D manifolds embedded in a 2-D plane.

Besides, since we do not know the relationship between observations and the underlying parameters, additional supervisions are needed to guide the aligning process. Usually, we will require information about a subset of samples and the structure of the whole data set in order to infer about the rest of samples. Thus,

Figure 1. Two 1-D manifolds embedded in a 2-D plane

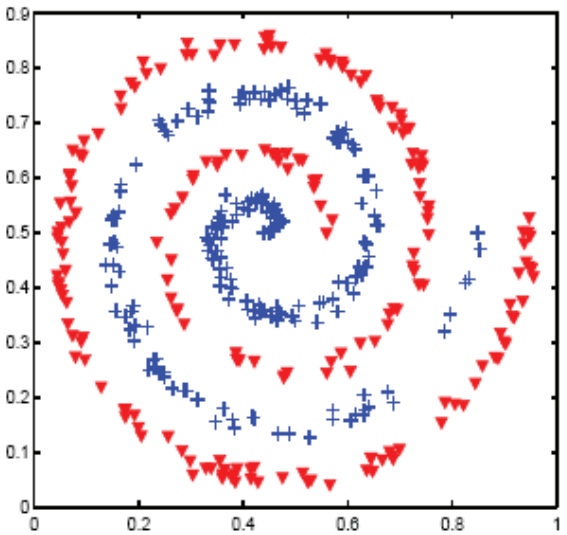

Figure 2. Guide the alignment of two manifolds by pairwise correspondence. A black line represents the supervision which indicates two samples with the same underlying parameters.

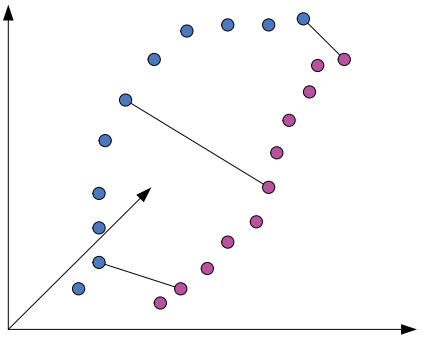


the alignment is often done in a semi-supervised way. The most common supervision used is pairwise correspondence, which specifies two samples that share the same parameters as shown in figure 2.

Take the facial expression alignment for example. In this task we are given face images of two different persons A and B, and the problem is to find two images, one of which is from A and the other is from B, with similar facial expression. Template matching in the feature space is not feasible here since different faces may have very different appearances. At present, directly estimating the expression parameters is also difficult because of the limitation of our knowledge and the variability of data. So we assume that images from the same person are lying on a low-dimensional manifold. Now the problem seems easier because we are now dealing with two structures, such as two curves, instead of discrete points. However, we still do not know how these two structures should be aligned. Then supervisions are needed to tell us how they correspond.

There have already been several methods proposed to align manifolds in a semi-supervised way (Ham, Ahn & Lee, 2006; Ham, Lee & Saul, 2003; Ham, Lee & Saul, 2005; Verbeek, Roweis & Vlassis, 2004; Verbeek & Vlassis, 2006). Specifically, they usually assumed that some pair-wise correspondences of samples in different data sets were already known, and then this information would be used to guide the alignment. However, in practice it might be difficult to obtain and use such information since:

1. The sizes of data sets can be very large, then finding high-quality correspondences between them can be very time consuming and even intractable.
2. There may be ambiguities in the images, which makes explicit matching a hard task. Brutally determine and enforce these unreliable constraints may lead to poor results;
3. Sometimes it may be hard to find the exact correspondences when the available samples are scarce. This situation may happen when the data source is restricted and users are only allowed to access a small subset.

To solve the above problems, we could apply another type of supervision to guide the process of manifold alignment. In particular, we consider a relative and qualitative supervision of the form "A is closer to B than A is to C". We believe that this type of information is more easily available in practice than traditional correspondence-based information. With the help of such information, we show that the manifold alignment problem can be formulated as a *Quadratically Constrained Quadratic Programming* (QCQP) (Boyd & Vandenberghe, 2004) problem. To make the optimization tractable, we further relax it to a *Semi-Definite Programming* (SDP) (Boyd & Vandenberghe, 2004) problem, which can be readily solved by popular optimization software packages. Besides, under this formulation we are able to incorporate both relative relations and correspondences to align manifolds in a very flexible way.

BACKGROUND

Before alignment, we need an infrastructure to capture the structure of each manifold. First, we will introduce manifold embedding.

The embedding algorithms find coordinates in a novel low-dimensional space for the data points so that certain geometric relations between them in the feature space are retained in the embedded space. Here we complete this task by graph regularization as in *Laplacian Eigenmaps* (Belkin & Niyogi, 2003). An undirected weighted graph is constructed over the data points to characterize their relations. Then this method aims at preserving the connectivity in this graph *i.e.* if two points are originally connected, then after embedding they are also connected; if two points

are close to each other in the feature space, then they will still be close in the embedded space.

The above problem is solved by using the Laplacian of graphs. More concretely, for data set $X = \{x_1, x_2, \cdots, x_N\} \subset R^{D_X}$, where D_X is the dimensionality of samples in X, we can construct a graph $G_X = (V_X, E_X)$, where $V_X = X$ corresponds to the nodes of G_X and E_X is the edge set in the graph. There is a non-negative weight w_{ij} associated with each edge $e_{ij} \in E_X$. When constructing the graph, we want to only capture local relations between data according to the traits of manifold. So k-nearest neighbor graphs are often used, in which only nearby nodes are connected. Plus, the edge weight w_{ij} are used to represent the similarity between nodes. If x_i and x_j are close to each other then w_{ij} is large, and vice versa. As for the calculation of edge weight w_{ij}, several methods have been proposed. Popular choices include the Gaussian kernel (Zhu, 2005) and LLE reconstruction (Roweis. & Saul, 2000; Wang & Zhang, 2006). Further discussion on this issue is beyond the scope of this chapter. Readers can refer to (Zhu, 2005) for more details. Here we assume that the edge weight is symmetric *i.e.* $w_{ij} = w_{ji}$, which means that the similarity from x_i to x_j is the same as that from x_j to x_i.

We collect all these edge weights to form an $N \times N$ weight matrix $\mathbf{W}_X$ with its entry $\mathbf{W}_X(i, j) = \mathbf{W}_{ij}$. The degree matrix $\mathbf{D}_X$ is an $N \times N$ diagonal matrix with its i-th diagonal entry $\mathbf{D}_X(i,i) = \sum_j w_{ij}$. Given $\mathbf{W}_X$ and $\mathbf{D}_X$, the combinatorial graph Laplacian is defined as

$$\mathbf{L}_X = \mathbf{D}_X - \mathbf{W}_X \tag{1}$$

Generally, the graph Laplacian can be used to enforce the smoothness constraint on a graph i.e. a manifold (Belkin & Niyogi, 2003), which means that the properties of nearby nodes should also be close. Suppose that there is a property function $p_i = (x_i)$ associated with each node, then the smoothness of p on the graph can be achieved by solving the following problem

$$p = \min_p S = \min_p p\mathbf{L}_X p^T \tag{2}$$

where $p = [p_1, p_2, \cdots, p_N]$. To see this, just consider the fact that

$$S = p\mathbf{L}_X p^T = \frac{1}{2}\sum_{i,j} w_{ij}(p_i - p_j)^2 \tag{3}$$

The same idea can be used to calculate the embedding of data by considering the embedded coordinates as the property function p in (2). Specifically, let $\mathbf{F} = [\mathbf{f}_1, \mathbf{f}_2, \cdots \mathbf{f}_N] \subset R^{d \times N}$ be the embedded coordinates of X, then $\mathbf{F}$ can be obtained by

$$\min_{\mathbf{F}} tr(\mathbf{F}\mathbf{L}_X\mathbf{F}^T) \tag{4}$$

where $tr(\cdot)$ means the trace of a matrix. By optimization (4) along with proper scale and translation invariance constraints, we can get a low-dimensional representation of X that preserves the underlying manifold structure.

MAIN FOCUS

Co-Embedding and Traditional Alignment

In the previous section, we showed how to calculate the embedding of a manifold. In essence, manifold alignment can also be seen as the embedding of manifolds. The difference is that in alignment, multiple manifolds have to be handled and their correspondence should be taken into consideration. Take the alignment of two manifolds X and Y for example, if we do not take account of correspondence, the embedding of these two manifolds can be obtained by *co-embedding*

$$\min_{\mathbf{F},\mathbf{G}} \left(tr(\mathbf{F}\mathbf{L}_X\mathbf{F}^T) + tr(\mathbf{G}\mathbf{L}_Y\mathbf{G}^T)\right)$$
$$s.t. \begin{cases} tr(\mathbf{F}\mathbf{F}^T) = tr(\mathbf{G}\mathbf{G}^T) = 1 \\ \mathbf{F}\mathbf{e} = 0, \mathbf{G}\mathbf{e} = 0 \end{cases} \tag{5}$$

where $\mathbf{F}$ and $\mathbf{G}$ are the embedded coordinates of X and Y respectively. The constraints are for scale and translation invariance, and $\mathbf{e}$ is an all-one column vector. These two constraints apply to all the optimization problems in the rest of this article, but for notational simplicity we will not write them explicit.

To achieve alignment, extra constraints or objective terms have to be appended to the co-embedding in (5). Traditional methods use pair-wise correspondence constraints to guide the alignment. Usually, a *fitting term* is added to the objective as (Ham, Lee & Saul, 2003; Ham, Lee & Saul, 2005; Verbeek, Roweis & Vlassis, 2004; Verbeek & Vlassis, 2006)

$$\min_{\mathbf{F},\mathbf{G}} \mu \sum_{i=1}^{c} \left\| \mathbf{f}_i - \mathbf{g}_i \right\| + tr(\mathbf{F}\mathbf{L}_X\mathbf{F}^T) + tr(\mathbf{G}\mathbf{L}_Y\mathbf{G}^T) \quad (6)$$

where μ is the parameter to control the tradeoff between the embedding smoothness and the match precision, while c is the number of given corresponding pairs. This formulation ensures that two indicated samples are close to each other in the embedded space.

Alignment Guided by Relative Comparison – A Quadratic Formulation

As we state in the introduction, pair-wise supervision for manifold alignment has some drawbacks for large data sets or when correspondence is not well defined. So we instead turned to use another type of guidance: relative comparison. Here, this guidance takes the form of "y_i is closer to x_j than x_k", notated by an ordered 3-tuple $t_c = \{y_i, x_j, x_k\}$. We translate t_c into the requirement that in the embedded space the distance between $\mathbf{g}_i$ and $\mathbf{f}_j$ is smaller than that between $\mathbf{g}_i$ and $\mathbf{f}_k$. More formally, t_c leads to the constraint

$$\left\| \mathbf{g}_i - \mathbf{f}_j \right\|^2 \le \left\| \mathbf{g}_i - \mathbf{f}_k \right\|^2 \quad (7)$$

Let $T = \{t_c\}^C_{c=1}$ denote the constraint set. Under these relative comparison constraints, our optimization problem can be formulated as

$$\min_{\mathbf{F},\mathbf{G}} tr(\mathbf{F}\mathbf{L}_X\mathbf{F}^T) + tr(\mathbf{G}\mathbf{L}_Y\mathbf{G}^T)$$
$$s.t. \begin{cases} \forall \{y_i, x_j, x_k\} \in T, \left\| \mathbf{g}_i - \mathbf{f}_j \right\|^2 \le \left\| \mathbf{g}_i - \mathbf{f}_k \right\|^2 \end{cases} \quad (8)$$

Let $\mathbf{H} = [\mathbf{F}, \mathbf{G}]$, $\mathbf{L} = \begin{bmatrix} \mathbf{L}_X & \\ & \mathbf{L}_Y \end{bmatrix}$, we can further simplify the problem to

$$\min_{\mathbf{H}} tr(\mathbf{H}\mathbf{L}\mathbf{H}^T)$$
$$s.t. \begin{cases} \forall \{y_i, x_j, x_k\} \in T, \left\| \mathbf{h}_{i+N} - \mathbf{h}_j \right\|^2 \le \left\| \mathbf{h}_{i+N} - \mathbf{h}_k \right\|^2 \end{cases} \quad (9)$$

Now we have formulated our tuple-constrained optimization as a *Quadratically Constrained Quadratic Programming* (QCQP) (Boyd & Vandenberghe, 2004) problem. However, since the relative comparison constraints are not *convex*, then 1) the solution is computationally difficult to derive and 2) the solution can be trapped in local minima. Therefore, a re-formulation is needed to make it tractable.

Alignment Guided by Relative Comparison – A Semi-definite Formulation

In this section we show how to convert the QCQP problem in the pervious section to a *Semi-Definite Programming* (SDP) (Boyd & Vandenberghe, 2004) problem. This conversion is motivated by the quadratic form of (9) and its relationship to the kernel matrix of data. The kernel matrix is defined as $\mathbf{K} = \mathbf{H}^T\mathbf{H}$ with its element $\mathbf{K}(i, j) = \mathbf{h}_i^T \mathbf{h}_j$. By some simple algebraic manipulations, problem (9) can be fully formulated in terms of $\mathbf{K}$. For notational simplicity, we divided $\mathbf{K}$ into four blocks as:

$$\mathbf{K} = \begin{bmatrix} \mathbf{F}^T\mathbf{F} & \mathbf{F}^T\mathbf{G} \\ \mathbf{G}^T\mathbf{F} & \mathbf{G}^T\mathbf{G} \end{bmatrix} = \begin{bmatrix} \mathbf{K}^{FF} & \mathbf{K}^{FG} \\ \mathbf{K}^{GF} & \mathbf{K}^{GG} \end{bmatrix}.$$

The objective function is

$$tr(\mathbf{H}\mathbf{L}\mathbf{H}^T) = tr(\mathbf{L}\mathbf{H}^T\mathbf{H}) = tr(\mathbf{L}\mathbf{K}) \quad (10)$$

The relative comparison constraints are

$$\begin{aligned} &\left\| \mathbf{h}_{i+N} - \mathbf{h}_j \right\|^2 \le \left\| \mathbf{h}_{i+N} - \mathbf{h}_k \right\|^2 \\ &\Leftrightarrow -2\mathbf{h}_{i+N}^T\mathbf{h}_j + 2\mathbf{h}_{i+N}^T\mathbf{h}_k + \mathbf{h}_j^T\mathbf{h}_j - \mathbf{h}_k^T\mathbf{h}_k \le 0 \\ &\Leftrightarrow -2\mathbf{K}_{i+N,j} + 2\mathbf{K}_{i+N,k} + \mathbf{K}_{j,j} - \mathbf{K}_{k,k} \le 0 \end{aligned} \quad (11)$$

The scale invariance constraints are

$$\begin{aligned} &tr(\mathbf{F}\mathbf{F}^T) = tr(\mathbf{K}^{FF}) = 1 \\ &tr(\mathbf{G}\mathbf{G}^T) = tr(\mathbf{K}^{GG}) = 1 \end{aligned} \quad (12)$$

The translation invariance is achieved by constraints

$$\sum_{i,j} K_{i,j}^{FF} = 0, \sum_{i,j} K_{i,j}^{GG} = 0 \quad (13)$$

Finally, to be a valid kernel matrix, $\mathbf{K}$ must be positive semi-definite, resulting that

$$\mathbf{K} \succeq 0 \quad (14)$$

Combining (10) to (14), the new optimization problem is derived as

$$\min_{\mathbf{K}} tr(\mathbf{LK})$$
$$s.t.\begin{cases}\forall\{y_i,x_j,x_k\}\in T,-2\mathbf{K}_{i+N,j}+2\mathbf{K}_{i+N,k}+\mathbf{K}_{j,j}-\mathbf{K}_{k,k}\le 0\\ \mathbf{K}\succeq 0\end{cases}$$

Moreover, to avoid the case of empty feasible set and to encourage the influence of the guidance information, we introduce slack variables $E = \{\varepsilon_c\}^C_{c=1}$ and relax the problem as follows

$$\min_{\mathbf{K},E} tr(\mathbf{LK})+\alpha\sum_{c=1}^{C}\varepsilon_c$$
$$s.t.\begin{cases}\forall\{y_i,x_j,x_k\}\in T,-2\mathbf{K}_{i+N,j}+2\mathbf{K}_{i+N,k}+\mathbf{K}_{j,j}-\mathbf{K}_{k,k}\le 0\\ \mathbf{K}\succeq 0\\ \forall\varepsilon_c\in E,\varepsilon_c\le 0\end{cases}$$
(11)

where α is a parameter to balance the data's inherent structure and the supervised information. When α is small, the embedding is dominated by the manifold structure; otherwise, the prior knowledge (i.e. the supervision plays a more important role).

Problem (16) is a standard SDP problem which can be readily solved by optimization software packages such as SeDuMi (Sturm, 1999). Therefore, the above aligning algorithm is called Semi-Definite Manifold Alignment (SDMA). When the kernel matrix **K** is solved, the embedded coordinates **F** and **G** can be recovered from **K**'s dominant eigenvectors as in kernel PCA (Schölkopf, Smola & Müller, 1998). Then, corresponding sample pairs can be obtained by either finding nearest neighbor or minimizing the total matching cost. More details about this method can be found in (Xiong, Wang & Zhang, 2007). An experimental result of aligning head poses by SDMA is illustrated in figure 3.

FUTURE TRENDS

One common footstone of manifold learning methods is the characterization of data's underlying manifold structure, which is the focus of manifold embedding algorithms. This is also true for manifold alignment. The more accurate manifolds are captured, the better the alignment will be. Thus alignment algorithms should be updated with the emergence of new embedding methods. In SDMA, we choose to use the graph regularization method. Recently, (Weinberger & Saul, 2006; Weinberger, Sha & Saul, 2004) proposed to achieve this goal by preserving the local isometry of data. This new infrastructure can also be integrated with SDMA to improve its performance.

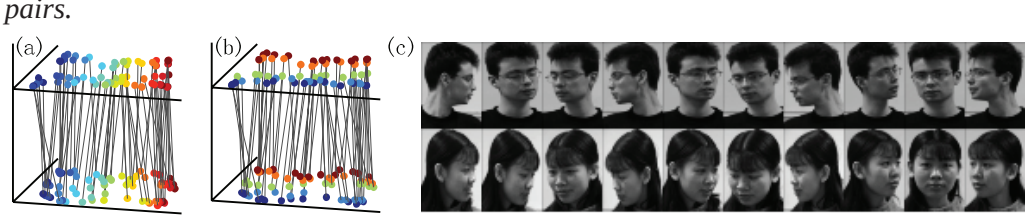
Another important aspect of manifold alignment is how to guide the process of finding correspondences. Traditional pair-wise constraints may not be suitable for some large data sets. SDMA provides a more flexible alternative. In the future, more forms of supervision should be developed to achieve superior performance and wider applicability.

To be a practical utility for data mining, the most important improvement needed for SDMA and other alignment algorithms are their speed and storage efficiencies. Currently, these methods rely on standard optimization routines and are often not directly applicable to large data sets. In general, this issue will benefit from the development of more efficient numeric optimization algorithms and careful algorithm design with respect to specific data sets.

CONCLUSION

Finding correspondences between different data set is an intuitive, useful, yet difficult problem. However, it

Figure 3. Alignment of head pose images. (a) and (b) shows the embedding by SDMA and the correspondences found. Points are colored according to horizontal angles in (a) and vertical angles in (b). (c) shows some samples of matched pairs.



can be made tractable by utilizing the manifold structure of data. Further, some human supervision can be incorporated to guide how two manifolds can be aligned. These two steps consists of the main component of a align algorithm. To achieve maximum flexibility, *Semi-Definite Manifold Alignment* (SDMA) chooses to guide the alignment by relative comparisons in the form of "A is closer to B than A is to C", in contrast to traditional methods that uses pairwise correspondences as supervision. This new type of constraint is well defined on many data sets and very easy to obtain. Therefore, its potential usage is very wide.

KEY TERMS

Convex Optimization: An optimization problem which consists of an objective function, inequality constraints, and equality constraints. The objective and the inequality constraints must be convex, and the equality constraint must be affine. In convex optimization, any locally optimal solution is also globally optimal.

Kernel Matrix: A square matrix that represents all the pairwise similarities within a set of vectors. When the similarity is measured by inner product, the kernel matrix is also the Gram matrix of data.

Manifold: A topological space which is locally Euclidean, i.e., "flat" in a small neighborhood.

Manifold Alignment: A special case of manifold embedding. The difference is that multiple manifolds are handled and in the embedded space correspond points from different manifolds are close to each other.

Manifold Embedding: A technique to represent manifolds in a certain space, which is usually more perceivable to human, while keeping the manifold's geometric or algebraic properties preserved.

Semi-Definite Programming (SDP): An optimization technique that deals with problems over symmetric positive semi-definite matrix. Its objective and the constraints are both linear.

Semi-Supervised Learning: A class of machine learning methods. In contrast to traditional supervised learning which relies solely on labeled data, semi-supervised learning incorporates unlabeled data in the learning process as well.

Guided Sequence Alignment

Abdullah N. Arslan
University of Vermont, USA

INTRODUCTION

Sequence alignment is one of the most fundamental problems in computational biology. Ordinarily, the problem aims to align symbols of given sequences in a way to optimize similarity score. This score is computed using a given scoring matrix that assigns a score to every pair of symbols in an alignment. The expectation is that scoring matrices perform well for alignments of all sequences. However, it has been shown that this is not always true although scoring matrices are derived from known similarities. Biological sequences share common sequence structures that are signatures of common functions, or evolutionary relatedness. The alignment process should be guided by constraining the desired alignments to contain these structures even though this does not always yield optimal scores. Changes in biological sequences occur over the course of millions of years, and in ways, and orders we do not completely know. Sequence alignment has become a dynamic area where new knowledge is acquired, new common structures are extracted from sequences, and these yield more sophisticated alignment methods, which in turn yield more knowledge. This feedback loop is essential for this inherently difficult task.

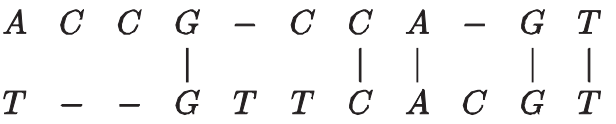
The ordinary definition of sequence alignment does not always reveal biologically accurate similarities. To overcome this, there have been attempts that redefined sequence similarity. Huang (1994) proposed an optimization problem in which close matches are rewarded more favorably than the same number of isolated matches. Zhang, Berman & Miller (1998) proposed an algorithm that finds alignments free of low scoring regions. Arslan, Eğecioğlu, & Pevzner (2001) proposed length-normalized local sequence alignment for which the objective is to find subsequences that yield maximum length-normalized score where the length-normalized score of a given alignment is its score divided by sum of subsequence-lengths involved in the alignment. This can be considered as a context-dependent sequence alignment where a high degree of local similarity defines a context. Arslan, Eğecioğlu, & Pevzner (2001) presented a fractional programming algorithm for the resulting problem. Although these attempts are important, some biologically meaningful alignments can contain *motif*s whose inclusions are not guaranteed in the alignments returned by these methods. Our emphasis in this chapter is on methods that guide sequence alignment by requiring desired alignments to contain given common structures identified in sequences (motifs).

BACKGROUND

Given two strings S_1, and S_2, the *pairwise sequence alignment* can be described as a writing scheme such that we use a two-row-matrix in which the first row is used for the symbols of S_1, and the second row is used for those of S_2, and each symbol of one string can be aligned to (i.e. it appears on the same column with) a symbol of the other string, or the blank symbol ´-´. A matrix obtained this way is called an alignment matrix. No column can be entirely composed of blank symbols. Each column has a weight. The score of an alignment is the total score of the columns in the corresponding alignment matrix. Fig. 1 illustrates an example alignment between two strings ACCGCCAGT and TGTTCACGT.

The following is the Needleman-Wunsch global alignment formulation (Durbin et al., 1998) that, for two given strings $S_1[1] \ldots S_1[n]$ and $S_2[1] \ldots S_2[m]$, computes

Figure 1. An example alignment with five matches



$$H_{i,j} = \max\{ H_{i-1,j}+\gamma(S_1[i],'-'),\ H_{i-1,j-1}+\gamma(S_1[i],S_2[j]),\ H_{i,j-1}+\gamma('-',S_2[j]) \} \quad (1)$$

for all $i, j,\ 1 \le i \le n,\ 1 \le j \le m$, with the boundary values $H_{0,0} = 0$, $H_{0,j} = H_{0,j-1} + \gamma('-',S_2[j])$, and $H_{i,0} = H_{i-1,0} + \gamma(S1[i], '-')$ where γ is a given score function. Then $H_{n,m}$ is the maximum global alignment score between S_1 and S_2. For the strings in Fig. 1, if $\gamma(x,y)$=1 when x=y, and 0 otherwise, then the maximum alignment score *is* $H_{9,9}$=5. The figure shows an optimal alignment matrix with 5 matches each indicated by a vertical line segment. The well-known Smith-Waterman local alignment algorithm (Durbin et al., 1998) modifies Equation (1) by adding 0 as a new max-term. This means that a new local alignment can start at any position in the alignment matrix if a positive score cannot be obtained by local alignments that start before this position. For the example strings in Fig. 1, if the score of a match is +1, and each of all other scores is -1, then the optimum local alignment score is 3, and it is obtained between the suffixes CAGT, and CACGT of the two strings, respectively.

The definition of pairwise sequence alignment for a pair of sequences can be generalized to the *multiple sequence alignment* problem (Durbin et al., 1998). A multiple sequence alignment of k sequences involves a k-row alignment matrix, and there are various scoring schemes (e.g. sum of pairwise distances) assigning a weight to each column.

Similarity measures based on computed scores only does not always reveal biologically relevant similarities (Comet & Henry, 2002). Some important local similarities can be overshadowed by other alignments (Zhang, Berman & Miller, 1998). A biologically meaningful alignment should include a region in it where common sequence structures (if they exist) are aligned together although this would not always yield higher scores. It has also been noted that biologists favor integrating their knowledge about common patterns, or structures into the alignment process to obtain biologically more meaningful similarities (Tang et al., 2002; Comet & Henry, 2002). For example, when comparing two protein sequences it may be important to take into account a common specific or putative structure which can be described as a subsequence. This gave rise to a number of constrained sequence alignment problems. Tang et al. (2002) introduced the *constrained multiple sequence alignment* (CMSA) problem where the constraint for the desired alignment(s) is inclusion of a given subsequence. This problem and its variations have been studied in the literature, and different algorithms have been proposed (e.g. He, Arslan, & Ling, 2006; Chin et al., 2003).

Arslan and Eğecioğlu (2005) suggested that the constraint could be inclusion of a subsequence within a given edit distance (number of edit operations to change one string to another). They presented an algorithm for the resulting constrained problem. This was a step toward allowing in the constraint patterns that may slightly differ in each sequence.

Arslan (2007) introduced the *regular expression constrained sequence alignment* (RECSA) problem in which alignments are required to contain a given common sequence described by a given regular expression, and he presented an algorithm for it.

MAIN FOCUS

Biologists prefer to incorporate their knowledge into the alignment process by guiding alignments to contain known sequence structures. We focus on motifs that are described as a subsequence, or a regular expression, and their use in guiding sequence alignment.

Subsequence Motif

The constraint for the alignments sought can be inclusion of a given pattern string as a subsequence. A motivation for this case comes from the alignment of RNase (a special group of enzymes) sequences. Such sequences are all known to contain "HKH'' as a substring. Therefore, it is natural to expect that in an alignment of RNase sequences, each of the symbols in "HKH'' should be aligned in the same column, i.e. an alignment sought satisfies the constraint described by the sequence "HKH". The alignment shown in Fig. 1 satisfies the constraint for the subsequence pattern "CAGT".

Chin et al. (2003) present an algorithm for the constrained multiple sequence alignment (CMSA) problem. Let S_1, S_2, ..., S_n be given n sequences to be aligned, and let $P[1..r]$ be a given pattern constraining the alignments. The algorithm modifies the dynamic-programming solution of the ordinary multiple sequence alignment (MSA). It adds a new dimension of size $r+1$ such that each position k, $0 \le k \le r$, on this dimension can be considered as a layer that corresponds to the ordi-

nary MSA matrix for sequences S_1, S_2, ..., S_n. The case when k=0 is the ordinary MSA. Alignments at layer k satisfy the constraint for the pattern sequence $P[1..k]$. An optimum alignment is obtained at layer $k=r$ in $O(2^n s_1 s_2 \ldots s_n)$ time.

There are several improved sequential and parallel algorithms for the CMSA problem (e.g. He, Arslan, & Ling, 2006).

Regular Expression Motif

The constraint for the sequence alignment problem can also be a regular expression. Arslan (2007) introduced the regular expression constrained sequence alignment (RECSA) as the following problem: given strings S_1, S_2, and a regular expression R, find the maximum alignment score between S_1 and S_2 over all alignments that satisfy a given regular expression constraint described by R. An alignment satisfies the constraint if it includes a segment in which a substring s_1 of S_1 is aligned to a substring s_2 of S_2, and both s_1 and s_2 match R. We can verify that the alignment in Fig. 1 satisfies the constraint if the given regular expression is $R=G(\epsilon+\Sigma)\Sigma CT$ where ϵ denotes the null-string, and Σ denotes the alphabet over which sequences are defined. This alignment includes a region where the substring GCCA of S_1 is aligned to substring GTTCA of S_2, and both substrings match R.

Considering common structures is especially important in aligning protein sequences. Family of protein sequences include conserved regions (motifs) which are associated with particular functions. Typically, motifs span 10 to 30 symbols where each symbol represents one of the 20 amino acids. These motifs are described in PROSITE format (http://www.expasy.org/txt/prosuser.txt). For example, in PROSITE, the famous P-loop motif (PS00017) is represented as *[GA]-X(4)-G-K-[ST]*, which means that the first position of the motif can be occupied by the symbol A or G, the second, third, fourth, and fifth positions can be occupied by any symbol (*X(4)* denotes four consecutive wildcards each of which matches all symbols), and the sixth and seventh positions have to be G and L, respectively, followed by either S or T.

Arslan (2007) presents an algorithm for the RECSA problem. He constructs a nondeterministic finite automaton M from a given motif, and modifies the underlying dynamic programming solution for the sequence alignment problem so that instead of optimal scores, optimal weights for states in M are computed. Arslan's algorithm runs in $O(t^4nm)$ time where t is the number of states in a nondeterministic finite automaton recognizing the given motif, and n and m are the lengths of the sequences aligned. Chung, Lu, & Tang (2007) present a faster, $O(t^3nm)$ time, algorithm for the problem. They also give a $O(t^2 \log t\, n)$-time algorithm when $t = O(\log n)$ where n is the common length of the sequences aligned.

FUTURE TRENDS

Using regular expression motifs in guiding alignments gives rise to several computationally challenging problems attracting further research. The regular expression constrained sequence alignment problem for multiple sequences is computationally expensive. There have been several attempts to solve this problem using various methods. Chung et al. (2007) uses the *progressive sequence alignment* technique (Durbin et al., 1998) for this case. Progressive alignment algorithms for the constrained sequence alignment problem when the constraint is inclusion of a subsequence were proposed earlier (e.g. Tang et al., 2002). Progressive alignment is an approximation for the original problem. It first picks a pair of sequences, and aligns them. Then, a third sequence is chosen and aligned to the first alignment. This process continues until all sequences are aligned.

Another interesting variation of the regular expression constrained sequence alignment problem is the case when motifs are not readily given but they are any in PROSITE database, or when sequences share multiple motifs that may appear in any order. There are several algorithms addressing these cases (e.g. Arslan, 2007).

Comparing complex molecules such as RNA is a very involved process in which we need to take into account the physical structures of the molecules. There are many proposed models for RNA sequence, and structure comparisons. A comprehensive summary of these techniques is given in Chapter 4 of Wang et al. (2005).

Many interesting RNA molecules conserve a secondary structure of base-pairing interactions more than they conserve their sequences. These base-pairing interactions can be described by a *context free grammar*. *Stochastic context free grammars* (SCFG)s have been used in the description of RNA secondary structures

(Durbin et al., 1998). An SCFG is a CFG where productions have probabilities. There are many SCFG-based methods (Durbin et al., 1998). For example, Dowell and Eddy (2006) use pair stochastic context-free grammars, *pairSCFGs*, for pairwise structural alignment of RNA sequences with the constraint that the structures are confidently aligned at positions (pins) which are known a priori. Dowell and Eddy (2006) assume a general SCFG that works well for all RNA sequences.

Arslan (2007) considers RNA sequence alignment guided by motifs described by CFGs, and presents a method that assumes a known database of motifs each of which is represented by a context free grammar. This method proposes a dynamic programming solution that finds the maximum score obtained by an alignment that is composed of pairwise *motif-matching regions*, and ordinary pairwise sequence alignments of non-motif-matching regions. A motif-matching region is a pair *(x,y)* of regions *x*, and *y*, respectively, in the given two sequences aligned such that both *x* and *y* are generated by the same CFG *G* in the given database. Each such pair *(x,y)* has a score assigned to that *G* (if there are multiple such CFG's, then the maximum score over all such G's is taken). The main advantage of this approach over the existing CFG (or SCFG)-based algorithms is that when we guide alignments by given motifs, base-pairing positions are not fixed in any of the sequences; there may be many candidate pairwise matches for common (sub)structures (determined by a given set of motifs) in both sequences, and there may be in various possible orders; one that yields the optimum score is chosen.

We project that with the increasing amount of raw biological data, the databases that store common structures will also grow rapidly. Sequence alignments, and discovering common sequence structures from sequences will go hand-in-hand affecting one another. We have witnessed this trend already. The notion of motif was first explicitly introduced by Russell Doolittle (1981). Discovery of sequence motifs has continued at a steady rate, and the motifs, in the form of amino acid patterns, were incorporated by Amos Bairoch in the PROSITE database (http://www.expasy.org/prosite). For many years, PROSITE (Falquet et al., 2002) has been a collection of thousands of sequence motifs. Now, this knowledge is used in regular expression constrained sequence alignments. A similar trend can be seen for the discovery of structural motifs identifiable in sequences. A large number of RNA motifs that bind proteins are already known (Burd and Dreyfus, 1994). New motifs continue to be discovered (Klein et al., 2001). Motifs that can be identified in sequences will be very helpful in guiding sequence alignment.

There are several topics that we did not cover in this chapter. Protein sequence motifs can also be described by a matrix in which each entry gives the probability of a given symbol appearing in a given position. We note that this definition can also be used to describe a constraint in sequence alignment.

Motif discovery is a very important area outside the scope of this chapter. We direct the reader to Wang et al. (2005) (Section 2.4) for a list of techniques on motif discovery, and Lu, R., Jia, C., Zhang S., Chen L., & Zhang, H. (2007) for a recent paper.

We think that the following are important future computational challenges in aligning sequences under the guidance of motifs:

- developing new representations for complex common structures (motifs),
- discovering new motifs from sequences, and building databases out of them,
- using known motif databases to guide alignments when multiple motifs are shared (in various possible orders) in sequences aligned.

CONCLUSION

Knowledge discovery from sequences yields better sequence alignment tools that use this knowledge in guiding the sequence alignment process. Better sequence alignments in turn yield more knowledge that can be fed into this loop. Sequence alignment has become an increasingly more knowledge-guided optimization problem.

KEY TERMS

Biological Sequences: DNA, and RNA sequences are strings of 4 nucleotides. Protein sequences are strings of 20 amino acids.

Constrained Sequence Alignment: Sequence alignment constrained to contain a given pattern. The pattern can be described in various ways. For example, it can be a string that will be contained as a subsequence, or a regular expression.

Context-Free Grammar: A 4-tuple (V,Σ,R,S) where V is a finite set of variables, Σ is a finite set of terminals disjoint from V, S in V is the start variable, and R is the set of rules of the for $A \rightarrow w$ where A is in

V, and *w* is in $(V \cup T)^*$, i.e. *w* is a string of variables and terminals.

Motif: A biological pattern in sequences that indicates evolutionary relatedness, or common function.

PROSITE Pattern: A regular expression-like pattern with two main differences from an ordinary regular expression: it does not contain the Kleene Closure *, and *X(i,j)* is used to denote wildcards whose lengths vary between *i, j*. Every PROSITE pattern can be converted to an equivalent regular expression.

Regular Expression: A null-string, a single symbol, or an empty set, or recursively defined as follows: if *R* is a regular expression so is *R**, and if *R* and *S* are regular expressions then so are *(R U S)*, and *RS*.

Scoring Matrix: A substitution matrix that assigns to every pair of amino acids a similarity score. There are several such matrices, e.g. PAM, BLOSUM.

Sequence Alignment: A scheme for writing sequences one under another to maximize the total column scores.

Subsequence of String *S*. A string that is obtained from *S* after deleting symbols from *S*.

Stochastic Grammar: A grammar whose rules have associated probabilities.

Hierarchical Document Clustering

INTRODUCTION

Document clustering is an automatic grouping of text documents into clusters so that documents within a cluster have high similarity in comparison to one another, but are dissimilar to documents in other clusters. Unlike document classification (Wang, Zhou, & He, 2001), no labeled documents are provided in clustering; hence, clustering is also known as unsupervised learning. Hierarchical document clustering organizes clusters into a tree or a hierarchy that facilitates browsing. The parent-child relationship among the nodes in the tree can be viewed as a topic-subtopic relationship in a subject hierarchy such as the Yahoo! directory.

This chapter discusses several special challenges in hierarchical document clustering: high dimensionality, high volume of data, ease of browsing, and meaningful cluster labels. State-of-the-art document clustering algorithms are reviewed: the partitioning method (Steinbach, Karypis, & Kumar, 2000), agglomerative and divisive hierarchical clustering (Kaufman & Rousseeuw, 1990), and frequent itemset-based hierarchical clustering (Fung, Wang, & Ester, 2003). The last one, which was developed by the authors, is further elaborated since it has been specially designed to address the hierarchical document clustering problem.

BACKGROUND

Document clustering is widely applicable in areas such as search engines, web mining, information retrieval, and topological analysis. Most document clustering methods perform several preprocessing steps including stop words removal and stemming on the document set. Each document is represented by a vector of frequencies of remaining terms within the document. Some document clustering algorithms employ an extra preprocessing step that divides the actual term frequency by the overall frequency of the term in the entire document set. The idea is that if a term is too common across different documents, it has little discriminating power (Rijsbergen, 1979). Although many clustering algorithms have been proposed in the literature, most of them do not satisfy the special requirements for clustering documents:

- **High dimensionality.** The number of relevant terms in a document set is typically in the order of thousands, if not tens of thousands. Each of these terms constitutes a dimension in a document vector. Natural clusters usually do not exist in the full dimensional space, but in the subspace formed by a set of correlated dimensions. Locating clusters in subspaces can be challenging.
- **Scalability.** Real world data sets may contain hundreds of thousands of documents. Many clustering algorithms work fine on small data sets, but fail to handle large data sets efficiently.
- **Accuracy.** A good clustering solution should have high intra-cluster similarity and low inter-cluster similarity, i.e., documents within the same cluster should be similar but are dissimilar to documents in other clusters. An external evaluation method, the F-measure (Rijsbergen, 1979), is commonly used for examining the accuracy of a clustering algorithm.
- **Easy to browse with meaningful cluster description.** The resulting topic hierarchy should provide a sensible structure, together with meaningful cluster descriptions, to support interactive browsing.
- **Prior domain knowledge.** Many clustering algorithms require the user to specify some input

parameters, e.g., the number of clusters. However, the user often does not have such prior domain knowledge. Clustering accuracy may degrade drastically if an algorithm is too sensitive to these input parameters.

MAIN FOCUS

Hierarchical Clustering Methods

One popular approach in document clustering is agglomerative hierarchical clustering (Kaufman & Rousseeuw, 1990). Algorithms in this family build the hierarchy bottom-up by iteratively computing the similarity between all pairs of clusters and then merging the most similar pair. Different variations may employ different similarity measuring schemes (Zhao & Karypis, 2001; Karypis, 2003). Steinbach (2000) shows that Unweighted Pair Group Method with Arithmatic Mean (UPGMA) (Kaufman & Rousseeuw, 1990) is the most accurate one in its category. The hierarchy can also be built top-down which is known as the divisive approach. It starts with all the data objects in the same cluster and iteratively splits a cluster into smaller clusters until a certain termination condition is fulfilled.

Methods in this category usually suffer from their inability to perform adjustment once a merge or split has been performed. This inflexibility often lowers the clustering accuracy. Furthermore, due to the complexity of computing the similarity between every pair of clusters, UPGMA is not scalable for handling large data sets in document clustering as experimentally demonstrated in (Fung, Wang, & Ester, 2003).

Partitioning Clustering Methods

K-means and its variants (Larsen & Aone, 1999; Kaufman & Rousseeuw, 1990; Cutting, Karger, Pedersen, & Tukey, 1992) represent the category of partitioning clustering algorithms that create a flat, non-hierarchical clustering consisting of k clusters. The k-means algorithm iteratively refines a randomly chosen set of k initial centroids, minimizing the average distance (i.e., maximizing the similarity) of documents to their closest (most similar) centroid. The bisecting k-means algorithm first selects a cluster to split, and then employs basic k-means to create two sub-clusters, repeating these two steps until the desired number k of clusters is reached. Steinbach (2000) shows that the bisecting k-means algorithm outperforms basic k-means as well as agglomerative hierarchical clustering in terms of accuracy and efficiency (Zhao & Karypis, 2002).

Both the basic and the bisecting k-means algorithms are relatively efficient and scalable, and their complexity is linear to the number of documents. As they are easy to implement, they are widely used in different clustering applications. A major disadvantage of k-means, however, is that an incorrect estimation of the input parameter, the number of clusters, may lead to poor clustering accuracy. Also, the k-means algorithm is not suitable for discovering clusters of largely varying sizes, a common scenario in document clustering. Furthermore, it is sensitive to noise that may have a significant influence on the cluster centroid, which in turn lowers the clustering accuracy. The k-medoids algorithm (Kaufman & Rousseeuw, 1990; Krishnapuram, Joshi, & Yi, 1999) was proposed to address the noise problem, but this algorithm is computationally much more expensive and does not scale well to large document sets.

Frequent Itemset-Based Methods

Wang et al. (1999) introduced a new criterion for clustering transactions using frequent itemsets. The intuition of this criterion is that many frequent items should be shared within a cluster while different clusters should have more or less different frequent items. By treating a document as a transaction and a term as an item, this method can be applied to document clustering; however, the method does not create a hierarchy of clusters.

The Hierarchical Frequent Term-based Clustering (HFTC) method proposed by (Beil, Ester, & Xu, 2002) attempts to address the special requirements in document clustering using the notion of frequent itemsets. HFTC greedily selects the next frequent itemset, which represents the next cluster, minimizing the overlap of clusters in terms of shared documents. The clustering result depends on the order of selected itemsets, which in turn depends on the greedy heuristic used. Although HFTC is comparable to bisecting k-means in terms of clustering accuracy, experiments show that HFTC is not scalable (Fung, Wang, Ester, 2003).

A Scalable Algorithm for Hierarchical Document Clustering: FIHC

A scalable document clustering algorithm, Frequent Itemset-based Hierarchical Clustering (FIHC) (Fung, Wang, & Ester, 2003), is discussed in greater detail because this method satisfies all of the requirements of document clustering mentioned above. We use "item" and "term" as synonyms below. In classical hierarchical and partitioning methods, the pairwise similarity between documents plays a central role in constructing a cluster; hence, those methods are "document-centered". FIHC is "cluster-centered" in that it measures the cohesiveness of a cluster directly using frequent itemsets: documents in the same cluster are expected to share more common itemsets than those in different clusters.

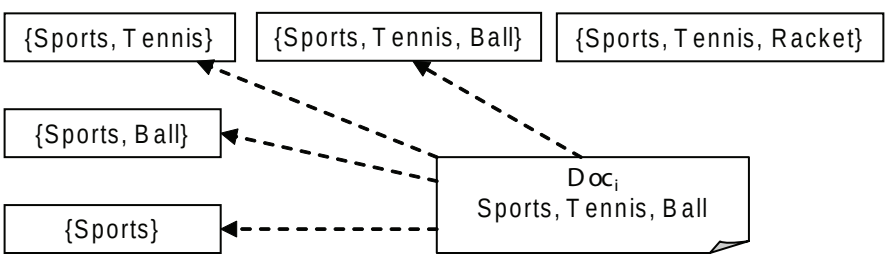
A frequent itemset is a set of terms that occur together in some minimum fraction of documents. To illustrate the usefulness of this notion for the task of clustering, let us consider two frequent items, "windows" and "apple". Documents that contain the word "windows" may relate to renovation. Documents that contain the word "apple" may relate to fruits. However, if both words occur together in many documents, then another topic that talks about operating systems should be identified. By precisely discovering these hidden topics as the first step and then clustering documents based on them, the quality of the clustering solution can be improved. This approach is very different from HFTC where the clustering solution greatly depends on the order of selected itemsets. Instead, FIHC assigns documents to the best cluster from among all available clusters (frequent itemsets). The intuition of the clustering criterion is that there are some frequent itemsets for each cluster in the document set, but different clusters share few frequent itemsets. FIHC uses frequent itemsets to construct clusters and to organize clusters into a topic hierarchy.

The following definitions are introduced in (Fung, Wang, Ester, 2003): A *global frequent itemset* is a set of items that appear together in more than a minimum fraction of the whole document set. A *global frequent item* refers to an item that belongs to some global frequent itemset. A global frequent itemset containing *k* items is called a *global frequent k-itemset*. A global frequent item is *cluster frequent* in a cluster C_i if the item is contained in some minimum fraction of documents in C_i. FIHC uses only the global frequent items in document vectors; thus, the dimensionality is significantly reduced.

The FIHC algorithm can be summarized in three phases: First, construct initial clusters. Second, build a cluster (topic) tree. Finally, prune the cluster tree in case there are too many clusters.

1. **Constructing clusters:** For each global frequent itemset, an initial cluster is constructed to include all the documents containing this itemset. Initial clusters are overlapping because one document may contain multiple global frequent itemsets. FIHC utilities this global frequent itemset as the cluster label to identify the cluster. For each document, the "best" initial cluster is identified and the document is assigned only to the best matching initial cluster. The goodness of a cluster C_i for a document doc_j is measured by some score function using cluster frequent items of initial clusters. After this step, each document belongs to exactly one cluster. The set of clusters can be viewed as a set of topics in the document set.
   Example: Figure 1 depicts a set of initial clusters. Each of them is labeled with a global frequent itemset. A document Doc_1 containing global

Figure 1. Initial clusters



frequent items "Sports", "Tennis", and "Ball" is assigned to clusters {Sports}, {Sports, Ball}, {Sports, Tennis} and {Sports, Tennis, Ball}. Suppose {Sports, Tennis, Ball} is the "best" cluster for Doc_1 measured by some score function. Doc_1 is then removed from {Sports}, {Sports, Ball}, and {Sports, Tennis}.

2. **Building cluster tree:** In the cluster tree, each cluster (except the root node) has exactly one parent. The topic of a parent cluster is more general than the topic of a child cluster and they are "similar" to a certain degree (see Figure 2 for an example). Each cluster uses a global frequent *k*-itemset as its cluster label. A cluster with a *k*-itemset cluster label appears at level *k* in the tree. The cluster tree is built bottom up by choosing the "best" parent at level *k-1* for each cluster at level *k*. The parent's cluster label must be a subset of the child's cluster label. By treating all documents in the child cluster as a single document, the criterion for selecting the best parent is similar to the one for choosing the best cluster for a document.
   Example: Cluster {Sports, Tennis, Ball} has a global frequent 3-itemset label. Its potential parents are {Sports, Ball} and {Sports, Tennis}. Suppose {Sports, Tennis} has a higher score. It becomes the parent cluster of {Sports, Tennis, Ball}.
3. **Pruning cluster tree:** The cluster tree can be broad and deep, which becomes not suitable for browsing. The goal of tree pruning is to efficiently remove the overly specific clusters based on the notion of inter-cluster similarity. The idea is that if two sibling clusters are very similar, they should be merged into one cluster. If a child cluster is very similar to its parent (high inter-cluster similarity), then replace the child cluster with its parent cluster. The parent cluster will then also include all documents of the child cluster.
   Example: Suppose the cluster {Sports, Tennis, Ball} is very similar to its parent {Sports, Tennis} in Figure 2. {Sports, Tennis, Ball} is pruned and its documents, e.g., Doc_1, are moved up into cluster {Sports, Tennis}.

Evaluation of FIHC

The FIHC algorithm was experimentally evaluated and compared to state-of-the-art document clustering methods. See (Fung, Wang, & Ester, 2003) for more details. FIHC uses only the global frequent items in document vectors, drastically reducing the dimensionality of the document set. Experiments show that clustering with reduced dimensionality is significantly more efficient and scalable. FIHC can cluster 100K documents within several minutes while HFTC and UPGMA cannot even produce a clustering solution. FIHC is not only scalable, but also accurate. The clustering accuracy of FIHC, evaluated based on F-measure (Steinbach, Karypis, & Kumar, 2000), consistently outperforms other methods. FIHC allows the user to specify an optional parameter, the desired number of clusters in the solution. However, close-to-optimal accuracy can still be achieved even if the user does not specify this parameter.

The cluster tree provides a logical organization of clusters which facilitates browsing documents. Each cluster is attached with a cluster label that summarizes the documents in the cluster. Different from other clustering methods, no separate post-processing is required for generating these meaningful cluster descriptions.

FUTURE TRENDS

Incrementally Updating the Cluster Tree

One potential research direction is to incrementally update the cluster tree (Guha, Mishra, Motwani, & O'Callaghan, 2000; Hennig & Wurst, 2006; Murua, Stuetzle, Tantrum & Sieberts, 2008). In many cases, the number of documents is growing continuously in a document set, and it is infeasible to rebuild the cluster tree upon every arrival of a new document. Using FIHC, one can simply assign new documents to the most similar existing cluster. The clustering accuracy, however, may degrade in the course of the time since the original global frequent itemsets may no longer reflect the current state of the overall document set. Incremental clustering is closely related to some of the recent research on data mining in stream data (Ordonez, 2003).

Incorporate with Natural Language Processing Techniques

Many existing document clustering algorithms consider a document as a bag of words. Although the semantic relationships among the words may be crucial for clustering, they are not utilized. Li and Chung (2005) considered a sequence of words is frequent if it occurs in more than certain percentage of the documents in a document set. Wang and Hodges (2006) proposed to use the sense disambiguation method to identify the sense of words to construct the feature vector for document representation. Future work could incorporate the natural language processing technique and utilize the Universal Networking Language (Uchida, Zhu, & Della Senta, 2000), a semantic representation for sentences, to generate feature vectors and computing scores.

CONCLUSION

Most traditional clustering methods do not address the special requirements for hierarchical document clustering, including high dimensionality, high volume, and ease of browsing. In this chapter, we review several document clustering methods in the context of these requirements, and a document clustering method, FIHC, is discussed a detail. Due to massive volumes of unstructured data generated in the globally networked environment, the importance of document clustering will continue to grow.

KEY TERMS

Cluster Frequent Item: A global frequent item is cluster frequent in a cluster C_i if the item is contained in some minimum fraction of documents in C_i.

Document Clustering: The automatic organization of documents into clusters or group so that documents within a cluster have high similarity in comparison to one another, but are very dissimilar to documents in other clusters.

Document Vector: Each document is represented by a vector of frequencies of remaining items after preprocessing within the document.

Global Frequent Itemset: A set of words that occur together in some minimum fraction of the whole document set.

Inter-cluster Similarity: The overall similarity among documents from two different clusters.

Intra-cluster Similarity: The overall similarity among documents within a cluster.

Medoid: The most centrally located object in a cluster.

Stop Words Removal: A preprocessing step for text mining. Stop words, like "the" and "this" which rarely help the mining process, are removed from input data.

Stemming: For text mining purposes, morphological variants of words that have the same or similar semantic interpretations can be considered as equivalent. For example, the words "computation" and "compute" can be stemmed into "comput".

Histograms for OLAP and Data-Stream Queries

Francesco Buccafurri
DIMET, Università di Reggio Calabria, Italy

Gianluca Caminiti
DIMET, Università di Reggio Calabria, Italy

Gianluca Lax
DIMET, Università di Reggio Calabria, Italy

INTRODUCTION

Histograms are an important tool for data reduction both in the field of data-stream querying and in OLAP, since they allow us to represent large amount of data in a very compact structure, on which both efficient mining techniques and OLAP queries can be executed. Significant time- and memory-cost advantages may derive from data reduction, but the trade-off with the accuracy has to be managed in order to obtain considerable improvements of the overall capabilities of mining and OLAP tools.

In this chapter we focus on histograms, that are shown in the recent literature to be one of the possible concrete answers to the above requirements.

BACKGROUND

Data synopses are widely exploited in many applications. Every time it is necessary to produce fast query answers and a certain estimation error can be accepted, it is possible to inquire summary data rather than the original ones and to perform suitable interpolations. This happens for example in OLAP, where a typical query is a *range query*, or in the case of continuous query over data streams.

A possible solution to this problem is using sampling methods (Gemulla, Lehner, & Haas, 2007; Gryz, Guo, Liu & Zuzarte, 2004): only a small number of suitably selected records of R, well *representing* R, are stored. The query is then evaluated by exploiting these samples instead of the full relation R. Sampling techniques are very easy to implement.

Regression techniques try to model data as a function in such a way that only a small set of coefficients representing such a function is stored, rather than the original data. The simplest regression technique is the linear one, modeling a data distribution as a linear function. Despite its simplicity, not allowing to capture complex relationships among data, this technique often produces acceptable results. There are also non-linear regressions, significantly more complex than the linear one from the computational point of view, yet applicable to a much larger set of cases.

Besides these techniques, another possible solution relies on the usage of histograms.

MAIN THRUST OF THE CHAPTER

Histograms are a lossy compression technique widely used in various application contexts, like query optimization, statistical and temporal databases and OLAP applications. In OLAP, compression allows us to obtain fast approximate answers by evaluating queries on reduced data in place of the original ones. Histograms are well-suited to this purpose, especially in case of range queries (Muthukrishnan & Strauss, 2003).

A histogram is a compact representation of a relation R. It is obtained by partitioning an attribute X of the relation R into k sub-ranges, called buckets, and by maintaining for each of them a few information, typically corresponding to the bucket boundaries, the number of tuples with value of X belonging to the sub-range associated to the bucket (often called *sum of the bucket*), and the number of distinct values of X of such a sub-range occurring in some tuple of R (i.e., the number of non-null frequencies of the sub-range).

Figure 1 reports an example of 3-bucket histogram, built on a domain of size 12 with 3 null elements. For each bucket (represented as an oval), we have reported the boundaries (on the left and the right side, respectively) and the value of the sum of the elements belonging to the bucket (inside the oval). Observe that, the null values (i.e. the values at 6, 7 and 9) do not occur in any bucket.

A range query, defined on an interval I of X, evaluates the number of occurrences in R with value of X in I. Thus, buckets embed a set of pre-computed disjoint range queries capable of covering the whole active domain of X in R (by "active" here we mean attribute values actually appearing in R). As a consequence, the histogram does not give, in general, the possibility of evaluating exactly a range query not corresponding to one of the pre-computed embedded queries. In other words, while the contribution to the answer coming from the sub-ranges coinciding with entire buckets can be returned exactly, the contribution coming from the sub-ranges which partially overlap buckets can be only estimated, since the actual data distribution inside the buckets is not available. For example, concerning the histogram shown in Figure 1, a range query from 4 to 8 is estimated by summing (1) the partial contribution of bucket 1 computed by CVA (see Section "Estimation inside a bucket"), that is 104.8, and (2) the *sum* of bucket 2, that is 122. As a consequence, the range query estimation is 226.8 whereas the exact result is 224.

Constructing the best histogram means defining the boundaries of buckets in such a way that the estimation of the non pre-computed range queries becomes more effective (e.g., by avoiding that large frequency differences arise inside a bucket). This approach corresponds to finding, among all possible sets of pre-computed range queries, the set which guarantees the best estimation of the other (non pre-computed) queries, once a technique for estimating such queries is defined.

Besides this problem, which we call the *partition problem*, there is another relevant issue to investigate: How to improve the estimation inside the buckets? We discuss about both the above issues in the following two sections.

The Partition Problem

This issue has been widely analyzed in the past and a number of techniques have been proposed. Among these, we first consider the Max-Diff histogram and the V-Optimal histogram. Even though they are not the most recent techniques, we deeply cite them since they are still considered points of reference.

We start by describing the Max-Diff histogram.

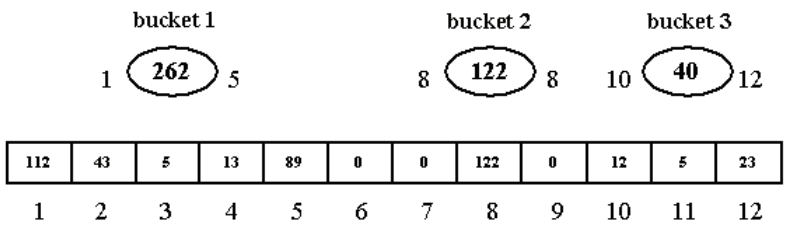
Let $V=\{v_1, \ldots, v_n\}$ be the set of values of the attribute X actually appearing in the relation R and $f(v_i)$ be the number of tuples of R having value v_i in X. A Max-Diff histogram with h buckets is obtained by putting a boundary between two adjacent attribute values v_i and v_{i+1} of V if the difference between $f(v_{i+1}) \cdot s_{i+1}$ and $f(v_i) \cdot s_i$ is one of the $h-1$ largest such differences (where s_i denotes the spread of v_i, that is the distance from v_i to the next non-null value).

A V-Optimal histogram, which is the other classical histogram we describe, produces more precise results than the Max-Diff histogram. It is obtained by selecting the boundaries for each bucket i so that the query approximation error is minimal. In particular, the boundaries of each bucket i, say lb_i and ub_i (with $1 \le i \le h$, where h is the total number of buckets), are fixed in such a way that:

$$\sum_{i=1}^{h} SSE_i$$

is minimum, where the standard squared error of the i-th bucket

Figure 1. An example of a 3-bucket histogram built on a domain of size 12.



$$SSE_i = \sum_{j=lb_i}^{ub_i} (f(j) - avg_i)^2$$

where *f(j)* is the frequency of the *j*-th value of the domain and avg_i is the average of the frequencies occurring in the *i*-th bucket. A V-Optimal histogram uses a dynamic programming technique in order to find the "optimal" partitioning w.r.t. the given error metrics.

Even though the V-Optimal histogram is more accurate than Max-Diff, its high space- and time-complexities make it rarely used in practice.

In order to overcome such a drawback, an approximate version of the V-Optimal histogram has been proposed. The basic idea is quite simple: First, data are partitioned into *l* disjoint chunks and then the V-Optimal algorithm is used in order to compute a histogram within each chuck. The consequent problem is how to allocate buckets to the chunks such that exactly *B* buckets are used. This is solved by implementing a dynamic programming scheme. It is shown that an approximate V-Optimal histogram with *B*+*l* buckets has the same accuracy as the non-approximate V-Optimal with *B* buckets. Moreover, the time required for executing the approximate algorithm is reduced by a multiplicative factor equal to1/*l*.

Besides the guarantee of accuracy, the histogram should efficiently support hierarchical range queries in order not to limit too much the capability of drilling-down and rolling-up over data.

This requirement was introduced by Koudas, Muthukrishnan & Srivastava (2000), who have shown the insufficient accuracy of classical histograms in evaluating hierarchical range queries. Therein, the Hierarchical Optimal histogram *H-Optimal* is proposed, that has the minimum total expected error for estimating prefix range queries, where the only queries allowed are one-sided ranges. The error metrics used is the SSE, described above for V-Optimal. Moreover, a polynomial-time algorithm for its construction is provided.

Guha, Koudas & Srivastava (2002) have proposed efficient algorithms for the problem of approximating the distribution of measure attributes organized into hierarchies. Such algorithms are based on dynamic programming and on a notion of sparse intervals.

Guha, Shim & Woo (2004) have proposed the Relative Error Histogram *RE-HIST*. It is the optimal histogram that minimizes the relative error measures for estimating prefix range queries. The relative error for a range query is computed as $(x_i\text{-}e_i)/\max\{|x_i|,c\}$ where x_i and e_i are the actual value and the estimation of the range query, respectively, and c is a *sanity constant* (typically fixed to 1), used to reduce excessive domination of relative error by small data values.

Buccafurri & Lax (2004a) have presented a histogram based on a hierarchical decomposition of the data distribution kept in a full binary tree. Such a tree, containing a set of pre-computed hierarchical queries, is encoded by using bit saving for obtaining a smaller structure and, thus, for efficiently supporting hierarchical range queries.

All the histograms presented above are widely used as synopses for persistent data, that is data rarely modified, like databases or data warehouses. However, more sophisticated histograms can be exploited also for *data streams*.

Data streams is an emergent issue that in the last years has captured the interest of many scientific communities. The crucial problem, arising in several application contexts like network monitoring, sensor networks, financial applications, security, telecommunication data management, Web applications, and so on, is dealing with continuous data flows (i.e. data streams) having the following characteristics: (1) they are time-dependent, (2) their size is very large, so that they cannot be totally stored due to the actual memory limitation, and (3) data arrival is very fast and unpredictable, so that each data management operation should be very efficient.

Since a data stream consists of a large amount of data, it is usually managed on the basis of a *sliding window*, including only the most recent data. Thus, any technique capable of compressing sliding windows by maintaining a good approximate representation of data distribution is relevant in this field. Typical queries performed on sliding windows are *similarity queries* and other analysis, like *change mining queries* (Dong, Han, Lakshmanan, Pei, Wang & Yu, 2003) useful for trend analysis and, in general, for understanding the dynamics of data. Also in this field, histograms may become an important analysis tool. The challenge is finding new histograms that (1) are fast to construct and to maintain, that is the required updating operations (performed at each data arrival) are very efficient, (2) maintain a good accuracy in approximating data distribution and (3) support continuous querying on data.

An example of the above emerging approaches is reported in (Buccafurri & Lax, 2004b), where a tree-like histogram with cyclic updating is proposed. By using

such a compact structure, many mining techniques, that would take very high computational costs when used on real data streams, can be effectively implemented. Guha, Koudas & Shim (2006) have presented a one-pass linear-time approximation algorithm for the histogram construction problem for a wide variety of error measures. Due to their fast construction, the histograms here proposed can be profitably extended to the case of data streams.

Besides bucket-based histograms, there are other kinds of histograms whose construction is not driven by the search of a suitable partition of the attribute domain and, further, their structure is more complex than simply a set of buckets. This class of histograms is called *non-bucket based* histograms. *Wavelets* are an example of such kind of histograms.

Wavelets are mathematical transformations storing data in a compact and hierarchical fashion, used in many application contexts, like image and signal processing (Khalifa, 2003; Kacha, Grenez, De Doncker & Benmahammed, 2003). There are several types of transformations, each belonging to a family of wavelets. The result of each transformation is a set of values, called *wavelet coefficients*. The advantage of this technique is that, typically, the value of a (possibly large) number of wavelet coefficients results to be below a fixed threshold, so that such coefficients can be approximated by 0. Clearly, the overall approximation of the technique as well as the compression ratio depends on the value of such a threshold. In the last years wavelets have been exploited in data mining and knowledge discovery in databases, thanks to time-and space-efficiency and data hierarchical decomposition characterizing them (Garofalakis & Kumar, 2004; Guha, Chulyun & Shim, 2004; Garofalakis & Gibbons, 2002; Karras & Mamoulis, 2005, Garofalakis & Gibbons, 2004).

In the next section we deal with the second problem introduced earlier, concerning the estimation of range queries partially involving buckets.

Estimation Inside a Bucket

While finding the optimal bucket partition has been widely investigated in the past years, the problem of estimating queries partially involving a bucket has received a little attention.

Histograms are well-suited to range query evaluation, since buckets basically correspond to a set of precomputed range queries. A range query that involves entirely one or more buckets can be computed exactly, while if it overlaps partially a bucket, then the result can be only estimated.

The simplest estimation technique is the Continuous Value Assumption (CVA): Given a bucket of size s and sum c, a range query overlapping the bucket in i points is estimated as $(i/s)\cdot c$. This corresponds to estimating the partial contribution of the bucket to the range query result by linear interpolation.

Another possibility is to use the Uniform Spread Assumption (USA). It assumes that values are distributed at equal distance from each other and the overall frequency sum is equally distributed among them. In this case, it is necessary to know the number of non-null frequencies belonging to the bucket. Denoting by t such a value, the range query is estimated by:

$$\frac{(s-1)\cdot(i-1)\cdot(t-1)}{(s-1)}\cdot\frac{c}{t}.$$

An interesting problem is understanding whether, by exploiting information typically contained in histogram buckets, and possibly adding some concise summary information, the frequency estimation inside buckets, and then, the histogram accuracy, can be improved. To this aim, starting from a theoretical analysis about limits of CVA and USA, Buccafurri, Lax, Pontieri, Rosaci & Saccà (2008) have proposed to use an additional storage space of 32 bits (called 4LT) in each bucket, in order to store the approximate representation of the data distribution inside the bucket. 4LT is used to save approximate cumulative frequencies at 7 equi-distant intervals internal to the bucket.

Clearly, approaches similar to that followed in (Buccafurri et al., 2008) have to deal with the trade-off between the extra storage space required for each bucket and the number of total buckets the allowed total storage space consents.

FUTURE TRENDS

The main limit of the first decade of research in querying-oriented histograms was certainly that they did not provide guarantees about the approximation error. The first significant work where the goal of error guarantee is reached, under some conditions, is by Datar, Gionis, Indyk & Motwani (2002). In particular, the

proposed histogram gives the error guarantee only in case of biased range queries (which are significant in the context of data streams), i.e. involving the last N data of the sliding window, for a given query size N. However, in the general case, the form of the queries cannot be limited to this kind of query (like in KDD applications). The current and future challenge is thus to find new histograms with good error-guarantee features and with no limitation about the kind of queries which can be approximated.

CONCLUSION

In many application contexts like OLAP and data streams the usage of histograms is becoming more and more frequent. Indeed they allow us to perform OLAP queries on summarized data in place of the original ones, or to arrange effective approaches requiring multiple scans on data streams, that, in such a way, may be performed over a compact version of the data stream. In these cases, the usage of histograms allows us to analyze a large amount of data very fast, guaranteeing at the same time good accuracy requirements.

KEY TERMS

Bucket: An element obtained by partitioning the domain of an attribute X of a relation into non-overlapping intervals. Each bucket consists of a tuple <*inf, sup, val*> where *val* is an aggregate information (for an instance sum, average, count, and so on) about tuples with value of X belonging to the interval (*inf, sup*).

Bucket-Based Histogram: A type of histogram whose construction is driven by searching for a suitable partition of the attribute domain into buckets.

Continuous Query: In the context of data stream it is a query issued once and running continuously over the data.

Data Stream: Data that is structured and processed in a continuous flow, like digital audio and video or data coming from digital sensors.

Histogram: A set of buckets implementing a partition of the overall domain of a relation attribute.

Range Query: A query returning an aggregate information (such as sum, average) about data belonging to a given interval of the domain.

Similarity Query: A kind of query aiming to discovering correlations and patterns in dynamic data streams and widely used to perform trend analysis.

Sliding Window: A sequence of the most recent values, arranged in arrival time order, that are collected from a data stream.

Wavelets: Mathematical transformations implementing hierarchical decomposition of functions leading to the representation of functions through sets of wavelet coefficients.

Homeland Security Data Mining and Link Analysis

Bhavani Thuraisingham
The MITRE Corporation, USA

INTRODUCTION

Data mining is the process of posing queries to large quantities of data and extracting information often previously unknown using mathematical, statistical, and machine-learning techniques. Data mining has many applications in a number of areas, including marketing and sales, medicine, law, manufacturing, and, more recently, homeland security. Using data mining, one can uncover hidden dependencies between terrorist groups as well as possibly predict terrorist events based on past experience. One particular data-mining technique that is being investigated a great deal for homeland security is link analysis, where links are drawn between various nodes, possibly detecting some hidden links.

This article provides an overview of the various developments in data-mining applications in homeland security. The organization of this article is as follows. First, we provide some background on data mining and the various threats. Then, we discuss the applications of data mining and link analysis for homeland security. Privacy considerations are discussed next as part of future trends. The article is then concluded.

BACKGROUND

We provide background information on both data mining and security threats.

Data Mining

Data mining is the process of posing various queries and extracting useful information, patterns, and trends often previously unknown from large quantities of data possibly stored in databases. Essentially, for many organizations, the goals of data mining include improving marketing capabilities, detecting abnormal patterns, and predicting the future, based on past experiences and current trends. There is clearly a need for this technology. There are large amounts of current and historical data being stored. Therefore, as databases become larger, it becomes increasingly difficult to support decision making. In addition, the data could be from multiple sources and multiple domains. There is a clear need to analyze the data to support planning and other functions of an enterprise.

Some of the data-mining techniques include those based on statistical reasoning techniques, inductive logic programming, machine learning, fuzzy sets, and neural networks, among others. The data-mining problems include classification (finding rules to partition data into groups), association (finding rules to make associations between data), and sequencing (finding rules to order data). Essentially, one arrives at some hypotheses, which is the information extracted from examples and patterns observed. These patterns are observed from posing a series of queries; each query may depend on the responses obtained to the previous queries posed.

Data mining is an integration of multiple technologies. These include data management, such as database management, data warehousing, statistics, machine learning, decision support, and others, such as visualization and parallel computing. There is a series of steps involved in data mining. These include getting the data organized for mining, determining the desired outcomes to mining, selecting tools for mining, carrying out the mining, pruning the results so that only the useful ones are considered further, taking actions from the mining, and evaluating the actions to determine benefits. There are various types of data mining. By this we do not mean the actual techniques used to mine the data, but what the outcomes will be. These outcomes also have been referred to as data-mining tasks. These include clustering, classification anomaly detection, and forming associations.

While several developments have been made, there also are many challenges. For example, due to the large volumes of data, how can the algorithms determine

which technique to select and what type of data mining to do? Furthermore, the data may be incomplete and/or inaccurate. At times, there may be redundant information, and at times, there may not be sufficient information. It is also desirable to have data-mining tools that can switch to multiple techniques and support multiple outcomes. Some of the current trends in data mining include mining Web data, mining distributed and heterogeneous databases, and privacy-preserving data mining, where one ensures that one can get useful results from mining and at the same time maintain the privacy of individuals (Berry & Linoff; Han & Kamber, 2000; Thuraisingham, 1998).

Security Threats

Security threats have been grouped into many categories (Thuraisingham, 2003). These include information-related threats, where information technologies are used to sabotage critical infrastructures, and non-information-related threats, such as bombing buildings. Threats also may be real-time threats and non-real-time threats. Real-time threats are threats where attacks have timing constraints associated with them, such as "building X will be attacked within three days." Non-real-time threats are those threats that do not have timing constraints associated with them. Note that non-real-time threats could become real-time threats over time.

Threats also include bioterrorism, where biological and possibly chemical weapons are used to attack, and cyberterrorism, where computers and networks are attacked. Bioterrorism could cost millions of lives, and cyberterrorism, such as attacks on banking systems, could cost millions of dollars. Some details on the threats and countermeasures are discussed in various texts (Bolz, 2001). The challenge is to come up with techniques to handle such threats. In this article, we discuss data-mining techniques for security applications.

MAIN THRUST

First, we will discuss data mining for homeland security. Then, we will focus on a specific data-mining technique called *link analysis* for homeland security. An aspect of homeland security is cyber security. Therefore, we also will discuss data mining for cyber security.

Applications of Data Mining for Homeland Security

Data-mining techniques are being examined extensively for homeland security applications. The idea is to gather information about various groups of people and study their activities and determine if they are potential terrorists. As we have stated earlier, data-mining outcomes include making associations, linking analyses, forming clusters, classification, and anomaly detection. The techniques that result in these outcomes are techniques based on neural networks, decisions trees, market-basket analysis techniques, inductive logic programming, rough sets, link analysis based on graph theory, and nearest-neighbor techniques. The methods used for data mining include top-down reasoning, where we start with a hypothesis and then determine whether the hypothesis is true, or bottom-up reasoning, where we start with examples and then come up with a hypothesis (Thuraisingham, 1998). In the following, we will examine how data-mining techniques may be applied for homeland security applications. Later, we will examine a particular data-mining technique called *link analysis* (Thuraisingham, 2003).

Data-mining techniques include techniques for making associations, clustering, anomaly detection, prediction, estimation, classification, and summarization. Essentially, these are the techniques used to obtain the various data-mining outcomes. We will examine a few of these techniques and show how they can be applied to homeland security. First, consider association rule mining techniques. These techniques produce results, such as John and James travel together or Jane and Mary travel to England six times a year and to France three times a year. Essentially, they form associations between people, events, and entities. Such associations also can be used to form connections between different terrorist groups. For example, members from Group A and Group B have no associations, but Groups A and B have associations with Group C. Does this mean that there is an indirect association between A and C?

Next, let us consider clustering techniques. Clusters essentially partition the population based on a characteristic such as spending patterns. For example, those living in the Manhattan region form a cluster, as they spend over $3,000 on rent. Those living in the Bronx from another cluster, as they spend around $2,000 on rent. Similarly, clusters can be formed based on terrorist activities. For example, those living in region X bomb

buildings, and those living in region Y bomb planes.

Finally, we will consider anomaly detection techniques. A good example here is learning to fly an airplane without wanting to learn to take off or land. The general pattern is that people want to get a complete training course in flying. However, there are now some individuals who want to learn to fly but do not care about take off or landing. This is an anomaly. Another example is John always goes to the grocery store on Saturdays. But on Saturday, October 26, 2002, he went to a firearms store and bought a rifle. This is an anomaly and may need some further analysis as to why he is going to a firearms store when he has never done so before. Some details on data mining for security applications have been reported recently (Chen, 2003).

Applications of Link Analysis

Link analysis is being examined extensively for applications in homeland security. For example, how do we connect the dots describing the various events and make links and connections between people and events? One challenge to using link analysis for counterterrorism is reasoning with partial information. For example, agency A may have a partial graph, agency B another partial graph, and agency C a third partial graph. The question is how do you find the associations between the graphs, when no agency has the complete picture? One would ague that we need a data miner that would reason under uncertainty and be able to figure out the links between the three graphs. This would be the ideal solution, and the research challenge is to develop such a data miner. The other approach is to have an organization above the three agencies that will have access to the three graphs and make the links.

The strength behind link analyses is that by visualizing the connections and associations, one can have a better understanding of the associations among the various groups. Associations such as A and B, B and C, D and A, C and E, E and D, F and B, and so forth can be very difficult to manage, if we assert them as rules. However, by using nodes and links of a graph, one can visualize the connections and perhaps draw new connections among different nodes. Now, in the real world, there would be thousands of nodes and links connecting people, groups, events, and entities from different countries and continents as well as from different states within a country. Therefore, we need link analysis techniques to determine the unusual connection, such as a connection between G and P, for example, which is not obvious with simple reasoning strategies or by human analysis.

Link analysis is one of the data-mining techniques that is still in its infancy. That is, while much has been written about techniques such as association rule mining, automatic clustering, classification, and anomaly detection, very little material has been published on link analysis. We need interdisciplinary researchers such as mathematicians, computational scientists, computer scientists, machine-learning researchers, and statisticians working together to develop better link analysis tools.

Applications of Data Mining for Cyber Security

Data mining also has applications in cyber security, which is an aspect of homeland security. The most prominent application is in intrusion detection. For example, our computers and networks are being intruded by unauthorized individuals. Data-mining techniques, such as those for classification and anomaly detection, are being used extensively to detect such unauthorized intrusions. For example, data about normal behavior is gathered, and when something occurs out of the ordinary, it is flagged as an unauthorized intrusion. Normal behavior could be that John's computer is never used between 2:00 A.M. and 5:00 A.M.. When John's computer is in use at 3:00 A.M., for example, then this is flagged as an unusual pattern.

Data mining is also being applied to other applications in cyber security, such a auditing. Here again, data on normal database access is gathered, and when something unusual happens, then this is flagged as a possible access violation. Digital forensics is another area where data mining is being applied. Here again, by mining the vast quantities of data, one could detect the violations that have occurred. Finally, data mining is being used for biometrics. Here, pattern recognition and other machine-learning techniques are being used to learn the features of a person and then to authenticate the person, based on the features.

FUTURE TRENDS

While data mining has many applications in homeland security, it also causes privacy concerns. This is

because we need to collect all kinds of information about people, which causes private information to be divulged. Privacy and data mining have been the subject of much debate during the past few years, although some early discussions also have been reported (Thuraisingham, 1996).

One promising direction is privacy-preserving data mining. The challenge here is to carry out data mining but at the same time ensure privacy. For example, one could use randomization as a technique and give out approximate values instead of the actual values. The challenge is to ensure that the approximate values are still useful. Many papers on privacy-preserving data mining have been published recently (Agrawal & Srikant, 2000).

CONCLUSION

This article has discussed data-mining applications in homeland security. Applications in national security and cyber security both are discussed. We first provided an overview of data mining and security threats and then discussed data-mining applications. We also emphasized a particular data-mining technique—link analysis. Finally, we discussed privacy-preserving data mining.

It is only during the past three years that data mining for security applications has received a lot of attention. Although a lot of progress has been made, there is also a lot of work that needs to be done. First, we need to have a better understanding of the various threats. We need to determine which data-mining techniques are applicable to which threats. Much research is also needed on link analysis. To develop effective solutions, data-mining specialists have to work with counter-terrorism experts. We also need to motivate the tool vendors to develop tools to handle terrorism.

NOTE

KEY TERMS

Cyber Security: Techniques used to protect the computer and networks from the threats.

Data Management: Techniques used to organize, structure, and manage the data, including database management and data administration.

Digital Forensics: Techniques to determine the root causes of security violations that have occurred in a computer or a network.

Homeland Security: Techniques used to protect a building or an organization from threats.

Intrusion Detection: Techniques used to protect the computer system or a network from a specific threat, which is unauthorized access.

Link Analysis: A data-mining technique that uses concepts and techniques from graph theory to make associations.

Privacy: Process of ensuring that information deemed personal to an individual is protected.

Privacy-Preserving Data Mining: Data-mining techniques that extract useful information but at the same time ensure the privacy of individuals.

Threats: Events that disrupt the normal operation of a building, organization, or network of computers.

Humanities Data Warehousing

Janet Delve
University of Portsmouth, UK

INTRODUCTION

Data Warehousing is now a well-established part of the business and scientific worlds. However, up until recently, data warehouses were restricted to modeling essentially numerical data – examples being sales figures in the business arena (in say Wal-Mart's data warehouse (Westerman, 2000)) and astronomical data (for example SKICAT) in scientific research, with textual data providing a descriptive rather than a central analytic role. The lack of ability of data warehouses to cope with mainly non-numeric data is particularly problematic for humanities[1] research utilizing material such as memoirs and trade directories. Recent innovations have opened up possibilities for 'non-numeric' data warehouses, making them widely accessible to humanities research for the first time. Due to its irregular and complex nature, humanities research data is often difficult to model, and manipulating time shifts in a relational database is problematic as is fitting such data into a normalized data model. History and linguistics are exemplars of areas where relational databases are cumbersome and which would benefit from the greater freedom afforded by data warehouse dimensional modeling.

BACKGROUND

Hudson (2001, p. 240) declared relational databases to be the predominant software used in recent, historical research involving computing. Historical databases have been created using different types of data from diverse countries and time periods. Some databases are modest and independent, others part of a larger conglomerate like the North Atlantic Population Project (NAPP) project that entails integrating international census data. One issue that is essential to good database creation is data modeling; which has been contentiously debated recently in historical circles.

When reviewing relational modeling in historical research, (Bradley, 1994) contrasted 'straightforward' business data with incomplete, irregular, complex- or semi-structured historical data. He noted that the relational model worked well for simply-structured business data, but could be tortuous to use for historical data. (Breure, 1995) pointed out the advantages of inputting data into a model that matches it closely, something that is very hard to achieve with the relational model. (Burt[2] and James, 1996) considered the relative freedom of using source-oriented data modeling (Denley, 1994) as compared to relational modeling with its restrictions due to normalization (which splits data into many separate tables), and highlighted the possibilities of data warehouses. Normalization is not the only hurdle historians encounter when using the relational model.

Date and time fields provide particular difficulties: historical dating systems encompass a number of different calendars, including the Western, Islamic, Revolutionary and Byzantine. Historical data may refer to 'the first Sunday after Michaelmas', requiring calculation before a date may be entered into a database. Unfortunately, some databases and spreadsheets cannot handle dates falling outside the late 20th century. Similarly, for researchers in historical geography, it might be necessary to calculate dates based on the local introduction of the Gregorian calendar, for example. These difficulties can be time-consuming and arduous for researchers. Awkward and irregular data with abstruse dating systems thus do not fit easily into a relational model that does not lend itself to hierarchical data. Many of these problems also occur in linguistics computing.

Linguistics is a data-rich field, with multifarious forms for words, multitudinous rules for coding sounds, words and phrases, and also numerous other parameters - geography, educational and social status. Databases are used for housing many types of linguistic data from a variety of research domains - phonetics, phonology, morphology, syntax, lexicography, computer-assisted learning (CAL), historical linguistics and dialectology. Data integrity and consistency are of utmost importance in this field. Relational DataBase Management Systems (RDBMSs) are able to provide this, together with powerful and flexible search facilities (Nerbonne, 1998, introduction).

Bliss and Ritter (2001 IRCS conference proceedings) discussed the constraints imposed on them when using 'the rigid coding structure of the database' developed to house pronoun systems from 109 languages. They observed that coding introduced interpretation of data and concluded that designing 'a typological database is not unlike trying to fit a square object into a round hole. Linguistic data is highly variable, database structures are highly rigid, and the two do not always "fit".' Brown (2001 IRCS conference proceedings) outlined the fact that different database structures may reflect a particular linguistic theory, and also mentioned the trade-off between quality and quantity in terms of coverage.

The choice of data model thus has a profound effect on the problems that can be tackled and the data that can be interrogated. For both historical and linguistic research, relational data modeling using normalization often appears to impose data structures which do not fit naturally with the data and which constrain subsequent analysis. Coping with complicated dating systems can also be very problematic. Surprisingly, similar difficulties have already arisen in the business community, and have been addressed by data warehousing.

MAIN THRUST

Data Warehousing in the Business Context

Data warehouses came into being as a response to the problems caused by large, centralized databases which users found unwieldy to query. Instead, they extracted portions of the databases which they could then control, resulting in the 'spider-web' problem where each department produces queries from its own, uncoordinated extract database (Inmon 2002, pp. 6-14). The need was thus recognized for a single, integrated source of clean data to serve the *analytical needs* of a company.

A data warehouse can provide answers to a completely different range of queries than those aimed at a traditional database. Using an estate agency as a typical business, the type of question their local databases should be able to answer might be 'How many three-bedroomed properties are there in the Botley area up to the value of £150,000?' The type of over-arching question a business analyst (and CEOs) would be interested in might be of the general form 'Which type of property sells for prices above the average selling price for properties in the main cities of Great Britain and how does this correlate to demographic data?' (Begg and Connolly, 2004, p. 1154). To trawl through each local estate agency database and corresponding local county council database, then amalgamate the results into a report would consume vast quantities of time and effort. The data warehouse was created to answer this type of need.

Basic Components of a Data Warehouse

Inmon (2002, p. 31), the 'father of data warehousing', defined a data warehouse as being *subject-oriented, integrated, non-volatile and time-variant.* Emphasis is placed on choosing the right *subjects* to model as opposed to being constrained to model around *applications*. Data warehouses do not replace databases as such - they co-exist alongside them in a symbiotic fashion. Databases are needed both to serve the clerical community who answer day-to-day queries such as 'what is A.R. Smith's current overdraft?' and also to 'feed' a data warehouse. To do this, snapshots of data are extracted from a database on a regular basis (daily, hourly and in the case of some mobile phone companies almost real-time). The data is then transformed (cleansed to ensure consistency) and loaded into a data warehouse. In addition, a data warehouse can cope with diverse data sources, including external data in a variety of formats and summarized data from a database. The myriad types of data of different provenance create an exceedingly rich and varied integrated data source opening up possibilities not available in databases. Thus all the data in a data warehouse is *integrated*. Crucially, data in a warehouse is not updated - it is only added to, thus making it *non-volatile*, which has a profound effect on data modeling, as the main function of normalization is to obviate update anomalies. Finally, a data warehouse has a time horizon (that is contains data over a period) of five to ten years, whereas a database typically holds data that is current for two to three months.

Data Modeling in a Data Warehouse: Dimensional Modeling

There is a fundamental split in the data warehouse community as to whether to construct a data warehouse from scratch, or to build them via data marts. A data mart is essentially a cut-down data warehouse that is

restricted to one department or one business process. Inmon (2002, p. 142) recommended building the data warehouse first, then extracting the data from it to fill up several data marts. The data warehouse modeling expert Kimball (2002) advised the incremental building of several data marts that are then carefully integrated into a data warehouse. Whichever way is chosen, the data is normally modeled via dimensional modeling. Dimensional models need to be linked to the company's corporate ERD (Entity Relationship Diagram) as the data is actually taken from this (and other) source(s). Dimensional models are somewhat different from ERDs, the typical star model having a central fact table surrounded by dimension tables. Kimball (2002, pp. 16-18) defined a fact table as 'the primary table in a dimensional model where the numerical performance measurements of the business are stored…Since measurement data is overwhelmingly the largest part of any data mart, we avoid duplicating it in multiple places around the enterprise.' Thus the fact table contains dynamic numerical data such as sales quantities and sales and profit figures. It also contains key data in order to link to the dimension tables. Dimension tables contain the textual descriptors of the business process being modeled and their depth and breadth define the analytical usefulness of the data warehouse. As they contain descriptive data, it is assumed they will not change at the same rapid rate as the numerical data in the fact table that will certainly change every time the data warehouse is refreshed. Dimension tables typically have 50-100 attributes (sometimes several hundreds) and these *are not usually normalized*. The data is often *hierarchical* in the tables and can be an accurate reflection of how data actually appears in its raw state (Kimball 2002, pp. 19-21). There is not the need to normalize as data is not updated in the data warehouse, although there are variations on the star model such as the snowflake and starflake models which allow varying degrees of normalization in some or all of their dimension tables. Coding is disparaged due to the long-term view that definitions may be lost and that the dimension tables should contain the fullest, most comprehensible descriptions possible (Kimball 2002, p. 21). The restriction of data in the fact table to numerical data has been a hindrance to academic computing. However, Kimball has recently developed 'factless' fact tables (Kimball 2002, p. 49) which do not contain measurements, thus opening the door to a much broader spectrum of possible data warehouses.

Applying the Data Warehouse Architecture to Historical and Linguistic Research

One of the major advantages of data warehousing is the enormous flexibility in modeling data. Normalization is no longer an automatic straightjacket and hierarchies can be represented in dimension tables. The expansive time dimension (Kimball 2002, p. 39) is a welcome by-product of this modeling freedom, allowing country-specific calendars, synchronization across multiple time zones and the inclusion of multifarious time periods. It is possible to add external data from diverse sources and summarized data from the source database(s). The data warehouse is built for analysis which immediately makes it attractive to humanities researchers. It is designed to continuously receive huge volumes (terabytes) of data, but is sensitive enough to cope with the idiosyncrasies of geographic location dimensions within GISs (Kimball, 2002, p. 227). Additionally a data warehouse has advanced indexing facilities that make it desirable for those controlling vast quantities of data. With a data warehouse it is theoretically possible to publish the 'right data' that has been collected from a variety of sources and edited for quality and consistency. In a data warehouse all data is collated so a variety of different subsets can be analyzed whenever required. It is comparatively easy to extend a data warehouse and add material from a new source. The data cleansing techniques developed for data warehousing are of interest to researchers, as is the tracking facility afforded by the meta data manager (Begg and Connolly 2004, pp. 1169-70).

In terms of using data warehouses 'off the shelf', some humanities research might fit into the 'numerical fact' topology, but some might not. The 'factless fact table' has been used to create several American university data warehouses, but expertise in this area would not be as widespread as that with normal fact tables. The whole area of data cleansing may perhaps be daunting for humanities researchers (as it is to those in industry). Ensuring vast quantities of data is clean and consistent may be an unattainable goal for humanities researchers without recourse to expensive data cleansing software (and may of course distort source data (Delve and Healey, 2005, p.110)). The data warehouse technology is far from easy and is based on having existing databases to extract from, hence double the work. It is unlikely that researchers would be taking

regular snapshots of their data, as occurs in industry, but they could equate to data sets taken at different periods of time to data warehouse snapshots (e.g. 1841 census, 1861 census). Whilst many data warehouses use familiar WYSIWYGs and can be queried with SQL-type commands, there is undeniably a huge amount to learn in data warehousing. Nevertheless, there are many areas in both linguistics and historical research where data warehouses may prove attractive.

FUTURE TRENDS

Data Warehouses and Linguistics Research

The problems related by Bliss and Ritter (2001 IRCS conference proceedings) concerning rigid relational data structures and pre-coding problems would be alleviated by data warehousing. Brown (2001 IRCS conference proceedings) outlined the dilemma arising from the alignment of database structures with particular linguistic theories, and also the conflict of quality and quantity of data. With a data warehouse there is room for both vast quantities of data and a plethora of detail. No structure is forced onto the data so several theoretical approaches can be investigated using the same data warehouse. Dalli (2001 IRCS conference proceedings) observed that many linguistic databases are standalone with no hope of interoperability. His proffered solution to create an interoperable database of Maltese linguistic data involved an RDBMS and XML. Using data warehouses to store linguistic data should ensure interoperability. There is growing interest in corpora databases, with the dedicated conference at Portsmouth, November 2003. Teich, Hansen and Fankhauser drew attention to the multi-layered nature of corpora and speculated as to how 'multi-layer corpora can be maintained, queried and analyzed in an integrated fashion.' A data warehouse would be able to cope with this complexity.

Nerbonne (1998) alluded to the 'importance of coordinating the overwhelming amount of work being done and yet to be done.' Kretzschmar (2001 IRCS conference proceedings) delineated 'the challenge of preservation and display for massive amounts of survey data.' There appears to be many linguistics databases containing data from a range of locations / countries. For example, ALAP, the American Linguistic Atlas Project; ANAE, the Atlas of North American English (part of the TELSUR Project); TDS, the Typological Database System containing European data; AMPER, the Multimedia Atlas of the Romance Languages. Possible research ideas for the future may include a broadening of horizons - instead of the emphasis on individual database projects, there may develop an 'integrated warehouse' approach with the emphasis on larger scale, collaborative projects. These could compare different languages or contain many different types of linguistic data for a particular language, allowing for new orders of magnitude analysis.

Data Warehouses and Historical Research

There are inklings of historical research involving data warehousing in Britain and Canada. A data warehouse of current census data is underway at the University of Guelph, Canada and the Canadian Century Research Infrastructure aims to house census data from the last 100 years in data marts constructed using IBM software at several sites based in universities across the country. At the University of Portsmouth, UK, a historical data warehouse of American mining data was created by Professor Richard Healey using Oracle Warehouse Builder (Delve, Healey and Fletcher, 2004), and (Delve and Healey, 2005, p109-110) expound the research advantages conferred by the data warehousing architecture used. In particular, dimensional modeling opened up the way to powerful OLAP querying which in turn led to new areas of investigation as well as contributing to traditional research (Healey, 2007). One of the resulting unexpected avenues of research pursued was that of spatial data warehousing, and (Healey and Delve, 2007) delineate significant research results achieved by the creation of a Census data warehouse of the US 1880 census which integrated GIS and data warehousing in a web environment, utilizing a factless fact table at the heart of its dimensional model. They conclude that 'the combination of original person level, historical census data with a properly designed spatially-enabled data warehouse framework confirms the important warehouse principle that the basic data should be stored in the most disaggregated manner possible. Appropriate hierarchical levels specified within the dimensions then give the maximum scope to the OLAP mechanism for providing an immensely rich and varied analytical capability that goes far beyond

anything previously seen in terms of census analysis' (Healey and Delve, 2007, p.33) and also "the most novel contribution of GIS to data warehousing identified to date is that it facilitates the utilisation of linked spatial data sets to provide ad hoc spatially referenced query dimensions that can feed into the OLAP pipeline" (Healey and Delve, 2007, p.34), and all carried out in real-time. These projects give some idea of the scale of project a data warehouse can cope with, that is, really large country / state -wide problems. Following these examples, it would be possible to create a data warehouse to analyze all British censuses from 1841 to 1901 (approximately 10^8 bytes of data). Data from a variety of sources over time such as hearth tax, poor rates, trade directories, census, street directories, wills and inventories, GIS maps for a city such as Winchester could go into a city data warehouse. Similarly, a Voting data warehouse could contain voting data – poll book data and rate book data up to 1870 for the whole country. A Port data warehouse could contain all data from portbooks for all British ports together with yearly trade figures. Similarly a Street directories data warehouse would contain data from this rich source for whole country for the last 100 years. Lastly, a Taxation data warehouse could afford an overview of taxation of different types, areas or periods. The fact that some educational institutions have Oracle site licenses opens to way for humanities researchers with Oracle databases to use Oracle Warehouse Builder as part of the suite of programs available to them. These are practical project suggestions which would be impossible to construct using relational databases, but which, if achieved, could grant new insights into our history. Comparisons could be made between counties and cities and much broader analysis would be possible than has previously been the case.

CONCLUSION

The advances made in business data warehousing are directly applicable to many areas of historical and linguistics research. Data warehouse dimensional modeling allows historians and linguists to model vast amounts of data on a countrywide basis (or larger), incorporating data from existing databases, spreadsheets and GISs. Summary data could also be included, and this would all lead to a data warehouse containing more data than is currently possible, plus the fact that the data would be richer than in current databases due to the fact that normalization is no longer obligatory. Whole data sources can be captured, and more post-hoc analysis is a direct result. Dimension tables particularly lend themselves to hierarchical modeling, so data does not need splitting into many tables thus forcing joins while querying. The time dimension particularly lends itself to historical research where significant difficulties have been encountered in the past. These suggestions for historical and linguistics research clearly resonate in other areas of humanities research, such as historical geography, and any literary or cultural studies involving textual analysis (for example biographies, literary criticism and dictionary compilation).

KEY TERMS

Data Modeling: The process of producing a model of a collection of data which encapsulates its semantics and hopefully its structure.

Dimensional Model: The dimensional model is the data model used in data warehouses and data marts, the most common being the star schema, comprising a fact table surrounded by dimension tables.

Dimension Table: Dimension tables contain the textual descriptors of the business process being modeled and their depth and breadth define the analytical usefulness of the data warehouse.

Fact Table: 'the primary table in a dimensional model where the numerical performance measurements of the business are stored' (Kimball, 2002).

Factless Tact Table: A fact table which contains no measured facts (Kimball 2002).

Normalization: The process developed by E.C. Codd whereby each attribute in each table of a relational database depend entirely on the key(s) of that table. As a result, relational databases comprise many tables, each containing data relating to one entity.

Spatial Data Warehouse: A data warehouse that can also incorporate Geographic Information System (GIS)-type queries.

Hybrid Genetic Algorithms in Data Mining Applications

Sancho Salcedo-Sanz
Universidad de Alcalá, Spain

Gustavo Camps-Valls
Universitat de València, Spain

Carlos Bousoño-Calzón
Universidad Carlos III de Madrid, Spain

INTRODUCTION

G**enetic algorithms** (**GAs**) are a class of problem solving techniques which have been successfully applied to a wide variety of hard problems (Goldberg, 1989). In spite of conventional GAs are interesting approaches to several problems, in which they are able to obtain very good solutions, there exist cases in which the application of a conventional GA has shown poor results. Poor performance of GAs completely depends on the problem. In general, problems severely *constrained* or problems with difficult *objective functions* are hard to be optimized using GAs. Regarding the difficulty of a problem for a GA there is a well established theory. Traditionally, this has been studied for binary encoded problems using the so called Walsh Transform (Liepins & Vose, 1991), and its associated *spectrum* (Hordijk & Stadler, 1998), which provides an idea of the distribution of the important schemas (building blocks) in the search space.

Several methods to enhance the performance of GAs in difficult applications have been developed. Firstly, the encoding of a problem determines the search space where the GA must work. Therefore, given a problem, the selection of the best *encoding* is an important pre-processing step. *Operators* which reduce the search space are then interesting in some applications. Secondly, variable length or transformed encodings are schemes, which can be successfully applied to some difficult problems. The hybridization of a GA with *local search* algorithms can also improve the performance of the GA in concrete applications. There are two types of hybridization:

- If the GA is hybridized with a local search heuristic in order to tackle the problem constraints, it is usually known as a *hybrid genetic algorithm*.
- If the GA is hybridized with a local search heuristic in order to improve its performance, then it is known as a *memetic algorithm*.

In this chapter we revise several hybrid methods involving GAs that have been applied to data mining problems. First, we provide a brief background with several important definitions on genetic algorithms, hybrid algorithms and operators for improving its performance. In the Main Trust section, we present a survey of several hybrid algorithms, which use GAs as search heuristic, and their main applications in data mining. Finally, we finish the chapter giving some conclusions and future trends.

BACKGROUND

Genetic Algorithms

Genetic algorithms are robust problems' solving techniques based on natural evolution processes. They are population-based algorithms, which encode a set of possible solutions to the problem, and evolve it through the application of the so called *genetic operators* (Goldberg, 1989). The standard genetic operators in a GA are:

- *Selection*, where the individuals of a new population are selected from the old one. In the standard implementation of the Selection operator, each individual has a probability of surviving for the

next generation proportional to its associated fitness (objective function) value. This procedure of selection is usually called roulette wheel selection mechanism.

- *Crossover*, where new individuals are searched starting from couples of individuals in the population. Once the couples are randomly selected, the individuals have the possibility of swapping parts of themselves with its couple, the probability of this happens is usually called *crossover probability*, *P_c*.
- *Mutation*, where new individuals are searched by randomly changing bits of current individuals with a low probability *P_m* (*probability of mutation*).

Operators for Enhancing Genetic Algorithms' Performance

Enhancing genetic algorithms with different new operators or local search algorithms to improve their performance in difficult problems is not a new topic. From the beginning of the use of these algorithms, researchers noted that there were applications too difficult to be successfully solved by the conventional GA. Thus, the use of new operators and the hybridization with other heuristics were introduced as mechanisms to improve GAs performance in many difficult problems.

The use of new operators is almost always forced by the problem encoding, usually in problems with constraints. The idea is to use the local knowledge about the problem by means of introducing these operators. Usually they are special *Crossover* and *Mutation* operators which results in feasible individuals. As an example, a *partially mapped crossover* operator is introduced when the encoding of the problem are permutations. Another example of special operators is the restricted search operators, which reduces the search space size, as we will describe later.

Another possibility to enhance the performance of GAs in difficult applications is their hybridization with local search heuristics. There are a wide variety of local search heuristics to be used in hybrid and memetic algorithms, neural networks, simulated annealing, tabu search or just hill-climbing, are some of the local heuristics used herein (Krasnogor & Smith, 2005). When the GA individual is modified after the application of the local search heuristic, the hybrid or memetic algorithm is called *Lamarckian* algorithm[1]. If the local heuristic does not modify the individual, but only its fitness value, it is called a *Baldwin* effect algorithm.

MAIN THRUST

Restricted Search in Genetic Algorithms

Encoding is an important point in genetic algorithms. Many problems in *data mining* require special encodings to be solved by means of GAs. However, the main drawback of not using a traditional binary encoding is that special operators must be used to carry on the crossover and mutation operations. Using binary encodings also have some drawback, mainly the large size of the search space in some problems. In order to reduce the search space size when using GAs with binary encoding, a restricted search operator can be used. Restricted search have been applied in different problems in data mining, such as feature selection (Salcedo-Sanz et al, 2002), (Salcedo-Sanz et al. 2004) or web mining (Salcedo-Sanz & Su, 2006). It consists of an extra operator to be added to the traditional selection, crossover and mutation. This new operator fixes the number of 1s that a given individual can have to a maximum of *p*, reducing the number of 1s if there are more than *p*, and adding 1s at random positions if there are less than *p*. This operation reduces the search space from 2^m to

$$\binom{m}{p},$$

being *m* the length of the binary strings that the GA encodes. Figure 1 shows the outline of the restricted search operator.

Hybrid and Memetic Algorithms

Hybrid algorithms are usually constituted by a genetic algorithm with a local search heuristic to repair infeasible individuals or to calculate the fitness function of the individual. They are specially used in constrained problems, where obtaining feasible individuals randomly is not a trivial task. No impact of the local search in the improvement fitness function value of

Figure 1. Outline of the restricted search operator

The restricted search operator

```
Select m (number of features) before running the GA
for every generation of the GA
    for every individual of the GA population
        check the number of 1s p.
            if(p < m)
                Add_ones(m − p);
            else
                Remove_ones(p − m)
            end(if)
    end(individual)
end(generation)
```

the individual is considered. Usually, the local search heuristic in hybrid genetic algorithms are repairing algorithms, such as Hopfield networks (Salcedo-Sanz et al. 2003), or specific repairing heuristics (Reichelt & Rothlauf, 2005). Other types of neural networks or support vector machines can be embedded if the objective of the local search is to calculate the fitness value of the individual (Sepúlveda-Sanchis, 2002).

The concept of *memetic algorithms* is slightly different. They are also population-based algorithms with a local search, but in this case the local search heuristic has the objective of improving the fitness function exclusively, without reparing anything in the individual.

Examples of memetic algorithms are (Krasnogor & Smith, 2005) (Hart, Krasnogor & Smith, 2005). Usually the local search heuristics used are hill-climbing, tabu search or simulated annealing.

Applications

The restricted search in genetic algorithms has been applied mainly to problems of feature selection and web mining. Salcedo-Sanz et al. introduced this concept in (Salcedo-Sanz et al. 2002) to improve the performance of a wrapper genetic algorithm in the problem of obtaining the best feature selection subset. This application was also the subject of the work (Salcedo-Sanz et al. 2004). An application of the restricted search to inductive query by example can be found in (Salcedo-Sanz & Su, 2006).

Hybrid genetic and memetic algorithms have been also applied to many classification and performance tuning applications in the domain of knowledge discovery in databases (KDD). There are a lot of applications of these approaches to feature selection: (Chakraborty, 2005) proposed a hybrid approach based on the hybridization of neural networks and rough sets, (Li et al. 2005) proposed a hybrid genetic algorithm with a support vector machine as wrapper approach to the problem and (Sabourin, 2005) proposed a multi-objective memetic algorithm for intelligent feature extraction.

Other applications of hybrid and memetic algorithms in data mining are (Buchtala et al., 2005), (Carvalho & Freitas, 2001), (Carvalho & Freitas, 2004), (Carvalho & Freitas, 2002), (Ishibuchi & Yamamoto, 2004), (Freitas, 2001), (Raymer et al. 2003), (Won & Leung, 2004) and in clustering (Cotta & Moscato, 2003), (Cotta & al., 2003), (Merz & Zell, 2003), (Speer et al. 2003), (Vermeulen-Jourdan et al. 2004).

FUTURE TRENDS

The use of hybrid and memetic algorithms is at present a well established trend in data mining applications.

The main drawback of these techniques is, however, the requirement of large computational times, mainly in applications with real databases. The research in hybrid algorithms is focused on developing novel hybrid techniques with low computational time, and still good performance. Also related to this point, it is well known the one of the main drawbacks of applying GAs to data mining is the number of *calls* to the fitness function. Researchers are working for trying to reduce as much as possible the number of scans over the databases in data mining algorithms. To this end, approximation algorithms to the fitness function can be considered, and it is an important line of research in the application of hybrid algorithms to data mining applications.

Also, new heuristic approaches have been discovered in the last few years, such that the *swarm particle optimization* algorithm (Palmer et al. 2005), or the *scattered search* (Glover et al. 2003), which can be successfully hybridized with genetic algorithm in some data mining applications.

CONCLUSION

Hybrid and memetic algorithms are interesting possibilities for enhancing the performance of genetic algorithms in difficult problems. Hybrid algorithms consist of a genetic algorithm with a local search for avoiding infeasible individuals. Also, it can be considered hybrid genetic algorithms those approaches whose fitness calculation involves a specific classifier or regressor. This way, the return of this fitness serves for optimization.

In this chapter, we have revised definitions of memetic algorithms, and how the local search serves to improve GAs individual fitness. Heuristics such as Tabu search, simulated annealing or hill climbing are the most used local search algorithms in memetic approaches. In this chapter, we have studied also other possibilities different from hybrid approaches: special operators for reducing the search space size of genetic algorithms. We have presented one of these possibilities, the restricted search, which has been useful in different applications in the field of feature selection in data mining. Certainly, data mining applications are appealing problems to be tackled with hybrid and memetic algorithms. The election of the encoding, local search heuristic and parameters of the genetic algorithm are the keys to obtain a good approach to this kind of problems.

KEY TERMS

Baldwin Effect Hybrid Algorithms: In hybrid genetic algorithms, a *Baldwin effect* approach is an algorithm in which the local search does not modify the individual genotype, but only its fitness value.

Fitness Function: In a genetic algorithm, the objective function of the problem is often called *fitness function*, since it measures how well an individual is adapted to its environment (i.e. how good is a given potential solution to the problem we are solving).

Genetic Algorithm: Meta-heuristic technique based on the principles of natural evolution and selection. It is a population based algorithm, where potential solutions (individuals) are evolved through the successive applications of *operators*, such as selection, crossover and mutation.

Hybrid Genetic Algorithms: A kind of global-local search algorithms, formed by a genetic algorithm as global search heuristic, and a local search procedure for ensuring the feasibility of the individuals in the genetic algorithm.

Lamarckian Hybrid Algorithms: In hybrid genetic algorithms, a *Lamarckian* approach is an algorithm in which the local search modifies the individual genotype after its application.

Memetic Algorithm: A hybrid algorithm in which the local search is used as another operator for improving the fitness of the individual.

Simulated Annealing: Another meta-heuristic algorithm also used as local search in memetic and hybrid algorithms. It is inspired by the physical process of heating a substance and then cooling it slowly, until a strong crystalline structure is obtained. This process is simulated by lowering an initial temperature by slow stages until the system reaches to an equilibrium point, and no more changes occur. Each stage of the process consists in changing the configuration several times, until a thermal equilibrium is reached, and a new stage starts, with a lower temperature. The solution of the problem is the configuration obtained in the last stage.

Tabu Search: Meta-heuristic often used as local search in memetic algorithms. It is based on a potential solution to the problem, which is mutated to obtain new solutions from the current one (neighborhood). A *tabu list* is implemented in order to avoid obtaining a solution already visited.

ENDNOTE

[1] The Lamarckian evolution theory states the idea that an organism can acquire characteristics during its life-time and pass them on to its offspring. In the so-called Lamarckian learning the traits acquired during the learning process are passed from parents to their offspring. This means that both the genetic structure of an individual and its associated fitness value are modified to reflect the changes in phenotype structure as a result of performing local search (Whitley et al. 1994).

Imprecise Data and the Data Mining Process

Marvin L. Brown
Grambling State University, USA

John F. Kros
East Carolina University, USA

INTRODUCTION

Missing or inconsistent data has been a pervasive problem in data analysis since the origin of data collection. The management of missing data in organizations has recently been addressed as more firms implement large-scale enterprise resource planning systems (see Vosburg & Kumar, 2001; Xu et al., 2002). The issue of missing data becomes an even more pervasive dilemma in the knowledge discovery process, in that as more data is collected, the higher the likelihood of missing data becomes.

The objective of this research is to discuss imprecise data and the data mining process. The article begins with a background analysis, including a brief review of both seminal and current literature. The main thrust of the chapter focuses on reasons for data inconsistency along with definitions of various types of missing data. Future trends followed by concluding remarks complete the chapter.

BACKGROUND

The analysis of missing data is a comparatively recent discipline. However, the literature holds a number of works that provide perspective on missing data and data mining. Afifi and Elashoff (1966) provide an early seminal paper reviewing the missing data and data mining literature. Little and Rubin's (1987) milestone work defined three unique types of missing data mechanisms and provided parametric methods for handling these types of missing data. These papers sparked numerous works in the area of missing data. Lee and Siau (2001) present an excellent review of data mining techniques within the knowledge discovery process. The references in this section are given as suggested reading for any analyst beginning their research in the area of data mining and missing data.

MAIN THRUST

The article focuses on the reasons for data inconsistency and the types of missing data. In addition, trends regarding missing data and data mining are discussed along with future research opportunities and concluding remarks.

REASONS FOR DATA INCONSISTENCY

Data inconsistency may arise for a number of reasons, including:

- Procedural Factors
- Refusal of Response
- Inapplicable Responses

These three reasons tend to cover the largest areas of missing data in the data mining process.

Procedural Factors

Data entry errors are common and their impact on the knowledge discovery process and data mining can generate serious problems. Inaccurate classifications, erroneous estimates, predictions, and invalid pattern recognition may also take place. In situations where databases are being refreshed with new data, blank responses from questionnaires further complicate the data mining process. If a large number of similar respondents fail to complete similar questions, the deletion or misclassification of these observations can take the researcher down the wrong path of investigation or lead to inaccurate decision-making by end users.

Refusal of Response

Some respondents may find certain survey questions offensive or they may be personally sensitive to certain

questions. For example, some respondents may have no opinion regarding certain questions such as political or religious affiliation. In addition, questions that refer to one's education level, income, age or weight may be deemed too private for some respondents to answer.

Furthermore, respondents may simply have insufficient knowledge to accurately answer particular questions. Students or inexperienced individuals may have insufficient knowledge to answer certain questions (such as salaries in various regions of the country, retirement options, insurance choices, etc).

Inapplicable Responses

Sometimes questions are left blank simply because the questions apply to a more general population rather than to an individual respondent. If a subset of questions on a questionnaire does not apply to the individual respondent, data may be missing for a particular expected group within a data set. For example, adults who have never been married or who are widowed or divorced are likely to not answer a question regarding years of marriage.

TYPES OF MISSING DATA

The following is a list of the standard types of missing data:

- Data Missing at Random
- Data Missing Completely at Random
- Non-Ignorable Missing Data
- Outliers Treated as Missing Data

It is important for an analyst to understand the different types of missing data before they can address the issue. Each type of missing data is defined next.

[Data] Missing at Random (MAR)

Rubin (1978), in a seminal missing data research paper, defined missing data as MAR "when given the variables X and Y, the probability of response depends on X but not on Y." Cases containing incomplete data must be treated differently than cases with complete data. For example, if the likelihood that a respondent will provide his or her weight depends on the probability that the respondent will not provide his or her age, then the missing data is considered to be Missing At Random (MAR) (Kim, 2001).

[Data] Missing Completely at Random (MCAR)

Kim (2001), based on an earlier work, classified data as MCAR when "the probability of response [shows that] independence exists between X and Y." MCAR data exhibits a higher level of randomness than does MAR. In other words, the observed values of Y are truly a random sample for all values of Y, and no other factors included in the study may bias the observed values of Y.

Consider the case of a laboratory providing the results of a chemical compound decomposition test in which a significant level of iron is being sought. If certain levels of iron are met or missing entirely and no other elements in the compound are identified to correlate then it can be determined that the identified or missing data for iron is MCAR.

Non-Ignorable Missing Data

In contrast to the MAR situation where data missingness is explained by other measured variables in a study; non-ignorable missing data arise due to the data missingness pattern being explainable — and only explainable — by the very variable(s) on which the data are missing.

For example, given two variables, X and Y, data is deemed Non-Ignorable when the probability of response depends on variable X and possibly on variable Y. For example, if the likelihood of an individual providing his or her weight varied within various age categories, the missing data is non-ignorable (Kim, 2001). Thus, the pattern of missing data is non-random and possibly predictable from other variables in the database.

In practice, the MCAR assumption is seldom met. Most missing data methods are applied upon the assumption of MAR. And in correspondence to Kim (2001), "Non-Ignorable missing data is the hardest condition to deal with, but unfortunately, the most likely to occur as well."

Outliers Treated as Missing Data

Many times it is necessary to classify these outliers as missing data. Pre-testing and calculating threshold

boundaries are necessary in the pre-processing of data in order to identify those values which are to be classified as missing. Data whose values fall outside of predefined ranges may skew test results. Consider the case of a laboratory providing the results of a chemical compound decomposition test. If it has been predetermined that the maximum amount of iron that can be contained in a particular compound is 500 parts/million, then the value for the variable "iron" should never exceed that amount. If, for some reason, the value does exceed 500 parts/million, then some visualization technique should be implemented to identify that value. Those offending cases are then presented to the end users.

COMMONLY USED METHODS OF ADDRESSING MISSING DATA

Several methods have been developed for the treatment of missing data. The simplest of these methods can be broken down into the following categories:

- Use Of Complete Data Only
- Deleting Selected Cases Or Variables
- Data Imputation

These categories are based on the randomness of the missing data, and how the missing data is estimated and used for replacement. Each category is discussed next.

Use of Complete Data Only

Use of complete data only is generally referred to as the "complete case approach" and is readily available in all statistical analysis packages. When the relationships within a data set are strong enough to not be significantly affected by missing data, large sample sizes may allow for the deletion of a predetermined percentage of cases. While the use of complete data only is a common approach, the cost of lost data and information when cases containing missing value are simply deleted can be dramatic. Overall, this method is best suited to situations where the amount of missing data is small and when missing data is classified as MCAR.

Delete Selected Cases or Variables

The simple deletion of data that contains missing values may be utilized when a non-random pattern of missing data is present. However, it may be ill-advised to eliminate ALL of the samples taken from a test. This method tends to be the method of last choice.

Data Imputation Methods

A number of researchers have discussed specific imputation methods. Seminal works include Little & Rubin (1987), and Rubin (1978) has published articles regarding imputation methodologies. Imputation methods are procedures resulting in the replacement of missing values by attributing them to other available data. This research investigates the most common imputation methods including:

- Case Deletion
- Mean Substitution
- Cold Deck Imputation
- Hot Deck Imputation
- Regression Imputation

These methods were chosen mainly as they are very common in the literature and their ease and expediency of application (Little & Rubin, 1987). However, it has been concluded that although imputation is a flexible method for handling missing-data problems it is not without its drawbacks. Caution should be used when employing imputation methods as they can generate substantial biases between real and imputed data. Nonetheless, imputation methods tend to be a popular method for addressing the issue of missing data.

Case Deletion

The simple deletion of data that contains missing values may be utilized when a nonrandom pattern of missing data is present. Large sample sizes permit the deletion of a predetermined percentage of cases, and/or when the relationships within the data set are strong enough to not be significantly affected by missing data. Case deletion is not recommended for small sample sizes or when the user knows strong relationships within the data exist.

Mean Substitution

This type of imputation is accomplished by estimating missing values by using the mean of the recorded or available values. It is important to calculate the mean only from valid responses that are chosen from a verified population having a normal distribution. If the data distribution is skewed, the median of the available data can be used as a substitute.

The main advantage of mean substitution is its ease of implementation and ability to provide all cases with complete information. Although a common imputation method, three main disadvantages to mean substitution do exist:

- Understatement of variance
- Distortion of actual distribution of values – mean substitution allows more observations to fall into the category containing the calculated mean than may actually exist
- Depression of observed correlations due to the repetition of a constant value

Obviously, a researcher must weigh the advantages against the disadvantages before implementation.

Cold Deck Imputation

Cold deck imputation methods select values or use relationships obtained from sources other than the current data. With this method, the end user substitutes a constant value derived from external sources or from previous research for the missing values. It must be ascertained by the end user that the replacement value used is more valid than any internally derived value. Unfortunately, feasible values are not always provided using cold deck imputation methods. Many of the same disadvantages that apply to the mean substitution method apply to cold deck imputation. Cold deck imputation methods are rarely used as the sole method of imputation and instead are generally used to provide starting values for hot deck imputation methods.

Hot Deck Imputation

Generally speaking, hot deck imputation replaces missing values with values drawn from the next most similar case. The implementation of this imputation method results in the replacement of a missing value with a value selected from an estimated distribution of similar responding units for each missing value. In most instances, the empirical distribution consists of values from responding units. For example, *Table 1* displays a data set containing missing data.

From *Table 1*, it is noted that case three is missing data for item four. In this example, case one, two, and four are examined. Using hot deck imputation, each of the other cases with complete data is examined and the value for the most similar case is substituted for the missing data value. Case four is easily eliminated, as it has nothing in common with case three. Case one and two both have similarities with case three. Case one has one item in common whereas case two has two items in common. Therefore, case two is the most similar to case three.

Once the most similar case has been identified, hot deck imputation substitutes the most similar complete case's value for the missing value. Since case two contains the value of 23 for item four, a value of 23 replaces the missing data point for case three. The advantages of hot deck imputation include conceptual simplicity, maintenance and proper measurement level of variables, and the availability of a complete set of data at the end of the imputation process that can be analyzed like any complete set of data. One of hot deck's disadvantages is the difficulty in defining what is "similar," Hence, many different schemes for deciding on what is "similar" may evolve.

Regression Imputation

Regression Analysis is used to predict missing values based on the variable's relationship to other variables in the data set. Single and/or multiple regression can be used to impute missing values. The first step consists of identifying the independent variables and the

Table 1. Illustration of hot deck imputation: incomplete data set

Case	Item 1	Item 2	Item 3	Item 4
1	10	22	30	25
2	23	20	30	23
3	25	20	30	**???**
4	11	25	10	12

dependent variable. In turn, the dependent variable is regressed on the independent variables. The resulting regression equation is then used to predict the missing values. *Table 2* displays an example of regression imputation.

From the table, twenty cases with three variables (income, age, and years of college education) are listed. Income contains missing data and is identified as the dependent variable while age and years of college education are identified as the independent variables.

The following regression equation is produced for the example

$$\hat{y} = \$79{,}900.95 + \$268.50(\text{age}) + \$2{,}180{,}97(\text{years of college education})$$

Predictions of income can be made using the regression equation and the right-most column of the table displays these predictions. For cases eighteen, nineteen, and twenty, income is predicted to be $107,591.43, $98,728.24, and $101,439.40, respectfully. An advantage to regression imputation is that it preserves the variance and covariance structures of variables with missing data.

Although regression imputation is useful for simple estimates, it has several inherent disadvantages:

- Regression imputation reinforces relationships that already exist within the data – as the method is utilized more often, the resulting data becomes more reflective of the sample and becomes less generalizable
- Understates the variance of the distribution
- An implied assumption that the variable being estimated has a substantial correlation to other attributes within the data set
- Regression imputation estimated value is not constrained and therefore may fall outside predetermined boundaries for the given variable

In addition to these points, there is also the problem of over-prediction. Regression imputation may lead to over-prediction of the model's explanatory power. For example, if the regression R^2 is too strong, multicollinearity most likely exists. Otherwise, if the R^2 value is modest, errors in the regression prediction equation will be substantial. Overall, regression imputation not only estimates the missing values but also derives inferences for the population.

Table 2. Illustration of regression imputation

Case	Income	Age	Years of College Education	Regression Prediction
1	$95,131.25	26	4	$96,147.60
2	$108,664.75	45	6	$104,724.04

20	???	39	5	$101,439.40

FUTURE TRENDS

Poor data quality has plagued the knowledge discovery process and all associated data mining techniques. Future data mining systems should be sensitive to noise and have the ability to deal with all types of data pollution, both internally and in conjunction with end users. Systems should still produce the most significant findings from the data set possible even if noise is present.

As data mining continues to evolve and mature as a viable business tool, it will be monitored to address its role in the technological life cycle. Tools for dealing with missing data will grow from being used as a horizontal solution (not designed to provide business-specific end solutions) into a type of vertical solution (integration of domain-specific logic into data mining

solutions). As gigabyte-, terabyte-, and petabyte-size data sets become more prevalent in data warehousing applications, the issue of dealing with missing data will itself become an integral solution for the use of such data rather than simply existing as a component of the knowledge discovery and data mining processes (Han & Kamber, 2001).

Although the issue of statistical analysis with missing data has been addressed since the early 1970s, the advent of data warehousing, knowledge discovery, data mining and data cleansing has pushed the concept of dealing with missing data into the limelight. Brown & Kros (2003) provide an overview of the trends, techniques, and impacts of imprecise data on the data mining process related to the *k*-Nearest Neighbor Algorithm, Decision Trees, Association Rules, and Neural Networks.

CONCLUSION

It can be seen that future generations of data miners will be faced with many challenges concerning the issues of missing data. This article gives a background analysis and brief literature review of missing data concepts. The authors addressed reasons for data inconsistency and methods for addressing missing data. Finally, the authors offered their opinions on future developments and trends on issues expected to face developers of knowledge discovery software and the needs of end users when confronted with the issues of data inconsistency and missing data.

KEY TERMS

[Data] Missing Completely at Random (MCAR): When the observed values of a variable are truly a random sample of all values of that variable (i.e., the response exhibits independence from any variables).

Data Imputation: The process of estimating missing data of an observation based on the valid values of other variables.

Data Missing at Random (MAR): When given the variables X and Y, the probability of response depends on X but not on Y.

Inapplicable Responses: Respondents omit answer due to doubts of applicability.

Knowledge Discovery Process: The overall process of information discovery in large volumes of warehoused data.

Non-Ignorable Missing Data: Arise due to the data missingness pattern being explainable, non-random, and possibly predictable from other variables.

Procedural Factors: Inaccurate classifications of new data, resulting in classification error or omission.

Refusal of Response: Respondents outward omission of a response due to personal choice, conflict, or inexperience.

Incremental Learning

Abdelhamid Bouchachia
University of Klagenfurt, Austria

INTRODUCTION

Data mining and knowledge discovery is about creating a comprehensible model of the data. Such a model may take different forms going from simple association rules to complex reasoning system. One of the fundamental aspects this model has to fulfill is adaptivity. This aspect aims at making the process of knowledge extraction continually maintainable and subject to future update as new data become available. We refer to this process as *knowledge learning*.

Knowledge learning systems are traditionally built from data samples in an off-line one-shot experiment. Once the learning phase is exhausted, the learning system is no longer capable of learning further knowledge from new data nor is it able to update itself in the future. In this chapter, we consider the problem of incremental learning (IL). We show how, in contrast to off-line or batch learning, IL learns knowledge, be it symbolic (e.g., rules) or sub-symbolic (e.g., numerical values) from data that evolves over time. The basic idea motivating IL is that as new data points arrive, new knowledge elements may be created and existing ones may be modified allowing the knowledge base (respectively, the system) to evolve over time. Thus, the acquired knowledge becomes self-corrective in light of new evidence. This update is of paramount importance to ensure the adaptivity of the system. However, it should be meaningful (by capturing only interesting events brought by the arriving data) and sensitive (by safely ignoring unimportant events). Perceptually, IL is a fundamental problem of cognitive development. Indeed, the perceiver usually learns how to make sense of its sensory inputs in an incremental manner via a filtering procedure.

In this chapter, we will outline the background of IL from different perspectives: machine learning and data mining before highlighting our IL research, the challenges, and the future trends of IL.

BACKGROUND

IL is a key issue in applications where data arrives over long periods of time and/or where storage capacities are very limited. Most of the knowledge learning literature reports on learning models that are one-shot experience. Once the learning stage is exhausted, the induced knowledge is no more updated. Thus, the performance of the system depends heavily on the data used during the learning (knowledge extraction) phase. Shifts of trends in the arriving data cannot be accounted for.

Algorithms with an IL ability are of increasing importance in many innovative applications, e.g., video streams, stock market indexes, intelligent agents, user profile learning, etc. Hence, there is a need to devise learning mechanisms that are able of accommodating new data in an incremental way, while keeping the system under use. Such a problem has been studied in the framework of adaptive resonance theory (Carpenter et al., 1991). This theory has been proposed to efficiently deal with the stability-plasticity dilemma. Formally, a learning algorithm is totally stable if it keeps the acquired knowledge in memory without any catastrophic forgetting. However, it is not required to accommodate new knowledge. On the contrary, a learning algorithm is completely plastic if it is able to continually learn new knowledge without any requirement on preserving the knowledge previously learned. The dilemma aims at accommodating new data (plasticity) without forgetting (stability) by generating knowledge elements over time whenever the new data conveys new knowledge elements worth considering.

Basically there are two schemes to accommodate new data. To retrain the algorithm from scratch using both old and new data is known as revolutionary strategy. In contrast, an evolutionary continues to train the algorithm using only the new data (Michalski, 1985). The first scheme fulfills only the stability requirement, whereas the second is a typical IL scheme that is able to fulfill both stability and plasticity. The goal is to make

a tradeoff between the stability and plasticity ends of the learning spectrum as shown in Figure 1.

As noted in (Polikar et al., 2000), there are many approaches referring to some aspects of IL. They exist under different names like *on-line learning*, *constructive learning*, *lifelong learning*, and *evolutionary learning*. Therefore, a definition of IL turns out to be vital:

- IL should be able to accommodate plasticity by learning knowledge from new data. This data can refer either to the already known structure or to a new structure of the system.
- IL can use only new data and should not have access at any time to the previously used data to update the existing system.
- IL should be able to observe the stability of the system by avoiding forgetting.

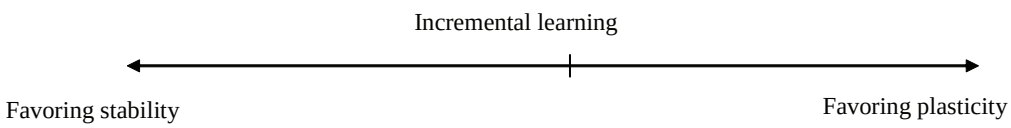
It is worth noting that the IL research flows in three directions: clustering, classification, and rule associations mining. In the context of classifcation and clustering, many IL approaches have been introduced. A typical incremental approach is discussed in (Parikh & Polikar, 2007) which consists of combining an ensemble of multilayer perceptron networks (MLP) to accommodate new data. Note that stand-alone MLPs, like many other neural networks, need retraining in order to learn from the new data. Other IL algorithms were also proposed as in (Domeniconi & Gunopulos, 2001), where the aim is to construct incremental support vector machine classifiers. Actually, there exist four neural models that are inherently incremental: (i) adaptive resonance theory (ART) (Carpenter et al., 1991), (ii) min-max neural networks (Simpson, 1992), (iii) nearest generalized exemplar (Salzberg, 1991), and (iv) neural gas model (Fritzke, 1995). The first three incremental models aim at learning hyper-rectangle categories, while the last one aims at building point-prototyped categories.

It is important to mention that there exist many classification approaches that are referred to as IL approaches and which rely on neural networks. These range from retraining misclassified samples to various weighing schemes (Freeman & Saad, 1997; Grippo, 2000). All of them are about sequential learning where input samples are sequentially, but iteratively, presented to the algorithm. However, sequential learning works only in close-ended environments where classes to be learned have to be reflected by the readily available training data and more important prior knowledge can also be forgotten if the classes are unbalanced.

In contrast to sub-symbolic learning, few authors have studied incremental symbolic learning, where the problem is incrementally learning simple classification rules (Maloof & Michalski, 2004; Reinke & Michalski, 1988).

In addition, the concept of incrementality has been discussed in the context of association rules mining (ARM). The goal of ARM is to generate all association rules in the form of $X \rightarrow Y$ that have support and confidence greater than a user-specified minimum support and minimum confidence respectively. The motivation underlying incremental ARM stems from the fact that databases grow over time. The association rules mined need to be updated as new items are inserted in the database. Incremental ARM aims at using only the incremental part to infer new rules. However, this is usually done by processing the incremental part separately and scanning the older database if necessary. Some of the algorithms proposed are FUP (Cheung et al., 1996), temporal windowing (Rainsford et al., 1997), and DELI (Lee & Cheung, 1997).

Figure 1. Learning spectrum



In contrast to static databases, IL is more visible in data stream ARM. The nature of data imposes such an incremental treatment of data. Usually data continually arrives in the form of high-speed streams. IL is particularly relevant for online streams since data is discarded as soon as it has been processed. Many algorithms have been introduced to maintain association rules (Charikar et al., 2004; Gama et al., 2007). Furthermore, many classification clustering algorithm, which are not fully incremental, have been developed in the context of stream data (Aggarwal et al., 2004; Last, 2002).

FOCUS

IL has a large spectrum of investigation facets. We shall focus in the following on classification and clustering which are key issues in many domains such as data mining, pattern recognition, knowledge discovery, and machine learning. In particular, we focus on two research avenues which we have investigated: (i) incremental fuzzy classifiers (IFC) (Bouchachia & Mittermeir, 2006) and (ii) incremental learning by function decomposition (IFD) (Bouchachia, 2006a).

The motivation behind IFC is to infer knowledge in the form of fuzzy rules from data that evolves over time. To accommodate IL, appropriate mechanisms are applied in all steps of the fuzzy system construction:

1. **Incremental supervised clustering:** Given a labeled data set, the first step is to cluster this data with the aim of achieving high purity and separability of clusters. To do that, we have introduced a clustering algorithm that is *incremental* and *supervised*. These two characteristics are vital for the whole process. The resulting labeled clusters' prototypes are projected onto each feature axis to generate some fuzzy partitions.
2. **Fuzzy partitioning and accommodation of change:** Fuzzy partitions are generated relying on two steps: Initially, each cluster is mapped onto a triangular partition. In order to optimize the shape of the partitions, the number and the complexity of rules, an aggregation of these triangular partitions is performed. As new data arrives, these partitions are systematically updated without referring to the previously used data. The consequent of rules are then accordingly updated.
3. **Incremental feature selection:** To find the most relevant features (which results in compact and transparent rules), an *incremental version* of Fisher's interclass separability criterion is devised. As new data arrives, some features may be substituted for new ones in the rules. Hence, the rules' premises are dynamically updated. At any time of the life of a classifier, the rule base should reflect the semantic contents of the already used data. To the best of our knowledge, there is no previous work on feature selection algorithms that observe the notion of *incrementality*.

In another research axis, IL has been thoroughly investigated in the context of neural networks. In (Bouchachia, 2006a) we have proposed a novel IL algorithm based on function decomposition (ILFD) that is realized by a neural network. ILFD uses clustering and vector quantization techniques to deal with classification tasks. The main motivation behind ILFD is to enable an on-line classification of data lying in different regions of the space allowing to generate non-convex partitions and, more generally, to generate disconnected partitions (not lying in the same contiguous space). Hence, each class can be approximated by a sufficient number of categories centered around their prototypes. Furthermore, ILFD differs from the aforementioned learning techniques (Sec. Background) with respect to the following aspects:

- Most of those techniques rely on geometric shapes to represent the categories, such as hyper-rectangles, hyper-ellipses, etc.; whereas the ILFD approach is not explicitly based on a particular shape since one can use different types of distances to obtain different shapes.
- Usually, there is no explicit mechanism (except for the neural gas model) to deal with redundant and dead categories, the ILFD approach uses two procedures to get rid of dead categories. The first is called *dispersion test* and aims at eliminating redundant category nodes. The second is called *staleness test* and aims at pruning categories that become stale.
- While all of those techniques modify the position of the winner when presenting the network with a data vector, the learning mechanism in ILFD consists of reinforcing the winning category from the class of the data vector and pushes away the

second winner from a neighboring class to reduce the overlap between categories.
- While the other approaches are either self-supervised or need to match the input with all existing categories, ILFD compares the input only with categories having the same label as the input in the first place and then with categories from other labels distinctively.
- The ILFD can also deal with the problem of partially labeled data. Indeed, even unlabeled data can be used during the training stage.

Moreover, the characteristics of ILFD can be compared to other models such as fuzzy ARTMAP (FAM), min-max neural networks (MMNN), nearest generalized exemplar (NGE), and growing neural gas (GNG) as shown in Table 1 (Bouchachia et al., 2007).

In our research, we have tried to stick to the spirit of IL. To put it clearly, an IL algorithm, in our view, should fulfill the following characteristics:

- Ability of life-long learning and to deal with plasticity and stability
- Old data is never used in subsequent stages
- No prior knowledge about the (topological) structure of the system is needed
- Ability to incrementally tune the structure of the system
- No prior knowledge about the statistical properties of the data is needed
- No prior knowledge about the number of existing classes and the number of categories per class and no prototype initialization are required.

FUTURE TRENDS

The problem of incrementality remains a key aspect in learning systems. The goal is to achieve adaptive systems that are equipped with self-correction and evolution mechanisms. However, many issues, which can be seen as shortcomings of existing IL algorithms, remain open and therefore worth investigating:

- **Order of data presentation:** All of the proposed IL algorithms suffer from the problem of sensitivity to the order of data presentation. Usually, the inferred classifiers are biased by this order. Indeed

Table 1. Characteristics of some IL algorithms

Characteristics	FAM	MMNN	NGE	GNG	ILFD
Online learning	Y	Y	Y	Y	Y
Type of prototypes	Hyperbox	Hyperbox	Hyperbox	Graph node	Cluster center
Generation control	Y	Y	Y	Y	Y
Shrinking of prototypes	N	Y	Y	U	U
Deletion of prototypes	N	N	N	Y	Y
Overlap of prototypes	Y	N	N	U	U
Growing of prototypes	Y	Y	Y	U	U
Noise resistance	U	Y	U	U	U
Sensitivity to data order	Y	Y	Y	Y	Y
Normalization	Y	Y	Y/N	N	Y/N

Legend: Y: yes N: no U: uknown/undefined

different presentation orders result in different classifier structures and therefore in different accuracy levels. It is therefore very relevant to look closely at developing algorithms whose behavior is data-presentation independent. Usually, this is a desired property.

- **Category proliferation:** The problem of category proliferation in the context of clustering and classification refers to the problem of generating a large number of categories. This number is in general proportional to the granularity of categories. In other terms, fine category size implies large number of categories and larger size implies less categories. Usually, there is a parameter in each IL algorithm that controls the process of category generation. The problem here is: what is the appropriate value of such a parameter. This is clearly related to the problem of plasticity that plays a central role in IL algorithms. Hence, the question: how can we distinguish between rare events and outliers? What is the controlling parameter value that allows making such a distinction? This remains a difficult issue.
- **Number of parameters:** One of the most important shortcomings of the majority of the IL algorithms is the huge number of user-specified parameters that are involved. It is usually hard to find the optimal value of these parameters. Furthermore, they are very sensitive to data, i.e., in general to obtain high accuracy values, the setting requires change from one data set to another. In this context, there is a real need to develop algorithms that do not depend heavily on many parameters or which can optimize such parameters.
- **Self-consciousness & self-correction:** The problem of distinction between noisy input data and rare event is not only crucial for category generation, but it is also for correction. In the current approaches, IL systems cannot correct wrong decisions made previously, because each sample is treated once and any decision about it has to be taken at that time. Now, assume that at the processing time the sample *x* was considered a noise, while in reality it was a rare event, then in a later stage the same rare event was discovered by the system. Therefore, in the ideal case the system has to recall that the sample *x* has to be reconsidered. Current algorithms are not able to adjust the systems by re-examining old decisions. Thus, IL systems have to be equipped with some memory in order to become smarter enough.
- **Data drift:** One of the most difficult questions that is worth looking at is related to drift. Little, if none, attention has been paid to the application and evaluation of the aforementioned IL algorithms in the context of drifting data although the change of environment is one of the crucial assumptions of all these algorithms. Furthermore, there are many publicly available datasets for testing systems within static setting, but there are very few benchmark data sets for dynamically changing problems. Those existing are usually artificial sets. It is very important for the IL community to have a repository, similar to that of the Irvine UCI, in order to evaluate the proposed algorithms in evolving environments.

As a final aim, the research in the IL framework has to focus on incremental but stable algorithms that have to be transparent, self-corrective, less sensitive to the order of data arrival, and whose parameters are less sensitive to the data itself.

CONCLUSION

Building adaptive systems that are able to deal with nonstandard settings of learning is one of key research avenues in machine learning, data mining and knowledge discovery. Adaptivity can take different forms, but the most important one is certainly incrementality. Such systems are continuously updated as more data becomes available over time. The appealing features of IL, if taken into account, will help integrate intelligence into knowledge learning systems. In this chapter we have tried to outline the current state of the art in this research area and to show the main problems that remain unsolved and require further investigations.

KEY TERMS

Data Drift: Unexpected change over time of the data values (according to one or more dimensions).

Incrementality: The characteristic of an algorithm that is capable of processing data which arrives over time sequentially in a stepwise manner without referring to the previously seen data.

Knowledge Learning: Knowledge Learning: The process of automatic extracting Knowledge from data.

Plasticity: A learning algorithm is completely plastic if it is able to continually learn new knowledge without any requirement on preserving previously seen data.

Stability: A learning algorithm is totally stable if it keeps the acquired knowledge in memory without any catastrophic forgetting.

Incremental Mining from News Streams

INTRODUCTION

With the rapid growth of the World Wide Web, Internet users are now experiencing overwhelming quantities of online information. Since manually analyzing the data becomes nearly impossible, the analysis would be performed by automatic data mining techniques to fulfill users' information needs quickly.

On most Web pages, vast amounts of useful knowledge are embedded into text. Given such large sizes of text collection, mining tools, which organize the text datasets into structured knowledge, would enhance efficient document access. This facilitates information search and, at the same time, provides an efficient framework for document repository management as the number of documents becomes extremely huge.

Given that the Web has become a vehicle for the distribution of information, many news organizations are providing newswire services through the Internet. Given this popularity of the Web news services, text mining on news datasets has received significant attentions during the past few years. In particular, as several hundred news stories are published everyday at a single Web news site, triggering the whole mining process whenever a document is added to the database is computationally impractical. Therefore, efficient incremental text mining tools need to be developed.

BACKGROUND

The simplest document access method within Web news services is keyword-based retrieval. Although this method seems effective, there exist at least three serious drawbacks. First, if a user chooses irrelevant keywords, then retrieval accuracy will be degraded. Second, since keyword-based retrieval relies on the syntactic properties of information (e.g., keyword counting), *semantic gap* cannot be overcome (Grosky, Sreenath, & Fotouhi, 2002). Third, only expected information can be retrieved since the specified keywords are generated from users' knowledge space. Thus, if users are unaware of the airplane crash that occurred yesterday, then they cannot issue a query about that accident even though they might be interested.

The first two drawbacks stated above have been addressed by query expansion based on domain-independent ontologies. However, it is well known that this approach leads to a degradation of precision. That is, given that the words introduced by term expansion may have more than one meaning, using additional terms can improve recall, but decrease precision. Exploiting a manually developed ontology with a controlled vocabulary would be helpful in this situation (Khan, McLeod, & Hovy, 2004). However, although ontology-authoring tools have been developed in the past decades, manually constructing ontologies whenever new domains are encountered is an error-prone and time-consuming process. Therefore, integration of knowledge acquisition with data mining, which is referred to as *ontology learning*, becomes a must (Maedche & Staab, 2001).

To facilitate information navigation and search on a news database, clustering can be utilized. Since a collection of documents is easy to skim if similar articles are grouped together, if the news articles are hierarchically classified according to their topics, then a query can be formulated while a user navigates a cluster hierarchy. Moreover, clustering can be used to identify and deal with near-duplicate articles. That is, when news feeds repeat stories with minor changes from hour to hour, presenting only the most recent articles is probably sufficient. In particular, a sophisticated incremental

hierarchical document clustering algorithm can be effectively used to address high rate of document update. Moreover, in order to achieve rich semantic information retrieval, an ontology-based approach would be provided. However, one of the main problems with concept-based ontologies is that topically related concepts and terms are not explicitly linked. That is, there is no relation between *court-attorney*, *kidnap-police*, and etcetera. Thus, concept-based ontologies have a limitation in supporting a topical search. In sum, it is essential to develop incremental text mining methods for intelligent news information presentation.

MAIN THRUST

In the following, we will explore text mining approaches that are relevant for news streams data.

Requirements of Document Clustering in News Streams

Data we are considering are high dimensional, large in size, noisy, and a continuous stream of documents. Many previously proposed document clustering algorithms did not perform well on this dataset due to a variety of reasons. In the following, we define application-dependent (in terms of news streams) constraints that the clustering algorithm must satisfy.

1. **Ability to determine input parameters:** Many clustering algorithms require a user to provide input parameters (e.g., the number of clusters), which is difficult to be determined in advance, in particular when we are dealing with incremental datasets. Thus, we expect the clustering algorithm not to need such kind of knowledge.
2. **Scalability with large number of documents:** The number of documents to be processed is extremely large. In general, the problem of clustering *n* objects into *k* clusters is NP-hard. Successful clustering algorithms should be scalable with the number of documents.
3. **Ability to discover clusters with different shapes and sizes:** The shape of document cluster can be of arbitrary shapes; hence we cannot assume the shape of document cluster (e.g., hyper-sphere in *k*-means). In addition, the sizes of clusters can be of arbitrary numbers, thus clustering algorithms should identify the clusters with wide variance in size.
4. **Outliers Identification:** In news streams, outliers have a significant importance. For instance, a unique document in a news stream may imply a new technology or event that has not been mentioned in previous articles. Thus, forming a singleton cluster for the outlier is important.
5. **Efficient incremental clustering:** Given different ordering of a same dataset, many incremental clustering algorithms produce different clusters, which is an unreliable phenomenon. Thus, the incremental clustering should be robust to the input sequence. Moreover, due to the frequent document insertion into the database, whenever a new document is inserted it should perform a fast update of the existing cluster structure.
6. **Meaningful theme of clusters:** We expect each cluster to reflect a meaningful theme. We define "meaningful theme" in terms of precision and recall. That is, if a cluster (*C*) is about "Turkey earthquake,'' then all documents about "Turkey earthquake'' should belong to *C*, and documents that do not talk about "Turkey earthquake" should not belong to *C*.
7. **Interpretability of resulting clusters:** A clustering structure needs to be tied up with a succinct summary of each cluster. Consequently, clustering results should be easily comprehensible by users.

Previous Document Clustering Approaches

The most widely used document clustering algorithms fall into two categories: partition-based clustering and hierarchical clustering. In the following, we provide a concise overview for each of them, and discuss why these approaches fail to address the requirements discussed above.

Partition-based clustering decomposes a collection of documents, which is optimal with respect to some pre-defined function (Duda, Hart, & Stork, 2001; Liu, Gong, Xu, & Zhu, 2002). Typical methods in this category include center-based clustering, Gaussian Mixture Model, and etcetera. Center-based algorithms identify the clusters by partitioning the entire dataset into a pre-determined number of clusters (e.g., *k*-means clustering). Although the center-based clustering algo-

rithms have been widely used in document clustering, there exist at least five serious drawbacks. First, in many center-based clustering algorithms, the number of clusters needs to be determined beforehand. Second, the algorithm is sensitive to an initial seed selection. Third, it can model only a spherical (*k*-means) or ellipsoidal (*k*-medoid) shape of clusters. Furthermore, it is sensitive to outliers since a small amount of outliers can substantially influence the mean value. Note that capturing an outlier document and forming a singleton cluster is important. Finally, due to the nature of an iterative scheme in producing clustering results, it is not relevant for incremental datasets.

Hierarchical (agglomerative) clustering (HAC) identifies the clusters by initially assigning each document to its own cluster and then repeatedly merging pairs of clusters until a certain stopping condition is met (Zhao & Karypis, 2002). Consequently, its result is in the form of a tree, which is referred to as a *dendrogram*. A dendrogram is represented as a tree with numeric levels associated to its branches. The main advantage of HAC lies in its ability to provide a view of data at multiple levels of abstraction. Although HAC can model arbitrary shapes and different sizes of clusters, and can be extended to the robust version (in outlier handling sense), it is not relevant for news streams application due to the following two reasons. First, since HAC builds a dendrogram, a user should determine where to cut the dendrogram to produce actual clusters. This step is usually done by human visual inspection, which is a time-consuming and subjective process. Second, the computational complexity of HAC is expensive since pairwise similarities between clusters need to be computed.

Topic Detection and Tracking

Over the past six years, the information retrieval community has developed a new research area, called TDT (Topic Detection and Tracking) (Makkonen, Ahonen-Myka, & Salmenkivi, 2004; Allan, 2002). The main goal of TDT is to detect the occurrence of a novel event in a stream of news stories, and to track the known event. In particular, there are three major components in TDT.

1. **Story segmentation:** It segments a news stream (e.g., including transcribed speech) into topically cohesive stories. Since online Web news (in HTML format) is supplied in segmented form, this task only applies to audio or TV news.
2. **First Story Detection (FSD):** It identifies whether a new document belongs to an existing topic or a new topic.
3. **Topic tracking:** It tracks events of interest based on sample news stories. It associates incoming news stories with the related stories, which were already discussed before. It can be also asked to monitor the news stream for further stories on the same topic.

Event is defined as "some unique thing that happens at some point in time". Hence, an event is different from a topic. For example, "airplane crash" is a topic while "Chinese airplane crash in Korea in April 2002" is an event. Note that it is important to identify events as well as topics. Although a user is not interested in a flood topic, the user may be interested in the news story on the Texas flood if the user's hometown is from Texas. Thus, a news recommendation system must be able to distinguish different events within a same topic.

Single-pass document clustering (Chung & McLeod, 2003) has been extensively used in TDT research. However, the major drawback of this approach lies in order-sensitive property. Although the order of documents is already fixed since documents are inserted into the database in chronological order, order-sensitive property implies that the resulting cluster is unreliable. Thus, new methodology is required in terms of incremental news article clustering.

Dynamic Topic Mining

Dynamic topic mining is a framework that supports the identification of meaningful patterns (e.g., events, topics, and topical relations) from news stream data (Chung & McLeod, 2003). To build a novel paradigm for an intelligent news database management and navigation scheme, it utilizes techniques in information retrieval, data mining, machine learning, and natural language processing.

In dynamic topic mining, a Web crawler downloads news articles from a news Web site on a daily basis. Retrieved news articles are processed by diverse information retrieval and data mining tools to produce useful higher-level knowledge, which is stored in a content description database. Instead of interacting with a Web news service directly, by exploiting the knowl-

edge in the database, an information delivery agent can present an answer in response to a user request (in terms of topic detection and tracking, keyword-based retrieval, document cluster visualization, etc). Key contributions of the dynamic topic mining framework are development of a novel hierarchical incremental document clustering algorithm, and a topic ontology learning framework.

Despite the huge body of research efforts on document clustering, previously proposed document clustering algorithms are limited in that it cannot address special requirements in a news environment. That is, an algorithm must address the seven application-dependent constraints discussed before. Toward this end, the dynamic topic mining framework presents a sophisticated incremental hierarchical document clustering algorithm that utilizes a neighborhood search. The algorithm was tested to demonstrate the effectiveness in terms of the seven constraints. The novelty of the algorithm is the ability to identify meaningful patterns (e.g., news events, and news topics) while reducing the amount of computations by maintaining cluster structure incrementally.

In addition, to overcome the lack of topical relations in conceptual ontologies, a topic ontology learning framework is presented. The proposed topic ontologies provide interpretations of news topics at different levels of abstraction. For example, regarding to a Winona Ryder court trial news topic (*T*), the dynamic topic mining could capture "winona, ryder, actress, shoplift, beverly" as specific terms describing *T* (i.e., the specific concept for *T*) while "attorney, court, defense, evidence, jury, kill, law, legal, murder, prosecutor, testify, trial" as general terms representing *T* (i.e., the general concept for *T*). There exists research work on extracting hierarchical relations between terms from a set of documents (Tseng, 2002). However, the dynamic topic mining framework is unique in that the topical relations are dynamically generated based on incremental hierarchical clustering rather than based on human defined topics, such as Yahoo directory.

FUTURE TRENDS

There are many future research opportunities in news streams mining. First, although a document hierarchy can be obtained using unsupervised clustering, as shown in Aggarwal, Gates, & Yu (2004), the cluster quality can be enhanced if a pre-existing knowledge base is exploited. That is, based on this priori knowledge, we can have some control while building a document hierarchy.

Second, document representation for clustering can be augmented with phrases by employing different levels of linguistic analysis (Hatzivassiloglou, Gravano, & Maganti, 2000). That is, representation model can be augmented by adding *n*-gram (Peng & Schuurmans, 2003), or frequent itemsets using association rule mining (Hand, Mannila, & Smyth, 2001). Investigating how different feature selection algorithms affect on the accuracy of clustering results is an interesting research work.

Third, besides exploiting text data, other information can be utilized since Web news articles are composed of text, hyperlinks, and multimedia data. For example, both terms and hyperlinks (which point to related news articles or Web pages) can be used for feature selection.

Finally, a topic ontology learning framework can be extended to accommodating rich semantic information extraction. For example, topic ontologies can be annotated within Protégé (Noy, Sintek, Decker, Crubezy, Fergerson, & Musen, 2001) WordNet tab. In addition, a query expansion algorithm based on ontologies needs to be developed for intelligent news information presentation.

CONCLUSION

Incremental text mining from news streams is an emerging technology as many news organizations are providing newswire services through the Internet. In order to accommodate dynamically changing topics, efficient incremental document clustering algorithms need to be developed. The algorithms must address the special requirements in news clustering, such as high rate of document update or ability to identify event level clusters, as well as topic level clusters.

In order to achieve rich semantic information retrieval within Web news services, an ontology-based approach would be provided. To overcome the problem of concept-based ontologies (i.e., topically related concepts and terms are not explicitly linked), topic ontologies are presented to characterize news topics at multiple levels of abstraction. In sum, coupling with topic ontologies and concept-based ontologies, support-

ing a topical search as well as semantic information retrieval can be achieved.

KEY TERMS

Clustering: An unsupervised process of dividing data into meaningful groups such that each identified cluster can explain the characteristics of underlying data distribution. Examples include characterization of different customer groups based on the customer's purchasing patterns, categorization of documents in the World Wide Web, or grouping of spatial locations of the earth where neighbor points in each region have similar short-term/long-term climate patterns.

Dynamic Topic Mining: A framework that supports the identification of meaningful patterns (e.g., events, topics, and topical relations) from news stream data.

First Story Detection: A TDT component that identifies whether a new document belongs to an existing topic or a new topic.

Ontology: A collection of concepts and inter-relationships.

Text Mining: A process of identifying patterns or trends in natural language text including document clustering, document classification, ontology learning, and etcetera.

Topic Detection And Tracking (TDT): Topic Detection and Tracking (TDT) is a DARPA-sponsored initiative to investigate the state of the art for news un-

derstanding systems. Specifically, TDT is composed of the following three major components: (1) segmenting a news stream (e.g., including transcribed speech) into topically cohesive stories; (2) identifying novel stories that are the first to discuss a new event; and (3) tracking known events given sample stories.

Topic Ontology: A collection of terms that characterize a topic at multiple levels of abstraction.

Topic Tracking: A TDT component that tracks events of interest based on sample news stories. It associates incoming news stories with the related stories, which were already discussed before or it monitors the news stream for further stories on the same topic.

Inexact Field Learning Approach for Data Mining

Honghua Dai
Deakin University, Australia

INTRODUCTION

Inexact fielding learning (IFL) (Ciesieski & Dai, 1994; Dai & Ciesieski, 1994a, 1994b, 1995, 2004; Dai & Li, 2001) is a rough-set, theory-based (Pawlak, 1982) machine learning approach that derives inexact rules from fields of each attribute. In contrast to a point-learning algorithm (Quinlan, 1986, 1993), which derives rules by examining individual values of each attribute, a field learning approach (Dai, 1996) derives rules by examining the fields of each attribute. In contrast to exact rule, an inexact rule is a rule with uncertainty. The advantage of the IFL method is the capability to discover high-quality rules from low-quality data, its property of low-quality data tolerant (Dai & Ciesieski, 1994a, 2004), high efficiency in discovery, and high accuracy of the discovered rules.

BACKGROUND

Achieving high prediction accuracy rates is crucial for all learning algorithms, particularly in real applications. In the area of machine learning, a well-recognized problem is that the derived rules can fit the training data very well, but they fail to achieve a high accuracy rate on new unseen cases. This is particularly true when the learning is performed on low-quality databases. Such a problem is referred as the Low Prediction Accuracy (LPA) problem (Dai & Ciesieski, 1994b, 2004; Dai & Li, 2001), which could be caused by several factors. In particular, overfitting low-quality data and being misled by them seem to be the significant problems that can hamper a learning algorithm from achieving high accuracy. Traditional learning methods derive rules by examining individual values of instances (Quinlan, 1986, 1993). To generate classification rules, these methods always try to find cut-off points, such as in well-known decision tree algorithms (Quinlan, 1986, 1993).

What we present here is an approach to derive rough classification rules from large low-quality numerical databases that appear to be able to overcome these two problems. The algorithm works on the fields of continuous numeric variables; that is, the intervals of possible values of each attribute in the training set, rather than on individual point values. The discovered rule is in a form called $\beta-$rule and is somewhat analogous to a decision tree found by an induction algorithm. The algorithm is linear in both the number of attributes and the number of instances (Dai & Ciesieski, 1994a, 2004).

The advantage of this inexact field-learning approach is its capability of inducing high-quality classification rules from low-quality data and its high efficiency that makes it an ideal algorithm to discover reliable knowledge from large and very large low-quality databases suitable for data mining, which needs higher discovering capability.

INEXACT FIELD-LEARNING ALGORITHM

Detailed description and the applications of the algorithm can be found from the listed articles (Ciesieski & Dai, 1994a; Dai & Ciesieski, 1994a, 1994b, 1995, 2004; Dai, 1996; Dai & Li, 2001; Dai, 1996). The following is a description of the inexact field-learning algorithm, the Fish_net algorithm:

Input: The input of the algorithm is a training data set with *m* instances and *n* attributes as follows:

Instances	X_1	X_2	...	X_n	Classes
$Instance_1$	a_{11}	a_{12}	...	a_{1n}	γ_1
$Instance_2$	a_{21}	a_{22}	...	a_{2n}	γ_2
...	...	...	...	...	...
$Instance_m$	a_{m1}	a_{m2}	...	a_{mn}	γ_m

(1)

Learning Process:

- **Step 1:** Work Out Fields of each attribute $\{x_i \mid 1 \le i \le n\}$ with respect to each class.

$$h_j^{(k)} = [h_{j_l}^{(k)}, h_{j_u}^{(k)}] \quad (k = 1,2,...,s;\ j = 1,2,...n). \tag{2}$$

$$h_{j_u}^{(k)} = \max_{a_{ij} \in a_j^{(k)}} \{a_{ij} \mid i = 1,2,...,m\} \quad (k = 1,2,...,s;\ j = 1,2,...n) \tag{3}$$

$$h_{j_l}^{(k)} = \min_{a_{ij} \in a_j^{(k)}} \{a_{ij} \mid i = 1,2,...,m\} \quad (k = 1,2,...,s;\ j = 1,2,...n). \tag{4}$$

- **Step 2:** Construct Contribution Function based on the fields found in Step 1.

$$\mu_{c_k}(x_j) = \begin{cases} 0 & x_j \in \bigcup_{i \ne k}^{s} h_j^{(i)} - h_j^{(k)} \\ 1 & x_j \in h_j^{(k)} - \bigcup_{i \ne k}^{s} h_j^{(i)} \\ \dfrac{x_j - a}{b - a} & x_j \in h_j^{(k)} \bigcap (\bigcup_{i \ne k}^{s} h_j^{(i)}) \end{cases} \quad (k = 1,2,...,s) \tag{5}$$

The formula (5) is given on the assumption that $[a,b] = h_j^{(k)} \bigcap (\bigcup_{i \ne k}^{s} h_j^{(i)})$, and for any small number $\varepsilon > 0, b \pm \varepsilon \in h_j^{(k)}$ and $a + \varepsilon \notin \bigcup_{i \ne k}^{s} h_j^{(i)}$ or $a - \varepsilon \notin \bigcup_{i \ne k}^{s} h_j^{(i)}$. Otherwise, the formula (5) becomes,

$$\mu_{c_k}(x_j) = \begin{cases} 0 & x_j \in \bigcup_{i \ne k}^{s} h_j^{(i)} - h_j^{(k)} \\ 1 & x_j \in h_j^{(k)} - \bigcup_{i \ne k}^{s} h_j^{(i)} \\ \dfrac{x_j - b}{a - b} & x_j \in h_j^{(k)} \bigcap (\bigcup_{i \ne k}^{s} h_j^{(i)}) \end{cases} \quad (k = 1,2,...,s) \tag{6}$$

- **Step 3:** Work Out Contribution Fields by applying the constructed contribution functions to the training data set.
  - Calculate the contribution of each instance.

$$\alpha(I_i) = (\sum_{j=1}^{n} \mu(x_{ij}))/n \quad (i = 1,2,...,m) \tag{7}$$

  - Work out the contribution field for each class $h^+ = < h_l^+, h_u^+ >$.

$$h_u^{(+)} = \max_{\alpha(I_i), I_i \in +} \{\alpha(I_i) \mid i = 1,2,...,m\} \tag{8}$$

$$h_l^{(+)} = \min_{\alpha(I_i), I_i \in +} \{\alpha(I_i) \mid i = 1,2,...,m\} \tag{9}$$

Similarly we can find $h^- = < h_l^-, h_u^- >$

- **Step 4:** Construct Belief Function using the derived contribution fields.

$$B_r(C) = \begin{cases} -1 & \text{Contribution} \in \text{NegativeRegion} \\ 1 & \text{Contribution} \in \text{PositiveRegion} \\ \dfrac{c - a}{b - a} & \text{Contribution} \in \text{RoughRegion} \end{cases} \tag{10}$$

- **Step 5:** Decide Threshold. It could have 6 different cases to be considered. The simplest case is to take the threshold

$$\alpha = \text{midpoint of } h^+ \text{and } h^- \tag{11}$$

- **Step 6:** Form the Inexact Rule.

$$\text{If} \quad \bar{\alpha}(I) = \frac{1}{N} \sum_{i=1}^{N} \mu(x_i) > \alpha$$
$$\text{Then} \quad \gamma = 1(B_r(c)) \tag{12}$$

This algorithm was tested on three large real observational weather data sets containing both high-quality and low-quality data. The accuracy rates of the forecasts were 86.4%, 78%, and 76.8%. These are significantly better than the accuracy rates achieved by C4.5 (Quinlan, 1986, 1993), feed forward neural networks, discrimination analysis, K-nearest neighbor classifiers, and human weather forecasters. The fish-net algorithm exhibited significantly less overfitting than the other algorithms. The training times were shorter, in some cases by orders of magnitude (Dai & Ciesieski, 1994a, 2004; Dai 1996).

FUTURE TRENDS

The inexact field-learning approach has led to a successful algorithm in a domain where there is a high

level of noise. We believe that other algorithms based on fields also can be developed. The $\beta-$rules, produced by the current FISH-NET algorithm involve linear combinations of attributes. Non-linear rules may be even more accurate.

While extensive tests have been done on the fish-net algorithm with large meteorological databases, nothing in the algorithm is specific to meteorology. It is expected that the algorithm will perform equally well in other domains. In parallel to most existing exact machine-learning methods, the inexact field-learning approaches can be used for large or very large noisy data mining, particularly where the data quality is a major problem that may not be dealt with by other data-mining approaches. Various learning algorithms can be created, based on the fields derived from a given training data set. There are several new applications of inexact field learning, such as Zhuang and Dai (2004) for Web document clustering and some other inexact learning approaches (Ishibuchi et al., 2001; Kim et al., 2003). The major trends of this approach are in the following:

1. Heavy application for all sorts of data-mining tasks in various domains.
2. Developing new powerful discovery algorithms in conjunction with IFL and traditional learning approaches.
3. Extend current IFL approach to deal with high dimensional, non-linear, and continuous problems.

CONCLUSION

The inexact field-learning algorithm: Fish-net is developed for the purpose of learning rough classification/forecasting rules from large, low-quality numeric databases. It runs high efficiently and generates robust rules that do not overfit the training data nor result in low prediction accuracy.

The inexact field-learning algorithm, fish-net, is based on fields of the attributes rather than the individual point values. The experimental results indicate that:

1. The fish-net algorithm is linear both in the number of instances and in the number of attributes. Further, the CPU time grows much more slowly than the other algorithms we investigated.
2. The Fish-net algorithm achieved the best prediction accuracy tested on new unseen cases out of all the methods tested (i.e., C4.5, feed-forward neural network algorithms, a k-nearest neighbor method, the discrimination analysis algorithm, and human experts.
3. The fish-net algorithm successfully overcame the LPA problem on two large low-quality data sets examined. Both the absolute LPA error rate and the relative LPA error rate (Dai & Ciesieski, 1994b) of the fish-net were very low on these data sets. They were significantly lower than that of point-learning approach, such as C4.5, on all the data sets and lower than the feed-forward neural network. A reasonably low LPA error rate was achieved by the feed-forward neural network but with the high time cost of error back-propagation. The LPA error rate of the KNN method is comparable to fish-net. This was achieved after a very high-cost genetic algorithm search.
4. The FISH-NET algorithm obviously was not affected by low-quality data. It performed equally well on low-quality data and high-quality data.

KEY TERMS

β-Rule: A type of inexact rule that represent the uncertainty with contribution functions and belief functions.

Exact Learning: The learning approaches that are capable of inducing exact rules.

Exact Rules: Rules without uncertainty.

Field Learning: Derives rules by looking at the field of the values of each attribute in all the instances of the training data set.

Inexact Learning: The learning by which inexact rules are induced.

Inexact Rules: Rules with uncertainty.

Low-Quality Data: Data with lots of noise, missing values, redundant features, mistakes, and so forth.

LPA (Low Prediction Accuracy) Problem: The problem when derived rules can fit the training data very well but fail to achieve a high accuracy rate on new unseen cases.

Point Learning: Derives rules by looking at each individual point value of the attributes in every instance of the training data set.

Information Fusion for Scientific Literature Classification

Gary G. Yen
Oklahoma State University, USA

INTRODUCTION

Scientific literatures can be organized to serve as a roadmap for researchers by pointing where and when the scientific community has been and is heading to. They present historic and current state-of-the-art knowledge in the interesting areas of study. They also document valuable information including author lists, affiliated institutions, citation information, keywords, etc., which can be used to extract further information that will assist in analyzing their content and relationship with one another. However, their tremendously growing size and the increasing diversity of research fields have become a major concern, especially for organization, analysis, and exploration of such documents. This chapter proposes an automatic scientific literature classification method (ASLCM) that makes use of different information extracted from the literatures to organize and present them in a structured manner. In the proposed ASLCM, multiple similarity information is extracted from all available sources and fused to give an optimized and more meaningful classification through using a genetic algorithm. The final result is used to identify the different research disciplines within the collection, their emergence and termination, major collaborators, centers of excellence, their influence, and the flow of information among the multidisciplinary research areas.

BACKGROUND

In addition to the body content, which is sometimes hard to analyze using a computer, scientific literatures incorporate essential information such as title, abstract, author, references and keywords that can be exploited to assist in the analysis and organization of a large collection (Singh, Mittal & Ahmad, 2007; Guo, 2007). This kind of analysis and organization proves helpful while dealing with a large collection of articles with a goal of attaining efficient presentation, visualization, and exploration in order to search for hidden information and useful connections lying within the collection. It can also serve as a historic roadmap that can be used to sketch the flow of information during the past and as a tool for forecasting possible emerging technologies. The ASLCM proposed in this study makes use of the above-mentioned types of information, which are available in most scientific literatures, to achieve an efficient classification and presentation of a large collection.

Many digital libraries and search engines make use of title, author, keyword, or citation information for indexing and cataloging purposes. Word-hit-based cataloging and retrieval using such types of information tends to miss related literatures that does not have the specified phrase or keyword, thus requiring the user to try several different queries to obtain the desired search result. In this chapter, these different information sources are fused to give an optimized and all-rounded view of a particular literature collection so that related literatures can be grouped and identified easily.

Title, abstract, author, keyword, and reference list are among the most common elements that are documented in typical scientific literature, such as a journal article. These sources of information can be used to characterize or represent literature in a unique and meaningful way, while performing computation for different information retrievals including search, cataloguing or organization. However, most of the methods that have been developed (Lawrence, Giles & Bollacker, 1999; Morris & Yen, 2004; White & McCain, 1998; Berry, Dramac & Jessup, 1999) use only one of these while performing the different information retrieval tasks, such as search and classification, producing results that focus only on a particular aspect of the collection. For example, usage of reference or citation information leads to a good understanding of the flow of information within the literature collection. This is because most literatures provide a link to the original base knowledge they used

within their reference list. In a similar fashion, use of information extracted from the authors list can lead to a good understanding of various author collaboration groups within the community along with their areas of expertise. This concept can be extended analogously to different information types provided by scientific literatures.

The theory behind the proposed ASLCM can be summarized and stated as follows:

- Information extracted from a particular field (e.g., citation alone) about a scientific literature collection conveys limited aspect of the real scenario.
- Most of the information documented in scientific literature can be regarded useful in some aspect toward revealing valuable information about the collection.
- Different information extracted from available sources can be fused to infer a generalized and complete knowledge about the entire collection.
- There lies an optimal proportion in which each source of information can be used in order to best represent the collection.

The information extracted from the above mentioned types of sources can be represented in the form of a matrix by using the vector space model (Salton, 1989). This model represents a document as a multi-dimensional vector. A set of selected representative features, such as keywords or citations, serves as a dimension and their frequency of occurrence in each article of interest is taken as the magnitude of that particular dimension, as shown in Equation (1).

$$M = \begin{array}{c} \\ D_1 \\ D_2 \\ \dots \\ D_n \end{array} \begin{array}{c} \begin{array}{cccc} T_1 & T_2 & \dots & T_t \end{array} \\ \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1t} \\ a_{21} & a_{22} & \dots & a_{21} \\ \dots & & & \\ a_{n1} & a_{n2} & \dots & a_{nt} \end{bmatrix} \end{array}. \quad (1)$$

In the above matrix, hereafter referred to as *adjacency matrix*, every row corresponds to a particular document and every column to a selected feature. For example, if t terms are chosen as representative features for n documents, $a_{i,j}$ corresponds to the frequency of occurrence of term j in document i. This technique of document modeling can be used to summarize and represent a collection of scientific literatures in terms of several adjacency matrices in an efficient manner. These adjacency matrices are later transformed into similarity matrices that measure the inter-document similarities so that classification, search, or other information retrieval tasks can be performed efficiently. The procedure of similarity matrix computation can be carried out by using either cosine coefficient, inner product, or dice coefficient (Jain, Murty & Flynn, 1999).

Selection of the type of similarity computation method to be used depends on the nature of the feature and the desired purpose. Once the different available inter-document similarity matrices are calculated, the information contained in each matrix can be fused into one generalized similarity matrix that can be used to classify and give a composite picture of the entire collection.

MAIN FOCUS

This chapter presents an information fusion scheme at the *similarity matrix* level in order to incorporate as much information as possible about the literature collection that would help better classify and discover hidden and useful knowledge. Information fusion is the concept of combining information obtained from multiple sources such as databases, sensors, human collected data, etc. in order to obtain a more precise and complete knowledge of a specific subject under study. The idea of information fusion is widely used in different areas such as image recognition, sensor fusion, information retrieval, etc. (Luo, Yih & Su, 2002).

Similarity Information Gathering

The scope of this research is mainly focused on similarity information extracted from bibliographic citations, author information, and word content analysis.

Bibliographic Citation Similarity: Given a collection of n documents and m references, an $n \times m$ paper-reference representation matrix PR can be formed, where P stands for paper and R for references. Here usually m tends to be much larger than n because a paper commonly cites more than one reference and different papers have different reference lists. An element of the PR matrix, $PR(i, j)$, is set to one if reference j is cited in paper i. As a result, this matrix is normally a sparse matrix with most of its entities having a value of zero. Having this PR matrix, the *citation similarity*

matrix can be calculated using the dice coefficient as follows:

$$S_r(i, j) = \frac{2 \times C_r(i, j)}{N_r(i) + N_r(j)} \quad (2)$$

where $S_r(i, j)$ is the citation similarity between documents i and j, $N_r(i)$ is the number of total references in document i, and C_r is a reference co-occurrence matrix, which can be calculated as $C_r = PR \times PR^T$. The value of $C_r(i, j)$ indicates the total number of common references between documents i and j.

Author Similarity: In a similar fashion, the *author similarity matrix* can be computed as follows,

$$S_a(i, j) = \frac{2 \times C_a(i, j)}{N_a(i) + N_a(j)}, \quad (3)$$

where $S_a(i,j)$ is the author similarity between documents i and j, $N_a(i)$ denotes the number of total authors in document i, and C_a is an author co-occurrence matrix, which can be calculated as $C_a = PA \times PA^T$. PA refers to the paper-author matrix defined in the same way as the PR matrix.

Term Similarity: The other similarity matrix constructed for the collection of the articles is the *term similarity matrix*. The steps taken toward the construction of this matrix are as follows: First, each word in the abstract of every article was parsed and entered into a database excluding a list of user-specified stop-words that did not bear any particular meaning. A basic word processing was also performed on the parsed words to avoid different versions of the same word by removing common prefix and suffixes such as *re*, *ing*, *ous*, etc. After this, the top t most frequent terms were selected as representing features for the document collection of interest. This value of the threshold was set depending on the total number of words extracted and the size of the document collection. Next, an $n \times t$ paper-term information matrix PT that contained the frequency or number of occurrence of each term in each document was constructed. $PT(i, j) = b$ implies that paper i contains term j b number of times. Next, the same approach as the previous ones was taken to calculate the term similarity matrix of the entire document collection as follows:

$$S_t(i, j) = \frac{2 \times C_t(i, j)}{N_t(i) + N_t(j)}, \quad (4)$$

where $S_t(i, j)$ is the term similarity between documents i and j, $N_t(i)$ is the number of selected terms in document i, and C_t is a term co-occurrence matrix, which can be calculated as $C_t = PT \times PT^T$.

The method of information fusion proposed in this chapter brings together the various similarity matrices obtained from different sources into one by linear weighting on each matrix as shown in Equation (5).

$$S_f = \sum_{i=1}^{n} w_i S_i, \quad (5)$$

where w_i is the weighting coefficient assigned to similarity matrix S_i by a genetic search algorithm and

$$\sum_{i=1}^{n} w_i = 1.$$

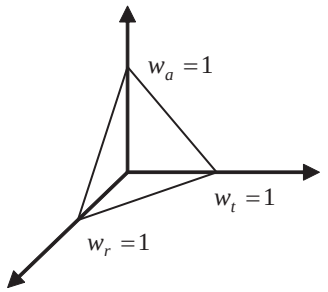
In the above case, $S_f = w_r \bullet S_r + w_a \bullet S_a + w_t \bullet S_t$ and $w_r + w_a + w_t = 1$.

Genetic Algorithms for Weighting Coefficient Search

The choice of the weighting coefficient assigned to each particular matrix is made depending on the content of information that it provides in order to attain *a good clustering*. However, there are infinite numbers of possible combinations from which the weighting parameters can be chosen, especially when dealing with a large number of similarity matrices. Figure 1 shows the input space of the weighting parameters for combining three similarity matrices (i.e., $n = 3$). Every point lying in the plane shown in this figure is a possible candidate for this particular problem, and this makes the search for the optimal weighting parameters even more complex.

This chapter proposes a genetic algorithm (GA) (Goldberg, 1989; Yen & Lu, 2003) based weighting parameter search method that can be effectively used to search for the best weighting parameters even in the case where there are a large number of similarity matrices to be fused. GA is a population-based, point-by-point search and optimization algorithm with

Figure 1. Input space of the weighting coefficients



a characteristic of avoiding local minima, which is the major challenge of optimization problems with a higher number of dimensions. GA encodes candidate solutions to a particular problem in the form of binary bits, which are later given the chance to undergo genetic operations such as reproduction, mutation, crossover, etc. At every generation a fitness value is calculated for each individual member, and those individuals with higher fitness values are given more chance to reproduce and express their schema until a stopping criterion is reached. This stopping criterion can be either a maximum number of generations or achievement of the minimum desired error for the criterion function that is being evaluated. Table 1 gives the general flow structure of a typical GA. The actual coding implementation of the genes for searching n weighting coefficients is shown in Figure 2.

In Figure 2, $B_{i,j}$ refers to the j^{th} binary bit of the i^{th} weighting parameter, which is calculated as:

$$w_i = \frac{(B_{i1}B_{i2}...B_{im})_2}{2^m}, \qquad (6)$$

where m is the number of bits used to encode the coefficients. The choice for the value of m is determined by the required resolution of the parameters, i.e., larger choice of m gives more variety of choices but with increasing level of computational complexity. In this coding, the n^{th} weighting coefficient is obtained by

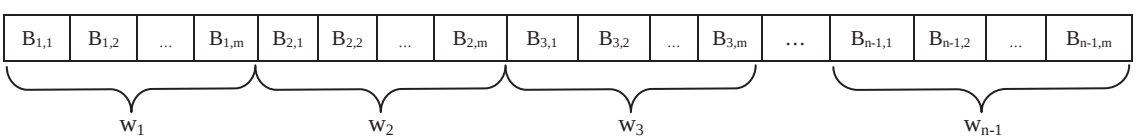
$$w_n = 1 - \sum_{i=1}^{n-1} w_i .$$

Table 1. Flow structure of a typical genetic algorithm

1. Set iteration index i to 0.
2. Generate $P(i)$ number of populations at random.
3. *REPEAT*
   a. Evaluate the fitness of each individual in $P(i)$.
   b. Select parents from $P(i)$ based on a fitness criterion function.
   c. Produce next generation $P(i+1)$ using genetic operations.
   d. Set $i=i+1$.

   UNTIL the stopping criterion is met.

Figure 2. Genetic encoding for n-1 similarity weighting coefficients



Performance Evaluation

Having the above genetic structure setup, the composite similarity matrix resulting from each individual member of the population is passed to an agglomerative hierarchical classification routine (Griffiths, Robinson & Willett, 1984), and its performance is evaluated using the technique described below until the GA reaches its stopping criteria. Classification, in a broad sense, is the act of arranging or categorizing a set of elements on the basis of a certain condition (Gordon, 1998). In this particular problem that we are dealing with, the criterion for classifying a collection of scientific literatures is mainly to be able to group documents that belong to related areas of research based solely upon features, such as citations, authorship and keywords. The method introduced here to measure the performance of literature classification is *minimization of the Discrete Pareto Distribution coefficient*. Pareto Distribution (Johnson, Kotz & Kemp, 1992) is a type of distribution with heavy tail and exists in many natural incidents. In this distribution function, large occurrences are very rare and few occurrences are common. Figure 3 shows an example of the citation pattern of documents obtained in the area of Micro-Electro Mechanical Systems (MEMS) (Morris *et al*., 2003). In this example collection, almost 18,000 papers were cited only once, and there are only few papers that received a citation-hit greater than five.

Plotting the above distribution on a log-log scale gives the result shown in Figure 4. From the graph we see that a linear curve can be fit through the data, and the slope of the curve is what is referred to as the Pareto-Distribution Coefficient (γ).

Measuring clustering performance in terms of minimization of the Pareto Distribution coefficient of citation trends directly relates to clustering documents that have common reference materials together. The slope of the line fit through the log-log plot decreases as more and more documents with common references are added to the same group. This criterion function can thus be used to measure a better classification of the literatures according to their research area.

The overall structure of this classification architecture is shown in Figure 5. As can be seen in the diagram, different similarity information matrices that are extracted from the original data are fused according to the parameters provided by the GA, and performance evaluation feedback is carried on until a stopping criterion is met. Upon termination of the GA, the best result is taken for visualization and interpretation.

Presentation

A hierarchical time line (Morris *et al*., 2003; Morris, Asnake & Yen, 2003) map visualization technique is used to present the final result of the classification, and exploration and interpretation are performed on it. In this hierarchical time line mapping technique (as shown in Figure 6), documents are plotted as circles on a date versus cluster membership axis. Their size is made to correspond to the relative number of times

Figure 3. Frequency (f) versus number of papers cited f times

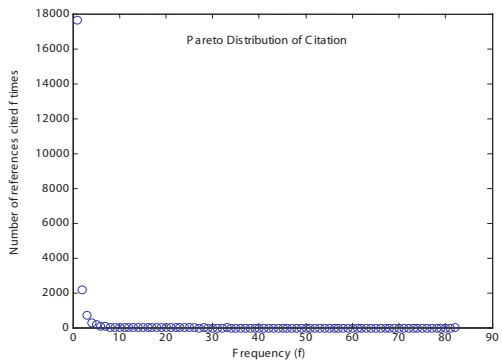


Figure 4. Log-log plot of frequency (f) versus number of papers cited f times

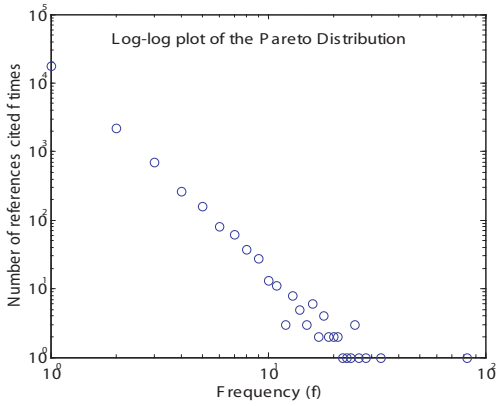

Figure 5. Proposed classification architecture

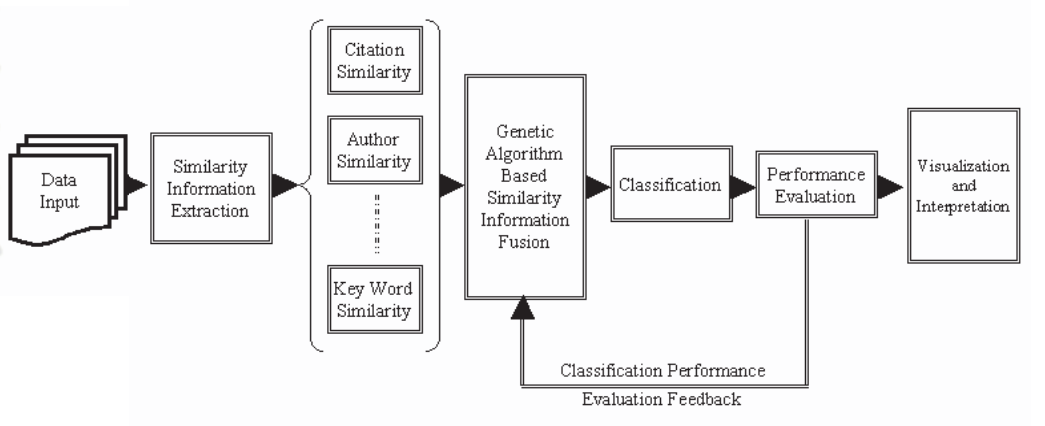
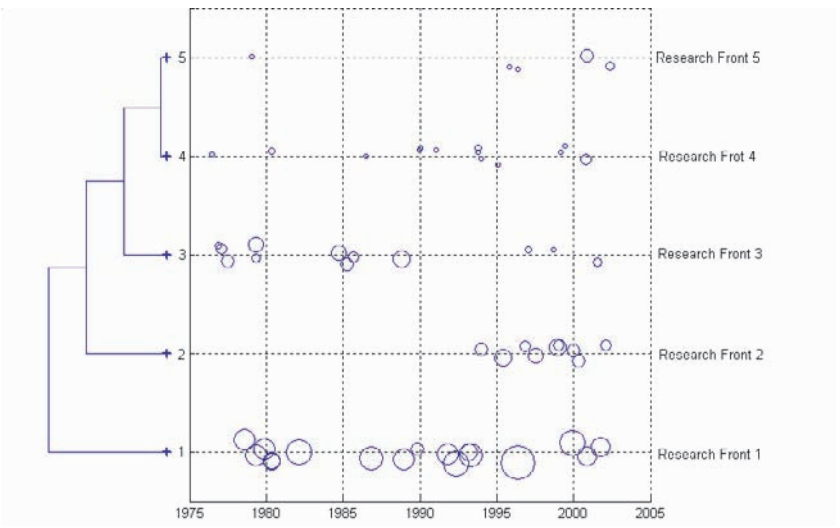


each was cited. Hence, large circles indicate documents that have been heavily cited and vice versa. Each horizontal line corresponds to a cluster that refers to a particular research area. The tree structure on the left side of the map shows the hierarchical organization and relationship between the clusters formed. The labels to the right of the map are produced manually by taking a closer note at the titles and most frequent words of the documents belonging to that particular cluster. This representation also provides temporal information that can be used to investigate the historic timing of the different research areas.

CASE STUDY

This section presents a case study performed on the subject of anthrax using the information fusion technique of scientific literature classification proposed in this chapter. The study was performed based on a collection of articles obtained from the ISI Science Citation Index library using the query phrase "anthrax anthracis." This query returned 2,472 articles published from early 1945 to the beginning of 2003. The summary of this collection is given in Table 2.

Figure 6. Hierarchical time line layout



Standard procedures were applied to filter and store these articles into a Microsoft Access database for later use. Out of the returned 2,472 articles only those articles that had five or more citation links to others were considered for further analysis. As a result, the number of articles under the study was reduced to 987. This helped exclude documents that were not strongly connected to others. Three similarity matrices out of the citation, author, and keyword frequency information as discussed above were constructed and passed to the genetic algorithm based optimization routine, which resulted in 0.78, 0.15, and 0.07 weighting coefficients for w_r, w_a, and w_t, respectively. The population size is chosen to be 50, each with total number of bits equal to 30. The stopping criterion based on Pareto distribution coefficient is set for $\gamma = 2.0$, which is chosen heuristically based upon a few trials and errors. This is in a similar spirit as one would choose a maximum number of generations to evolve the genetic algorithm. The ultimate classification result is presented in a visualization map, which is then subjected to personal preference. This result was used to classify the 987 documents, and the map shown in Figure 7 was obtained.

This map was then manually labeled after studying the title, abstract, and keyword content of the documents belonging to each cluster. One and two word frequency tables were also generated to cross check the labels generated with the most frequent words within each cluster. The labeled version of the map is shown in Figure 8. The result shown in Figure 8 identifies the different research areas within the collection as shown in the labels. Also, the important documents are shown as larger circles, of which two by Friedlander and Leppla are labeled. Friedlander's paper related to macrophages is cited 173 times within this collection and Leppla's finding on the edema factor, one part of the anthrax toxin, was cited 188 times. These two papers are among the few seminal papers in this collection where significant findings were documented. It can also be noted that Friedlander's finding opened a new dimension in the area of protective antigen study that started after his publication in 1986.

Table 2. Summary of the collected articles on anthrax

Total number of	Count
Papers	2,472
References	25,007
Authors	4,493

The similarity connection between documents was also analyzed in order to identify the most connected clusters and the flow of information among the different research areas. This is shown in Figure 9. Thin lines connect those documents that have a citation similarity value greater than a threshold value of 0.3. From this connection we can draw a conclusion about the flow of information among the different research areas shown by the dashed line. This line starts from the cluster on *preliminary anthrax research* extending until the latest development on biological warfare, which includes all the publications on bioterrorism related to the 2001 US postal attacks.

We can also see the active period of the research areas. For example, most research on preliminary anthrax was done from mid 1940s to early 1970s. Interestingly, research on bioterrorism is shown to be active from late 1990s to present.

The effect of Leppla's finding was also further studied and is shown in Figure 10. The dotted lines connect Leppla's article to its references and the solid lines connect it to those articles citing Leppla's paper. This figure shows that Leppla's finding was significant and has been used by many of the other identified research areas.

The following example shows a summary of the collaboration of Leppla, who has 74 publications in this collection. Table 5.2 below gives a summary of those people with whom Leppla published at least seven times.

FUTURE TRENDS

Future research on the technique proposed to classify scientific literatures includes application of the concept of similarity information fusion to a collection of free information sources such as news feeds, Web pages, e-mail messages, etc., in order to identify the hidden trends and links lying within. This requires the incorporation of natural language processing techniques to extract word frequency information for similarity matrix computation. In addition, significant effort should be made to automate the complete process, from literature collection, to classification and visual-

ization, to interpretation and reasoning. Additionally, computational complexity analysis of the proposed algorithm is necessary to justify its applications to real-world problems.

CONCLUSION

The method presented in this chapter aimed at the identification of the different research areas, their time of emergence and termination, major contributing authors, and the flow of information among the different research areas by making use of different available information within a collection of scientific literatures. Similarity information matrices were fused to give a generalized composite similarity matrix based on optimal weighting parameters obtained by using a genetic algorithm based search method. Minimization of the Pareto distribution coefficient was used as a measure for achieving a good clustering. A good cluster, in the case of scientific classification, contains many documents that share the same set of reference materials or base knowledge. The final classification result was presented in the form of a hierarchical time line, and further exploration was carried out on it. From the result, it was possible to clearly identify the different areas of research, major authors and their radius of influence, and the flow of information among the different research areas. The results clearly show the dates of emergence and termination of specific research disciplines.

KEY TERMS

Bibliometrics: Bibliometrics is a set of methods used to study or measure texts and information. Citation analysis and content analysis are commonly used bibliometric methods. While bibliometric methods are most often used in the field of library and information science, bibliometrics have wide applications in other areas. In fact, many research fields use bibliometric methods to explore the impact of their field, the impact of a set of researchers, or the impact of a particular paper.

Genetic Algorithm: A search technique used in computing to find true or approximate solutions to optimization and search problems. Genetic algorithms are categorized as global search heuristics. Genetic algorithms are a particular class of evolutionary algorithms that use techniques inspired by evolutionary biology such as inheritance, mutation, selection, and crossover (also called recombination).

Information Fusion: Refers to the field of study of techniques attempting to merge information from disparate sources despite differing conceptual, contextual and typographical representations. This is used in data mining and consolidation of data from semi- or unstructured resources.

Information Visualization: Information visualization is a branch of computer graphics and user interface design that are concerned with presenting data to users, by means of interactive or animated digital images. The goal of this area is usually to improve understanding of the data being presented.

Pareto Distribution: The Pareto distribution, named after the Italian economist Vilfredo Pareto, is a power law probability distribution that coincides with social, scientific, geophysical, and many other types of observable phenomena.

Statistical Classification: Statistical classification is a statistical procedure in which individual items are placed into groups based on quantitative information on one or more characteristics inherent in the items (referred to as traits, variables, characters, etc) and based on a training set of previously labeled items.

Information Veins and Resampling with Rough Set Theory

Benjamin Griffiths
Cardiff University, UK

Malcolm J. Beynon
Cardiff University, UK,

INTRODUCTION

Rough Set Theory (RST), since its introduction in Pawlak (1982), continues to develop as an effective tool in data mining. Within a set theoretical structure, its remit is closely concerned with the classification of objects to decision attribute values, based on their description by a number of condition attributes. With regards to RST, this classification is through the construction of '*if .. then ..*' decision rules. The development of RST has been in many directions, amongst the earliest was with the allowance for miss-classification in the constructed decision rules, namely the Variable Precision Rough Sets model (VPRS) (Ziarko, 1993), the recent references for this include; Beynon (2001), Mi et al. (2004), and Ślęzak and Ziarko (2005). Further developments of RST have included; its operation within a fuzzy environment (Greco et al., 2006), and using a dominance relation based approach (Greco et al., 2004).

The regular major international conferences of 'International Conference on Rough Sets and Current Trends in Computing' (RSCTC, 2004) and 'International Conference on Rough Sets, Fuzzy Sets, Data Mining and Granular Computing' (RSFDGrC, 2005) continue to include RST research covering the varying directions of its development. This is true also for the associated book series entitled 'Transactions on Rough Sets' (Peters and Skowron, 2005), which further includes doctoral theses on this subject. What is true, is that RST is still evolving, with the eclectic attitude to its development meaning that the definitive concomitant RST data mining techniques are still to be realised. Grzymala-Busse and Ziarko (2000), in a defence of RST, discussed a number of points relevant to data mining, and also made comparisons between RST and other techniques.

Within the area of data mining and the desire to identify relationships between condition attributes, the effectiveness of RST is particularly pertinent due to the inherent intent within RST type methodologies for data reduction and feature selection (Jensen and Shen, 2005). That is, subsets of condition attributes identified that perform the same role as all the condition attributes in a considered data set (termed β-reducts in VPRS, see later). Chen (2001) addresses this, when discussing the original RST, they state it follows a reductionist approach and is lenient to inconsistent data (contradicting condition attributes - one aspect of underlying uncertainty). This encyclopaedia article describes and demonstrates the practical application of a RST type methodology in data mining, namely VPRS, using nascent software initially described in Griffiths and Beynon (2005). The use of VPRS, through its relative simplistic structure, outlines many of the rudiments of RST based methodologies.

The software utilised is oriented towards 'hands on' data mining, with graphs presented that clearly elucidate 'veins' of possible information identified from β-reducts, over different allowed levels of miss-classification associated with the constructed decision rules (Beynon and Griffiths, 2004). Further findings are briefly reported when undertaking VPRS in a resampling environment, with leave-one-out and bootstrapping approaches adopted (Wisnowski et al., 2003). The importance of these results is in the identification of the more influential condition attributes, pertinent to accruing the most effective data mining results.

BACKGROUND

VPRS development on RST is briefly described here (see Ziarko, 1993; Beynon, 2001). It offers the allowance for miss-classification of objects in the constructed decision rules (determined by a β value over its allowed domain, see later), as well as correct classification and

the non-classification of objects (the β value infers a level of certainty in the model). This is one of a number of directions of development in RST based research. By way of example, the Bayesian rough set model moves away from the requirement for a particular β value (Ślęzak and Ziarko, 2005), instead it considers an appropriate certainty gain expression (using Bayesian reasoning). The relative simplicity of VPRS offers the reader the opportunity to perceive the appropriateness of RST based approaches to data mining.

Central to VPRS (and RST) is the information system (termed here as the data set), which contains a universe of objects U (o_1, o_2, …), each characterised by a set condition attributes C (c_1, c_2, …) and classified to a set of decision attributes D (d_1, d_2, …). Through the indiscernibility of objects based on C and D, respective condition and decision classes of objects are found. For a defined proportionality value β, the β-positive region corresponds to the union of the set of condition classes (using a subset of condition attributes P), with conditional probabilities of allocation to a set of objects Z (using a decision class $Z \in E(D)$), which are at least equal to β. More formally:

β-positive region of the set $Z \subseteq U$ and $P \subseteq C$: $POS_P^{\beta}(Z) = \bigcup_{\Pr(Z \mid X_i) \geq \beta} \{X_i \in E(P)\}$,

where β is defined here to lie between 0.5 and 1 (Beynon, 2001), and contributes to the context of a *majority inclusion* relation. That is, those condition classes in a β-positive region, $POS_P^{\beta}(Z)$, each have a majority of objects associated with the decision class $Z \in E(D)$. The numbers of objects included in the condition classes that are contained in the respective β-positive regions for each of the decision classes, subject to the defined β value, make up a measure of the *quality of classification*, denoted $\gamma^{\beta}(P, D)$, and given by:

$$\gamma^{\beta}(P, D) = \frac{\text{card}(\bigcup_{Z \in E(D)} POS_P^{\beta}(Z))}{\text{card}(U)},$$

where $P \subseteq C$. The $\gamma^{\beta}(P, D)$ measure with the β value means that for the objects in a data set, a VPRS analysis may define them in one of three states; not classified, correctly classified and miss-classified. Associated with this is the $\beta_{\min}$ value, the lowest of the (largest) proportion values of β that allowed the set of condition classes to be in the β-positive regions constructed. That is, a β value above this upper bound would imply at least one of the contained condition classes would then not be given a classification.

VPRS further applies these defined terms by seeking subsets of condition attributes (termed β-*reducts*), capable of explaining the associations given by the whole set of condition attributes, subject to the majority inclusion relation (using a β value). Within data mining, the notion of a β-reduct is directly associated with the study of data reduction and feature selection (Jensen and Shen, 2005). Ziarko (1993) states that a β-reduct (R) of the set of conditional attributes C, with respect to a set of decision attributes D, is:

i) A subset R of C that offers the same quality of classification, subject to the β value, as the whole set of condition attributes.

ii) No proper subset of R has the same quality of the classification as R, subject to the associated β value.

An identified β-reduct is then used to construct the decision rules, following the approach utilised in Beynon (2001). In summary, for the subset of attribute values that define the condition classes associated with a decision class, the values that discern them from the others are identified. These are called prime implicants and form the condition parts of the constructed decision rules (further reduction in the prime implicants also possible).

Main Focus

When large data sets are considered, the identification of β-reducts and adopted balance between classification/miss-classification of objects infers small veins of relevant information are available within the whole β domain of (0.5, 1]. This is definitive of data mining and is demonstrated here using the VPRS software introduced in Griffiths and Beynon (2005). A large European bank data set is utilised to demonstrate the characteristics associated with RST in data mining (using VPRS).

The Bank Financial Strength Rating (BFSR) introduced by Moody's rating agency is considered (Moody's, 2004), which represent their opinion of a bank's intrinsic safety and soundness (see Poon et al., 1999). Thirteen BFSR levels exist, but here a more general grouping of ratings of (A or B), C and (D or E) are considered (internally labelled 0 to 2). This article considers an exhaustive set of 309 European banks for which a BFSR rating has been assigned to them. The numbers of banks assigned a specific rating is; (A or B)

- 102, C - 162 and (D or E) - 45, which indicates a level of imbalance in the allocation of ratings to the banks. This issue of an unbalanced data set has been considered within RST, see Grzymala-Busse et al. (2003).

Nine associated financial variables were selected from within the bank data set, with limited concern for their independence or association with the BFSR rating of the European banks, denoted by; C1 - Equity/Total Assets, C2 - Equity/Net Loans, C3 - Equity/Dep. & St. Funding, C4 - Equity/Liabilities, C5 - Return on average assets, C6 - Return on average equity, C7 - Cap. Funds/Liabilities, C8 - Net Loans/ Total Assets and C9 - Net Loans/ Cust. & St. Funding. With VPRS a manageable granularity of the considered data set affects the number and specificity of the resultant decision rules constructed (Grzymala-Busse and Ziarko, 2000). Here a simple equal-frequency intervalisation is employed, which intervalises each condition attribute into two groups, in this case with evaluated cut-points; C1 (5.53), C2 (9.35), C3 (8.18), C4 (5.96), C5 (0.54), C6 (10.14), C7 (8.4), C8 (60.25) and C9 (83.67).

Using the subsequently produced discretised data set, a VPRS analysis, would firstly consider the identification of β-reducts (see Figure 1).

The presented software snapshot in Figure 1 shows veins of solid lines in each row, along the β domain, associated with subsets of condition attributes and where they would be defined as β-reducts. With respect to data mining, an analyst is able to choose any such vein, from which a group of decision rules are constructed that describes the accrued information (see later), because by definition they offer the same information as the whole data set. The decision rules associated with the different 'solid line' sub-domains offer varying insights into the information inherent in the considered data set.

The VPRS resampling based results presented next, offer further information to the analyst(s), in terms of importance of the condition attributes, and descriptive statistics relating to the results of the resampling process. Firstly, there is a need to have a criterion to identify a single β-reduct in each resampling run. The criterion considered here (not the only approach), considers those β-reducts offering the largest possible level of quality of classification (those associated with the solid lines towards the left side of the graph in Figure 1), then those which have the higher β_{min} values (as previously defined), then those β-reducts based on the least number of condition attributes included in the β-reducts and finaly those based on the largest associated β sub-domains.

The first resampling approach considered is 'leave-one-out' (Weiss & Kulikowski, 1991), where within each run, the constructed classifier (set of decision rules in VPRS) is based on $n - 1$ objects (the training set), and tested on the remaining single object (the test set). There are subsequently n runs in this process, for every run the classifier is constructed on nearly all the objects, with each object at some point during the process used as a test object. For sample sizes of over 100, leave-one-out is considered an accurate, almost completely unbiased, estimator of the true error rate (Weiss & Kulikowski, 1991). In the case of the BFSR bank data set, 309 runs were undertaken and varying results available, see Figure 2.

In Figure 2, the top table exposits descriptive statistics covering relevant measures in the 'leave-one-out'

Figure 1. Example VPRS analysis 'information veins' on BFSR bank data set

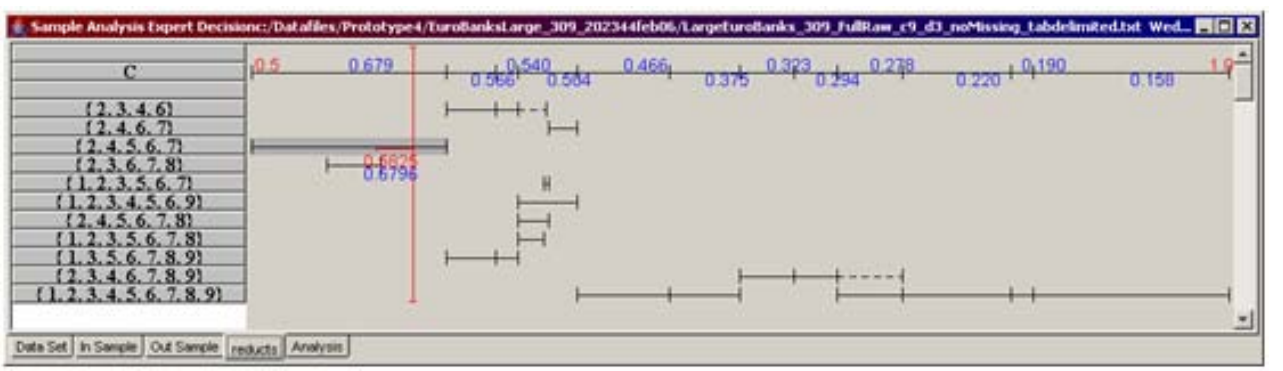

Figure 2. Descriptive statistics and one histogram from 'leave-one-out' analysis

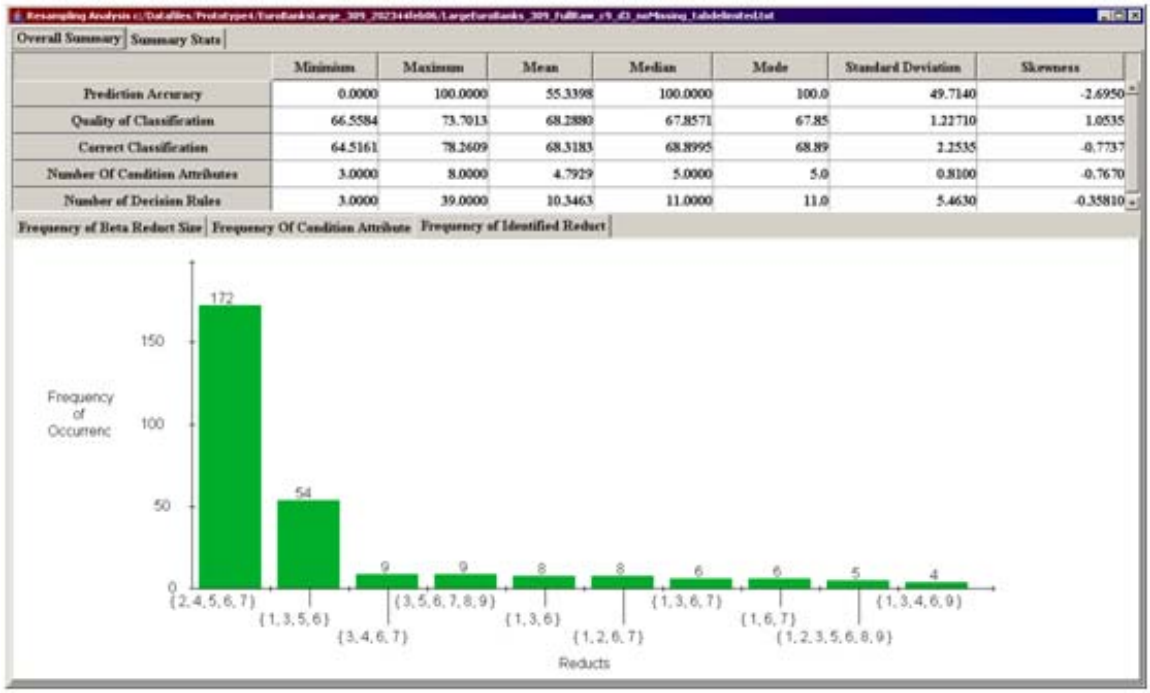

VPRS analysis. The first measure is predictive accuracy, next and pertinent to VPRS is the quality of classification (number of objects assigned a classification) and then below this is a measure of the number of objects that are asigned a correct classification. The remaining two rows are significant to the individual β-reducts identified in the runs performed, namely the average number of condition attributes included and average number of associated decision rules constructed.

The presented histogram lists the top ten most frequently identified β-reducts, the most frequent being {C2, C4, C5, C6, C7}, identified in 172 out of the 309 runs performed. This β-reduct includes five condition attributes, near to the mean number of 4.7929 found from the 309 runs in the whole 'leave-one-out' analysis.

The second resampling approach considered is 'bootstrapping' (Wisnowski et al., 2003), which draws a random sample of *n* objects, from a data set of size *n*, using sampling with replacement. This constitutes the training set, objects that do not appear within the training set constitute the test set. On average the proportion of the objects appearing in the original data set and the training set is 0.632 (0.368 are therefore duplicates of them), hence the average proportion of the testing set is 0.368. One method that yields strong results is the 0.632B bootstrap estimator (Weiss & Kulikowski, 1991). In the case of the BFSR bank data set, 500 runs were undertaken and varying results available, see Figure 3.

The descriptive statistics reported in the top table in Figure 3 are similar to those found from the leave-one-out analysis, but the presented histogram showing the top ten most frequently identified β-reducts is noticeably different from the previous analysis. This highlights that the training data sets constructed from the two resampling approaches must be inherently different with respect to advocating the importance of different subsets of condition attributes (β-reducts).

Following the 'leave-one-out' findings, the β-reduct {C2, C4, C5, C6, C7} was further considered on the whole data set, importantly it is present in the graph presented in Figure 1, from which a set of decision rules was constructed, see Figure 4.

The presented decision rules in Figure 4 are a direct consequence from the data mining undertaken on all possible solid line veins of pertinent information elucidated in Figure 1 (using the evidence from the leave-one-out analysis). To interpret the decision rules presented, rule 2 is further written in full.

Figure 3. Descriptive statistics and one histogram from 'bootstrapping' analysis with 500 runs

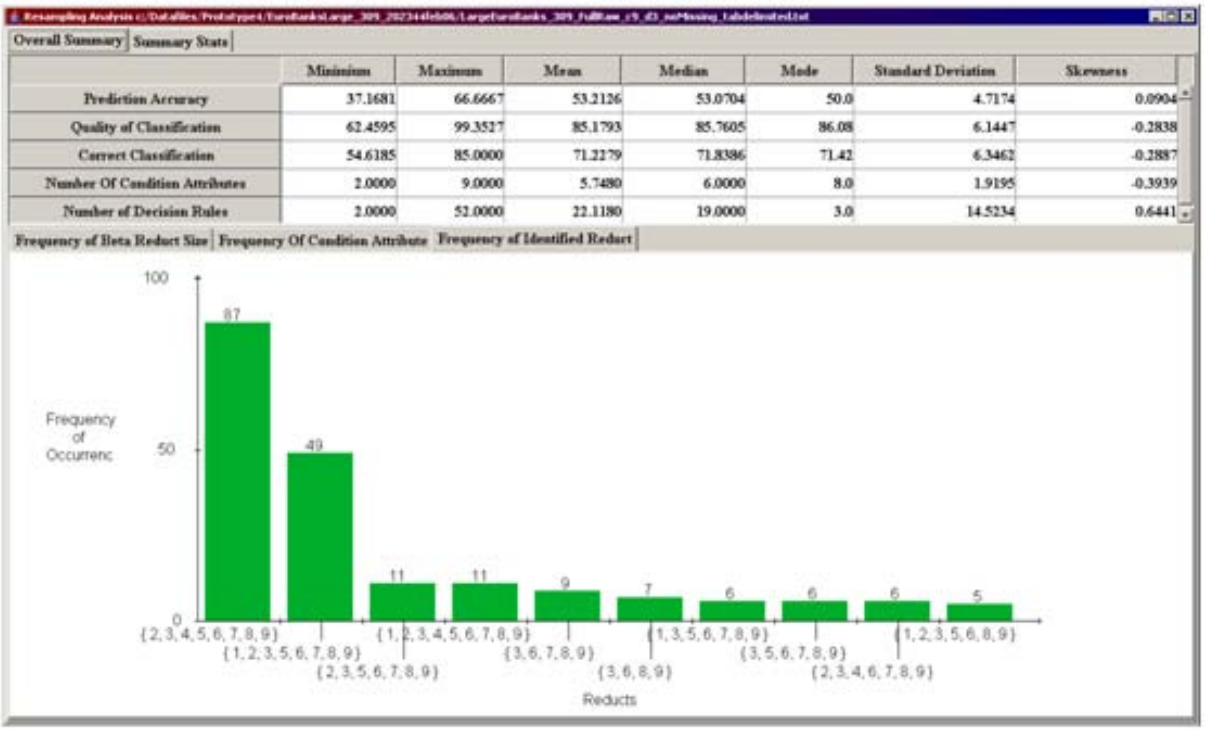

Figure 4. Decision rules associated with β-reduct {C2, C4, C5, C6, C7}

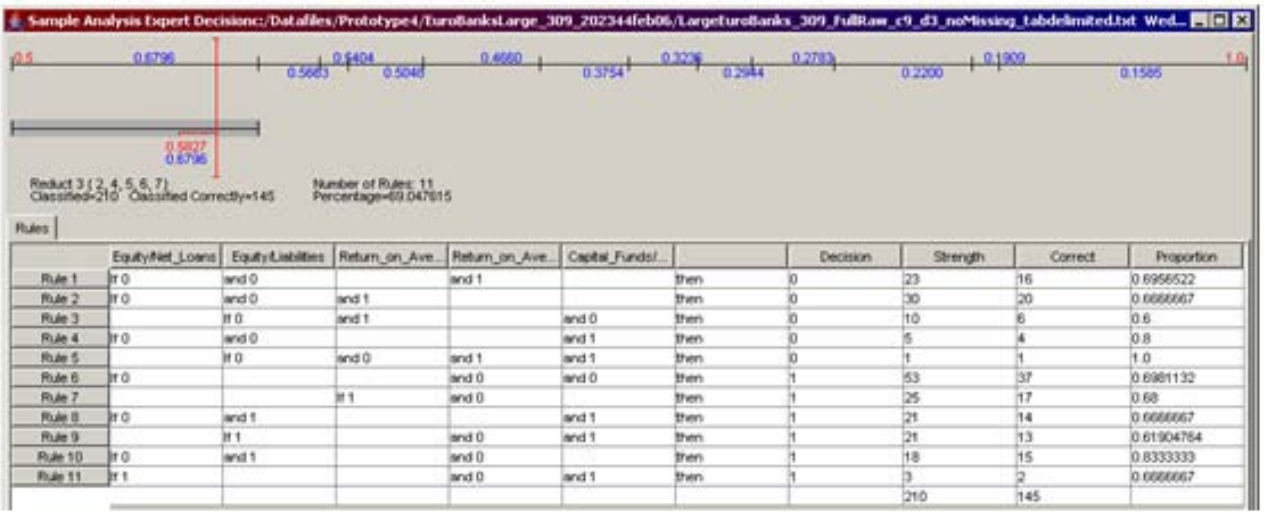

"If 'Equity/Net Loans' is less than 9.35, 'Equity/Liabilities' is less than 8.18 and 'Return on average equity' greater than or equal to 10.14 then BFSR rating is (A or B), which classifies 30 banks of which 20 were correctly classified (having a 66.66% accuracy)."

This level of interpretability available from a VPRS analysis is most important to effective data mining.

FUTURE TRENDS

The development of data mining techniques needs to keep in touch with the requirements and desires of the relevant analyst(s). Further, they need to offer analyst(s) every opportunity to inspect the data set, including any varying directions of investigation available. The

VPRS approach, while the more open of the RST variations to follow, through the prescribed software certainly allows for these requirements. Perhaps the role of Occam's razor may play more importance in future developments, with the simplicity of techniques allowing the analyst(s) to understand why the results are what they are.

CONCLUSION

Data mining, while often a general term for the analysis of data, is specific in its desire to identify relationships within the attributes present in a data set. Techniques to undertake this type of investigation have to offer practical information to the analyst(s). Rough Set Theory (RST) certainly offers a noticeable level of interpretability to any findings accrued in terms of the decision rules constructed, this is true for any of its nascent developments also. In the case of Variable Precision Rough Sets Model (VPRS), the allowed miss-classification in the decision rules may purport more generality to the interpretations given.

In the desire for feature selection, the notion of reducts (β-reducts in VPRS) fulfils this role effectively, since their identification is separate to the construction of the associated decision rules. That is, their identification is more concerned with obtaining similar levels of quality of classification of the data set with the full set of condition attributes. Within a resampling environment VPRS (and RST in general), offers a large amount of further information to the analyst(s). This includes the importance of the individual condition attributes, and general complexity of the data set, in terms of number of condition attributes in the identified β-reducts and number of concomitant decision rules constructed.

KEY TERMS

Bootstrapping: Resampling approach whereby a random sample of *n* objects are drawn from a data set of size *n* (using sampling with replacement), which constitutes the training set, objects that do not appear within the training set constitute the test set.

Decision Rules: Set of decision rules of the form 'if … then …'.

Feature Selection: Subsets of condition attributes identified and used to perform the same role as all the condition attributes in a considered data set.

Indiscernibility Relation: Process of grouping objects based on having the same series of attributes values.

Leave-One-Out: Resampling approach whereby each single object is left out as the testing set and the classifiers built on the remaining objects that make up the associated training set.

Miss-Classification: The incorrect classification of an object to one decision class, when known to be associated with another.

Quality of Classification: Number of objects assigned a classification (correctly or incorrectly).

Reduct: Subset of condition attributes that offers the same quality of classification as the whole set.

VPRS: Variable Precision Rough Sets Model.

Instance Selection

Arizona State University, USA

Lei Yu
Arizona State University, USA

INTRODUCTION

The amounts of data become increasingly large in recent years as the capacity of digital data storage worldwide has significantly increased. As the size of data grows, the demand for data reduction increases for effective data mining. Instance selection is one of the effective means to data reduction. This article introduces basic concepts of instance selection, its context, necessity and functionality. It briefly reviews the state-of-the-art methods for instance selection.

Selection is a necessity in the world surrounding us. It stems from the sheer fact of limited resources. No exception for data mining. Many factors give rise to data selection: data is not purely collected for data mining or for one particular application; there are missing data, redundant data, and errors during collection and storage; and data can be too overwhelming to handle. Instance selection is one effective approach to data selection. It is a process of choosing a subset of data to achieve the original purpose of a data mining application. The ideal outcome of instance selection is a model independent, minimum sample of data that can accomplish tasks with little or no performance deterioration.

BACKGROUND AND MOTIVATION

When we are able to gather as much data as we wish, a natural question is "how do we efficiently use it to our advantage?" Raw data is rarely of direct use and manual analysis simply cannot keep pace with the fast accumulation of massive data. Knowledge discovery and data mining (KDD), an emerging field comprising disciplines such as databases, statistics, machine learning, comes to the rescue. KDD aims to turn raw data into nuggets and create special edges in this ever competitive world for science discovery and business intelligence. The KDD process is defined (Fayyad *et al.*, 1996) as *the nontrivial process of identifying valid, novel, potentially useful, and ultimately understandable patterns in data*. It includes data selection, preprocessing, data mining, interpretation and evaluation. The first two processes (data selection and preprocessing) play a pivotal role in successful data mining (Han and Kamber, 2001). Facing the mounting challenges of enormous amounts of data, much of the current research concerns itself with scaling up data mining algorithms (Provost and Kolluri, 1999). Researchers have also worked on scaling down the data - an alternative to the algorithm scaling-up. The major issue of scaling down data is to select the relevant data and then present it to a data mining algorithm. This line of work is in parallel with the work on algorithm scaling-up and the combination of the two is a two-edged sword in mining nuggets from massive data.

In data mining, data is stored in a *flat file* and described by terms called *attributes* or *features*. Each line in the file consists of attribute-values and forms an *instance*, also named as a *record*, *tuple*, or *data point* in a multi-dimensional space defined by the attributes. Data reduction can be achieved in many ways (Liu and Motoda, 1998; Blum and Langley, 1997; Liu and Motoda, 2001). By selecting features, we reduce the number of columns in a data set; by discretizing feature-values, we reduce the number of possible values of features; and by selecting instances, we reduce the number of rows in a data set. We focus on instance selection here.

Instance selection reduces data and enables a data mining algorithm to function and work effectively with huge data. The data can include almost everything related to a domain (recall that data is not solely collected for data mining), but one application is normally about using one aspect of the domain. It is natural and sensible to focus on the relevant part of the data for the application so that search is more focused and mining is more efficient. It is often required to clean data before mining. By selecting relevant instances, we can

usually remove irrelevant, noise, and redundant data. The high quality data will lead to high quality results and reduced costs for data mining.

MAJOR LINES OF RESEARCH AND DEVELOPMENT

A spontaneous response to the challenge of instance selection is, without fail, some form of sampling. Although it is an important part of instance selection, there are other approaches that do not rely on sampling, but resort to search or take advantage of data mining algorithms. In the following, we start with sampling methods, and proceed to other instance selection methods associated with data mining tasks such as classification and clustering.

Sampling Methods

Sampling methods are useful tools for instance selection (Gu, Hu, and Liu, 2001).

$\binom{N}{n}$ *Simple random sampling* is a method of selecting n instances out of the N such that every one of the distinct samples has an equal chance of being drawn. If an instance that has been drawn is removed from the data set for all subsequent draws, the method is called random sampling without replacement. Random sampling with replacement is entirely feasible: at any draw, all N instances of the data set are given an equal chance of being drawn, no matter how often they have already been drawn.

Stratified random sampling The data set of N instances is first divided into subsets of N_1, N_2,…, N_l instances, respectively. These subsets are non-overlapping, and together they comprise the whole data set (i.e., $N_1+N_2,\ldots,+N_l=N$). The subsets are called strata. When the strata have been determined, a sample is drawn from each stratum, the drawings being made independently in different strata. If a simple random sample is taken in each stratum, the whole procedure is described as stratified random sampling. It is often used in applications that we wish to divide a heterogeneous data set into subsets, each of which is internally homogeneous.

Adaptive sampling refers to a sampling procedure that selects instances depending on results obtained from the sample. The primary purpose of adaptive sampling is to take advantage of data characteristics in order to obtain more precise estimates. It takes advantage of the result of preliminary mining for more effective sampling and vise versa.

Selective sampling is another way of exploiting data characteristics to obtain more precise estimates in sampling. All instances are first divided into partitions according to some homogeneity criterion, and then random sampling is performed to select instances from each partition. Since instances in each partition are more similar to each other than instances in other partitions, the resulting sample is more representative than a randomly generated one. Recent methods can be found in (Liu, Motoda, and Yu, 2002) in which samples selected from partitions based on data variance result in better performance than samples selected from random sampling.

Methods for Labeled Data

One key data mining application is classification – predicting the class of an unseen instance. The data for this type of application is usually labeled with class values. Instance selection in the context of classification has been attempted by researchers according to the classifiers being built. We include below five types of selected instances.

Critical points are the points that matter the most to a classifier. The issue was originated from the learning method of Nearest Neighbor (NN) (Cover and Thomas, 1991). NN usually does not learn during the training phase. Only when it is required to classify a new sample does NN search the data to find the nearest neighbor for the new sample and use the class label of the nearest neighbor to predict the class label of the new sample. During this phase, NN could be very slow if the data is large and be extremely sensitive to noise. Therefore, many suggestions have been made to keep only the critical points so that noisy ones are removed as well as the data set is reduced. Examples can be found in (Yu *et al.*, 2001) and (Zeng, Xing, and Zhou, 2003) in which critical data points are selected to improve the performance of collaborative filtering.

Boundary points are the instances that lie on borders between classes. Support vector machines (SVM) provide a principled way of finding these points through minimizing structural risk (Burges, 1998). Using a non-linear function φ to map data points to a high-dimensional feature space, a non-linearly separable

data set becomes linearly separable. Data points on the boundaries, which maximize the margin band, are the support vectors. Support vectors are instances in the original data sets, and contain all the information a given classifier needs for constructing the decision function. Boundary points and critical points are different in the ways how they are found.

Prototypes are representatives of groups of instances via averaging (Chang, 1974). A prototype that represents the typicality of a class is used in characterizing a class, instead of describing the differences between classes. Therefore, they are different from critical points or boundary points.

Tree based sampling Decision trees (Quinlan, 1993) are a commonly used classification tool in data mining and machine learning. Instance selection can be done via the decision tree built. In (Breiman and Friedman, 1984), they propose *delegate sampling*. The basic idea is to construct a decision tree such that instances at the leaves of the tree are approximately uniformly distributed. Delegate sampling then samples instances from the leaves in inverse proportion to the density at the leaf and assigns weights to the sampled points that are proportional to the leaf density.

Instance labeling In real world applications, although large amounts of data are potentially available, the majority of data are not labeled. Manually labeling the data is a labor intensive and costly process. Researchers investigate whether experts can be asked to only label a small portion of the data that is most relevant to the task if it is too expensive and time consuming to label all data. Usually an expert can be engaged to label a small portion of the selected data at various stages. So we wish to select as little data as possible at each stage, and use an adaptive algorithm to guess what else should be selected for labeling in the next stage. Instance labeling is closely associated with adaptive sampling, clustering, and active learning.

Methods for Unlabeled Data

When data is unlabeled, methods for labeled data cannot be directly applied to instance selection. The widespread use of computers results in huge amounts of data stored without labels (web pages, transaction data, newspaper articles, email messages) (Baeza-Yates and Ribeiro-Neto, 1999). Clustering is one approach to finding regularities from unlabeled data. We discuss three types of selected instances here.

Prototypes are pseudo data points generated from the formed clusters. The idea is that after the clusters are formed, one may just keep the prototypes of the clusters and discard the rest data points. The *k*-means clustering algorithm is a good example of this sort. Given a data set and a constant *k*, the *k*-means clustering algorithm is to partition the data into *k* subsets such that instances in each subset are similar under some measure. The *k* means are iteratively updated until a stopping criterion is satisfied. The prototypes in this case are the *k* means.

Prototypes plus sufficient statistics In (Bradley, Fayyad, and Reina, 1998), they extend the *k*-means algorithm to perform clustering in one scan of the data. By keeping some points that defy compression plus some sufficient statistics, they demonstrate a scalable *k*-means algorithm. From the viewpoint of instance selection, it is a method of representing a cluster using both defiant points and pseudo points that can be reconstructed from sufficient statistics, instead of keeping only the *k* means.

Squashed data are some pseudo data points generated from the original data. In this aspect, they are similar to prototypes as both may or may not be in the original data set. Squashed data points are different from prototypes in that each pseudo data point has a weight and the sum of the weights is equal to the number of instances in the original data set. Presently two ways of obtaining squashed data are (1) model free (DuMouchel *et al*., 1999) and (2) model dependent (or likelihood based (Madigan *et al*., 2002)).

FUTURE TRENDS

As shown above, instance selection has been studied and employed in various tasks (sampling, classification, and clustering). Each task is very unique in itself as each task has different information available and requirements. It is clear that a universal model of instance selection is out of the question. This short article provides some starting points that can hopefully lead to *more concerted study and development of new methods for instance selection*. Instance selection deals with scaling down data. When we understand better instance selection, it is natural to investigate if *this work can be combined with other lines of research* in overcoming the problem of huge amounts of data, such as algorithm scaling-up, feature selection and construction. It is a big challenge

to integrate these different techniques in achieving the common goal - effective and efficient data mining.

CONCLUSION

With the constraints imposed by computer memory and mining algorithms, we experience selection pressures more than ever. The central point of instance selection is *approximation*. Our task is to achieve as good mining results as possible by approximating the whole data with the selected instances and hope to do better in data mining with instance selection as it is possible to remove noisy and irrelevant data in the process. In this short article, we have presented an initial attempt to review and categorize the methods of instance selection in terms of sampling, classification, and clustering.

KEY TERMS

Classification: A process of predicting the classes of unseen instances based on patterns learned from available instances with predefined classes.

Clustering: A process of grouping instances into clusters so that instances are similar to one another within a cluster but dissimilar to instances in other clusters.

Data Mining: The application of analytical methods and tools to data for the purpose of discovering patterns, statistical or predictive models, and relationships among massive data.

Data Reduction: A process of removing irrelevant information from data by reducing the number of features, instances, or values of the data.

Instance: A vector of attribute-values in a multi-dimensional space defined by the attributes, also named as a record, tuple, or data point.

Instance Selection: A process of choosing a subset of data to achieve the original purpose of a data mining application as if the whole data is used.

Sampling: A procedure that draws a sample S_i by a random process in which each S_i receives its appropriate probability P_i of being selected.

Integration of Data Mining and Operations Research

Stephan Meisel
University of Braunschweig, Germany

Dirk C. Mattfeld
University of Braunschweig, Germany

INTRODUCTION

Basically, Data Mining (DM) and Operations Research (OR) are two paradigms independent of each other. OR aims at optimal solutions of decision problems with respect to a given goal. DM is concerned with secondary analysis of large amounts of data (Hand et al., 2001). However, there are some commonalities. Both paradigms are application focused (Wu et al., 2003; White, 1991). Many Data Mining approaches are within traditional OR domains like logistics, manufacturing, health care or finance. Further, both DM and OR are multidisciplinary. Since its origins, OR has been relying on fields such as mathematics, statistics, economics and computer science. In DM, most of the current textbooks show a strong bias towards one of its founding disciplines, like database management, machine learning or statistics.

Being multidisciplinary and application focused, it seems to be a natural step for both paradigms to gain synergies from integration. Thus, recently an increasing number of publications of successful approaches at the intersection of DM and OR can be observed. On the one hand, efficiency of the DM process is increased by use of advanced optimization models and methods originating from OR. On the other hand, effectiveness of decision making is increased by augmentation of traditional OR approaches with DM results. Meisel and Mattfeld (in press) provide a detailed discussion of the synergies of DM and OR.

BACKGROUND

The aim of DM is identification of models or patterns representing relationships in data. The DM process was shaped by two milestones. First, the discovery of relationships in data was established as a multi-step procedure (Fayyad et al., 1996). Secondly, a framework for the core DM step, including the definition of DM tasks was specified (Hand et al., 2001). One of the tasks is exploratory data analysis by means of interactive and visual techniques. Further, descriptive modeling aims at describing all of the data. Predictive modeling comprises classification and regression methods. The task of discovering patterns and rules focuses on particular aspects of the data instead of giving a description of the full data set at hand. Finally retrieval by content addresses the search for similar patterns in text and image datasets.

According to a DM task, a model or pattern structure is selected. The DM algorithm determines an instance of the structure best fitting a given set of target data. The target data set is tailored to the requirements of the DM algorithm in a preprocessing step modifying an initial set of collected data.

OR approaches require identification of decision variables and definition of a pursued objective. A decision model is developed, specifying the set of feasible values of the decision variables and an objective function. A search procedure is then applied in order to determine the optimal values for the decision variables. In case the structure of the decision model does not allow for efficient search methods, the decision model structure is often replaced by heuristic decision rules allowing for deliberate selection of a solution.

The use of optimization methods originating from OR is established since long for at least some of the DM tasks. Mangasarian (1997) discusses the relevance of mathematical programming for large-scale DM problems. A summary of early works in the field is given by Bradley et al. (1999). An application domain

specific article by Padmanabhan and Tuzhilin (2003) gives an overview on the use of optimization for DM in electronic customer relationship management.

However, the multitude of new developments at the intersection of DM and OR does not only comprise more advanced optimization models for DM. Rather, many bare improved OR approaches by integration of DM.

MAIN FOCUS

Regarding recent advances published in literature three types of synergies of DM and OR can be distinguished. On the one hand, application of optimization methods to increase DM efficiency. On the other hand, the use of DM to increase OR effectiveness either by improvement of a decision model structure or by improvement of decision model. Each of the three synergies is discussed below.

Increased Efficiency

Optimization problems may be encountered at several points in both of the major DM steps. Some of the works from literature focus on preprocessing operations. However, most papers are about the use of OR for efficient implementation of descriptive and predictive modeling, explorative data analysis as well as the discovery of patterns and rules.

1. *Preprocessing*—Preprocessing is split into a series of problems of different complexity. Some of these may not be met seriously without the application of OR methods. Examples are the feature subset selection problem, the discretization of a continuous domain of attribute values and de-duplication of information in databases.

Yang and Olafsson (2005) formulate the feature subset selection problem as combinatorial optimization problem. For solution they apply the nested partitions metaheuristic. Pendharkar (2006) considers feature subset selection as a constraint satisfaction optimization problem and proposes a hybrid heuristic based on simulated annealing and artificial neural networks. Meiri and Zahavi (2006) also apply simulated annealing to combinatorial feature subset selection and outperform the traditional stepwise regression method.

Janssens et al. (2006) model a discretization problem as shortest path network and solve it by integer programming.

OR-based de-duplication is considered by Spiliopoulos and Sofianopoulou (2007). They model the problem of calculating dissimilarity between data records as modified shortest path problem offering new insights into the structure of de-duplication problems.

2. *Descriptive Modeling*—The most common technique for the DM task of descriptive modeling is cluster analysis. Boginsiki et al. (2006) formulate the clustering problem as NP-hard clique partitioning problem and give a heuristic allowing for efficient solution.

Saglam et al. (2006) develop a heuristic for solving a mixed integer model for clustering. They show the procedure to outperform the well known k-means algorithm in terms of accuracy. Beliakov and King (2006) formulate the fuzzy c-means algorithm as a bi-level optimization problem and solve it by a discrete gradient method. The algorithm is capable of identifying non-convex overlapped d-dimensional clusters, a property present in only a few experimental methods before.

Kulkarni and Fathi (in press) apply a branch and cut algorithm to an integer programming model for clustering and find the quality of its LP relaxation to depend on the strength of the natural clusters present. Hence, they specify the conditions for an optimal solution to be expected by a branch and cut algorithm. Innis (2006) builds an integer program for seasonal clustering taking into account the time order of data.

3. *Predictive Modeling*—A number of recent publications offer elaborate approaches for the task of predictive modeling by use of OR-methods. Üney and Türkay (2006) present a multi-class data classification method based on mixed-integer programming. Exceeding traditional methods, they introduce the concept of hyperboxes for defining class boundaries increasing both classification accuracy and efficiency.

Jones et al. (2007) present a goal programming model allowing for flexible handling of the two class classification problem. The approach pursues both, maximization of the level of correct classifications and minimization of the level of misclassifications.

Carrizosa and Martin-Barragan (2006) address the same problem. They formulate a biobjective optimization problem and derive the set of pareto optimal solutions as well as a mechanism to select one out of these solutions. Trafalis and Gilbert (2006) derive new robust programming formulations enabling robust support vector machines for classification. Therefore they develop linear and second order cone programs and solve them with interior point methods.

Belacel et al. (2007) model the multicriteria fuzzy classification problem as nonlinear program and solve it using the RVNS metaheuristic. They show this method to outperform a number of traditional classifiers.

4. *Exploratory Data Analysis*—Most of the techniques for the DM task of exploratory data analysis aim at data visualization. Visualization of high volumes of high dimensional data records involves locating the records in a lower-dimensional space preserving the given distance measure.

Abbiw-Jackson et al. (2006) formulate the problem as a quadratic assignment problem and propose a divide and conquer local search heuristic for solution. Bernataviciene et al. (2006) realize visualization by a combination of self organizing maps and optimization based projection techniques.

5. *Discovering Patterns and Rules*—Rule induction methods and association rule algorithms are common techniques for the DM task of pattern and rule discovery. An example using optimization techniques well-known in OR is given by Baykasoglu and Özbakir (in press). They develop an evolutionary programming technique suitable for association rule mining. The method is shown to be very efficient and robust in comparison with standard DM algorithms.

Increased Effectiveness by Decision Structure Improvement

For some decision problems, nonlinearities or unknown system structure entail decision model structures not allowing for efficient search methods. In such cases, representation of decision variables is replaced by a higher order representation, e.g., by heuristic rules. If promising decision rules cannot be derived, DM is applied to achieve an improved representation.

Representation approaches in literature tend to be application domain specific. Therefore, they are classified according to the domains of manufacturing, logistics, warehousing, marketing, finance and health care management.

1. *Manufacturing*—Li and Olafsson (2005) present a DM approach to create decision rules for a single machine production scheduling environment. They apply a decision tree learning algorithm directly to production data to learn previously unknown dispatching rules. Huyet (2006) applies a decision tree algorithm to derive rules for a job shop composed of five workstations.

Shao et al. (2006) derive association rules for deciding on preferred product configuration alternatives given specific customer needs. Raheja et al. (2006) apply an association rule algorithm to derive rules for deciding on maintenance operations for systems in production environments.

2. *Warehousing*—Chen et al. (2005) and Wu (2006) provide two quite similar DM approaches. Both are shown to outperform commonly used heuristic decision rules.

Wu addresses the problem of selecting a subset of items to be stored in a special order completion zone. The number of items in the subset must not exceed a given threshold and the items must satisfy a given minimum percentage of orders. Wu transforms the problem into the well known DM problem of finding frequent itemsets. Application of a standard algorithm results in a ranking of itemsets.

Chen et al. address an order batching problem. They use an association rule algorithm to discover correlations between customer orders. Subsequently order batches are compiled according to the correlations with respect to the capacity constraints of storage/retrieval machines.

3. *Logistics*—Tseng et al. (2006) derive rules for supplier selection by a rough set procedure. Then they use a support vector machine learning procedure to increase rule accuracy. This method enables effective and timely supplier selection based on more features than lowest price only. Sawicki and Zak (2005) build an automatic deci-

sion making procedure for fleet maintenance. To this end, they derive maintenance rules using a rough set procedure.

4. *Marketing*—Cooper and Giuffrida (2000) decide on the amounts of stock needed for various products in retail stores. The number of units per product derived by a traditional market response model is adjusted according to rules derived by DM. The rule induction procedure considers attributes not taken into account by the market response model, hence includes more information into the decisions.
5. *Health Care Management*—Delesie and Croes (2000) apply a data visualization method to support multiple levels of decision making in the domain of health care management. A measure for similarity of hospitals represented by insurance reimbursements for a set of medical procedures is established. Then the hospitals are displayed according to mutual similarity. Finally the authors interpret the figures in order to derive decision guidelines.

Increased Effectiveness by Decision Model Improvement

DM can increase OR effectiveness by adaptation of a decision model allowing for efficient search methods. The following examples illustrate model adaptation in terms of parameters, decision variables and objective functions of well known decision models.

1. *Parameters*—Chen and Wu (2005) solve an order batching problem by a binary integer program. The aim is compiling batches to reduce travel distances in a warehouse. The decision variables indicate whether or not an order is assigned to a batch. An association rule algorithm is applied to characterize each pair of orders by a support value. This correlation measure is included as parameters into the decision model. Test results show reduced travel distance and a lower number of batches required compared to the results of standard batching procedures.
2. *Decision variables*—Brijs et al. (2004) determine the optimal product assortment for a retail store with respect to gross margin maximization. Given a maximum amount of handling and inventory costs, this can be modeled as a knapsack problem, i.e. as a binary integer program. An association rule algorithm is applied to determine sets of items offering cross-selling effects. Then, decision variables indicating whether a product set should be included into the assortment or not are added to the integer program. A branch and bound algorithm is applied to show the advantages of the approach.

Campbell et al. (2001) develop a decision model assigning the most profitable sequence of catalogs to each customer of a direct marketing company. However, optimizing over a set of 7 million customers is computationally infeasible. Hence, they choose an adequate representation of customers and form homogeneous customer groups by cluster analysis. Subsequently the optimization procedure is applied with customer groups instead of single customers as decision variables.

3. *Objective Function*—Bertsekas and Tsitsiklis (1996) introduce the neuro-dynamic methodology for adaptation of an objective function. The method provides an approximate dynamic programming approach suitable for sequential decision problems under uncertainty. The idea is determining the relation between the state of the optimized system and the cost-to-go value by application of a neural network to recorded system data.

FUTURE TRENDS

Increasing relevance of DM will encourage improved optimization approaches for all of the DM tasks and preprocessing. Further, economic developments create complex decision problems requiring elaborate decision models enabled by DM. DM-augmented OR approaches will emerge in the fields of supply chain management, as well as dynamic and stochastic vehicle routing and scheduling problems.

CONCLUSION

Three types of synergies of DM and OR are distinguished. The use of OR methods for increased efficiency of DM is the most established synergy. It results in an increasing number of significant improvements of DM

techniques. The use of DM for increased effectiveness by decision model structure improvement constitutes a younger field of research. A number of successful applications show that this synergy leads to an expansion of the OR problem domain. By decision model improvement DM enables application of traditional OR methods in complex environments. Though probably the most challenging of the three, this synergy is of high relevance with respect to a shifting focus of OR towards dynamic and stochastic problem environments.

KEY TERMS

Decision Model: Formal statement expressing goal and feasible solutions of a decision problem.

Decision Model Structure: Generic specification of decision models expressing the model type as

well as restricting the algorithms suitable for problem solution.

Descriptive Modeling: Data Mining task aiming at development of models describing all the records in a given data set.

Discovering Patterns and Rules: Data Mining task aiming at discovery of particular aspects of a data set. These aspects are expressed as rules and patterns and refer to only some of the records in a given data set.

Exploratory Data Analysis: Data Mining task of data exploration without a clear goal of what is being looked for. Typically conducted by use of visual and interactive methods.

Predictive Modeling: Data Mining task aiming at development of models for prediction of the value of one attribute from known values of other attributes for each record in a given data set.

Preprocessing: Modification of the set of collected data records in order to create a target data set matching the requirements of the data mining task and algorithm considered subsequently.

Integration of Data Sources through Data Mining

Andreas Koeller
Montclair State University, USA

INTRODUCTION

Integration of data sources refers to the task of developing a common schema as well as data transformation solutions for a number of data sources with related content. The large number and size of modern data sources make manual approaches at integration increasingly impractical. Data mining can help to partially or fully automate the data integration process.

BACKGROUND

Many fields of business and research show a tremendous need to integrate data from different sources. The process of data source integration has two major components.

Schema matching refers to the task of identifying related fields across two or more databases (Rahm & Bernstein, 2001). Complications arise at several levels, for example

- Source databases can be organized by using several different models, such as the relational model, the object-oriented model, or semistructured models (e.g., XML).
- Information stored in a single table in one relational database can be stored in two or more tables in another. This problem is common when source databases show different levels of normalization and also occurs in nonrelational sources.
- A single field in one database, such as *Name*, could correspond to multiple fields, such as *First Name* and *Last Name*, in another.

Data transformation (sometimes called instance matching) is a second step in which data in matching fields must be translated into a common format. Frequent reasons for mismatched data include data format (such as *1.6.2004* vs. *6/1/2004*), numeric precision (*3.5kg* vs. *3.51kg*), abbreviations (*Corp.* vs. *Corporation*), or linguistic differences (e.g., using different synonyms for the same concept across databases).

Today's databases are large both in the number of records stored and in the number of fields (dimensions) for each datum object. Database integration or migration projects often deal with hundreds of tables and thousands of fields (Dasu, Johnson, Muthukrishnan, & Shkapenyuk, 2002), with some tables having 100 or more fields and/or hundreds of thousands of rows. Methods of improving the efficiency of integration projects, which still rely mostly on manual work (Kang & Naughton, 2003), are critical for the success of this important task.

MAIN THRUST

In this article, I explore the application of data-mining methods to the integration of data sources. Although data transformation tasks can sometimes be performed through data mining, such techniques are most useful in the context of schema matching. Therefore, the following discussion focuses on the use of data mining in schema matching, mentioning data transformation where appropriate.

Schema-Matching Approaches

Two classes of schema-matching solutions exist: schema-only-based matching and instance-based matching (Rahm & Bernstein, 2001).

Schema-only-based matching identifies related database fields by taking only the schema of input databases into account. The matching occurs through linguistic means or through constraint matching. Linguistic matching compares field names, finds similarities in field descriptions (if available), and attempts to match field names to names in a given hierarchy of terms *(ontology)*. Constraint matching matches fields based

on their domains (data types) or their key properties (primary key, foreign key). In both approaches, the data in the sources are ignored in making decisions on matching. Important projects implementing this approach include ARTEMIS (Castano, de Antonellis, & de Capitani di Vemercati, 2001) and Microsoft's CUPID (Madhavan, Bernstein, & Rahm, 2001).

Instance-based matching takes properties of the data into account as well. A very simple approach is to conclude that two fields are related if their minimum and maximum values and/or their average values are equal or similar. More sophisticated approaches consider the distribution of values in fields. A strong indicator of a relation between fields is a complete inclusion of the data of one field in another. I take a closer look at this pattern in the following section. Important instance-based matching projects are SemInt (Li & Clifton, 2000) and LSD (Doan, Domingos, & Halevy, 2001).

Some projects explore a combined approach, in which both schema-level and instance-level matching is performed. Halevy and Madhavan (2003) present a *Corpus-based* schema matcher. It attempts to perform schema matching by incorporating known schemas and previous matching results and to improve the matching result by taking such historical information into account.

Data-mining approaches are most useful in the context of instance-based matching. However, some mining-related techniques, such as graph matching, are employed in schema-only-based matching as well.

Instance-Based Matching through Inclusion Dependency Mining

An *inclusion dependency* is a pattern between two databases, stating that the values in a field (or set of fields) in one database form a subset of the values in some field (or set of fields) in another database. Such subsets are relevant to data integration for two reasons. First, fields that stand in an inclusion dependency to one another might represent related data. Second, knowledge of foreign keys is essential in successful schema matching. Because a foreign key is necessarily a subset of the corresponding key in another table, foreign keys can be discovered through inclusion dependency discovery.

The discovery of inclusion dependencies is a very complex process. In fact, the problem is in general NP-hard as a function of the number of fields in the largest inclusion dependency between two tables. However, a number of practical algorithms have been published.

De Marchi, Lopes, and Petit (2002) present an algorithm that adopts the idea of *levelwise discovery* used in the famous Apriori algorithm for association rule mining. Inclusion dependencies are discovered by first comparing single fields with one another and then combining matches into pairs of fields, continuing the process through triples, then 4-sets of fields, and so on. However, due to the exponential growth in the number of inclusion dependencies in larger tables, this approach does not scale beyond inclusion dependencies with a size of about eight fields.

A more recent algorithm (Koeller & Rundensteiner, 2003) takes a graph-theoretic approach. It avoids enumerating all inclusion dependencies between two tables and finds candidates for only the largest inclusion dependencies by mapping the discovery problem to a problem of discovering patterns (specifically cliques) in graphs. This approach is able to discover inclusion dependencies with several dozens of attributes in tables with tens of thousands of rows. Both algorithms rely on the antimonotonic property of the inclusion dependency discovery problem. This property is also used in association rule mining and states that patterns of size k can only exist in the solution of the problem if certain patterns of sizes smaller than k exist as well. Therefore, it is meaningful to first discover small patterns (e.g., single-attribute inclusion dependency) and use this information to restrict the search space for larger patterns.

Instance-Based Matching in the Presence of Data Mismatches

Inclusion dependency discovery captures only part of the problem of schema matching, because only *exact* matches are found. If attributes across two relations are not exact subsets of each other (e.g., due to entry errors), then data mismatches requiring data transformation, or partially overlapping data sets, it becomes more difficult to perform data-driven mining-based discovery. Both false negatives and false positives are possible. For example, matching fields might not be discovered due to different encoding schemes (e.g., use of a numeric identifier in one table, where text is used to denote the same values in another table). On the other hand, purely data-driven discovery relies on the assumption that semantically related values are

also syntactically equal. Consequently, fields that are discovered by a mining algorithm to be matching might not be semantically related.

Data Mining by Using Database Statistics

The problem of false negatives in mining for schema matching can be addressed by more sophisticated mining approaches. If it is known which attributes across two relations relate to one another, *data transformation* solutions can be used. However, automatic discovery of matching attributes is also possible, usually through the evaluation of statistical patterns in the data sources. In the classification of Kang and Naughton (2003), interpreted matching uses artificial intelligence techniques, such as Bayesian classification or neural networks, to establish hypotheses about related attributes. In the uninterpreted matching approach, statistical features, such as the unique value count of an attribute or its frequency distribution, are taken into consideration. The underlying assumption is that two attributes showing a similar distribution of unique values might be related even though the actual data values are not equal or similar.

Another approach for detecting a semantic relationship between attributes is to use information entropy measures. In this approach, the concept of *mutual information*, which is based on entropy and conditional entropy of the underlying attributes, "measures the reduction in uncertainty of one attribute due to the knowledge of the other attribute" (Kang & Naughton, 2003, p. 207).

Further Problems in Information Integration through Data Mining

In addition to the approaches mentioned previously, several other data-mining and machine-learning approaches, in particular classification and rule-mining techniques, are used to solve special problems in information integration.

For example, a common problem occurring in real-world integration projects is related to duplicate records across two databases, which must be identified. This problem is usually referred to as the *record-linking problem* or the *merge/purge problem* (Hernandéz & Stolfo, 1998). Similar statistical techniques as the ones described previously are used to approach this problem. The Commonwealth Scientific and Industrial Research Organisation (2003) gives an overview of approaches, which include decision models, predictive models such as support vector machines, and a Bayesian decision cost model.

In a similar context, data-mining and machine-learning solutions are used to improve the data quality of existing databases as well. This important process is sometimes called *data scrubbing*. Lübbers, Grimmer, and Jarke (2003) present a study of the use of such techniques and refer to the use of data mining in data quality improvement as *data auditing*.

Recently, the emergence of *Web Services* such as XML, SOAP, and UDDI promises to open opportunities for database integration. Hansen, Madnick, and Siegel (2002) argue that Web services help to overcome some of the technical difficulties of data integration, which mostly stem from the fact that traditional databases are not built with integration in mind. On the other hand, Web services by design standardize data exchange protocols and mechanisms. However, the problem of identifying semantically related databases and achieving schema matching remains.

FUTURE TRENDS

Increasing amounts of data are being collected at all levels of business, industry, and science. Integration of data also becomes more and more important as businesses merge and research projects increasingly require interdisciplinary efforts. Evidence for the need for solutions in this area is provided by the multitude of partial software solutions for such business applications as ETL (Pervasive Software, Inc., 2003), and by the increasing number of integration projects in the life sciences, such as Genbank by the National Center for Biotechnology Information (NCBI) or Gramene by the Cold Spring Harbor Laboratory and Cornell University. Currently, the integration of data sources is a daunting task, requiring substantial human resources. If automatic methods for schema matching were more readily available, data integration projects could be completed much faster and could incorporate many more databases than is currently the case.

Furthermore, an emerging trend in data source integration is the move from batch-style integration, where a set of given data sources is integrated at one time into one system, to real-time integration, where

data sources are immediately added to an integration system as they become available. Solutions to this new challenge can also benefit tremendously from semiautomatic or automatic methods of identifying database structure and relationships.

CONCLUSION

Information integration is an important and difficult task for businesses and research institutions. Although data sources can be integrated with each other by manual means, this approach is not very efficient and does not scale to the current requirements. Thousands of databases with the potential for integration exist in every field of business and research, and many of those databases have a prohibitively high number of fields and/or records to make manual integration feasible. Semiautomatic or automatic approaches to integration are needed.

Data mining provides very useful tools to automatic data integration. Mining algorithms are used to identify schema elements in unknown source databases, to relate those elements to each other, and to perform additional tasks, such as data transformation. Essential business tasks such as extraction, transformation, and loading (ETL) and data integration and migration in general become more feasible when automatic methods are used.

Although the underlying algorithmic problems are difficult and often show exponential complexity, several interesting solutions to the schema-matching and data transformation problems in integration have been proposed. This is an active area of research, and more comprehensive and beneficial applications of data mining to integration are likely to emerge in the near future.

KEY TERMS

Antimonotonic: A property of some pattern-finding problems stating that patterns of size *k* can only exist if certain patterns with sizes smaller than *k* exist in the same dataset. This property is used in levelwise algorithms, such as the Apriori algorithm used for association rule mining or some algorithms for inclusion dependency mining.

Database Schema: A set of names and conditions that describe the structure of a database. For example, in a relational database, the schema includes elements such as table names, field names, field data types, primary key constraints, or foreign key constraints.

Domain: The set of permitted values for a field in a database, defined during database design. The actual data in a field are a subset of the field's domain.

Extraction, Transformation, and Loading (ETL): Describes the three essential steps in the process of data source integration: extracting data and schema from the sources, transforming it into a common format, and loading the data into an integration database.

Foreign Key: A key is a field or set of fields in a relational database table that has unique values, that is, no duplicates. A field or set of fields whose values form a subset of the values in the key of *another* table is called a foreign key. Foreign keys express relationships between fields of different tables.

Inclusion Dependency: A pattern between two databases, stating that the values in a field (or set of fields) in one database form a subset of the values in some field (or set of fields) in another database.

Levelwise Discovery: A class of data-mining algorithms that discovers patterns of a certain size by first discovering patterns of size 1, then using information from that step to discover patterns of size 2, and so on. A well-known example of a levelwise algorithm is the Apriori algorithm used to mine association rules.

Merge/Purge: The process of identifying duplicate records during the integration of data sources. Related data sources often contain overlapping information extents, which have to be reconciled to improve the quality of an integrated database.

Relational Database: A database that stores data in *tables,* which are sets of tuples (rows). A set of corresponding values across all rows of a table is called an *attribute, field,* or *column.*

Schema Matching: The process of identifying an appropriate mapping from the schema of an input data source to the schema of an integrated database.

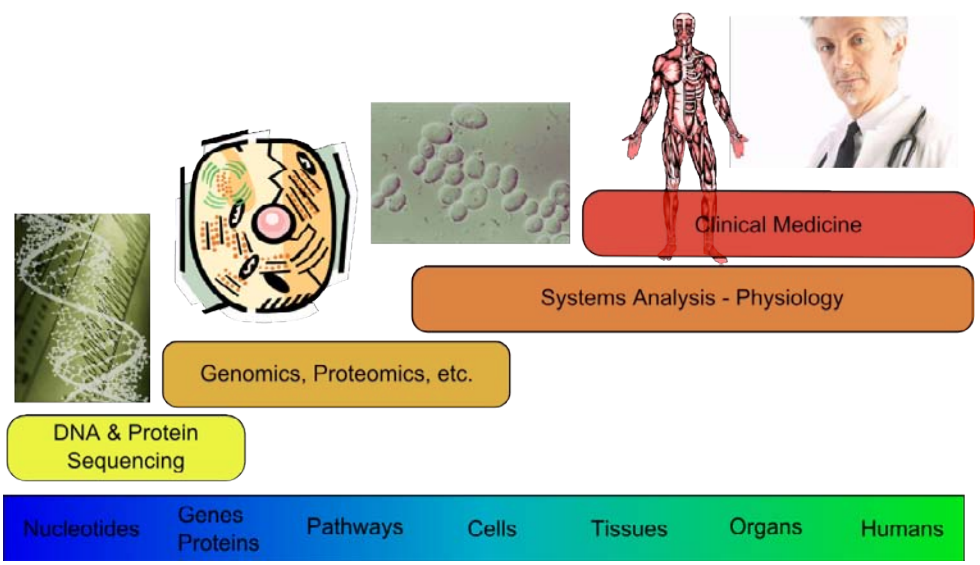
INTRODUCTION

As John Muir noted, "When we try to pick out anything by itself, we find it hitched to everything else in the Universe" (Muir, 1911). In tune with Muir's elegantly stated notion, research in molecular biology is progressing toward a systems level approach, with a goal of modeling biological systems at the molecular level. To achieve such a lofty goal, the analysis of multiple datasets is required to form a clearer picture of entire biological systems (Figure 1). Traditional molecular biology studies focus on a specific process in a complex biological system. The availability of high-throughput technologies allows us to sample tens of thousands of features of biological samples at the molecular level. Even so, these are limited to one particular view of a biological system governed by complex relationships and feedback mechanisms on a variety of levels. Integrated analysis of varied biological datasets from the genetic, translational, and protein levels promises more accurate and comprehensive results, which help discover concepts that cannot be found through separate, independent analyses. With this article, we attempt to provide a comprehensive review of the existing body of research in this domain.

Figure 1. Complexity increases from the molecular and genetic level to the systems level view of the organism (Poste, 2005).



BACKGROUND

The rapid development of high-throughput technologies has allowed biologists to obtain increasingly comprehensive views of biological samples at the genetic level. For example, microarrays can measure gene expression for the complete human genome in a single pass. The output from such analyses is generally a list of genes (features) that are differentially expressed (upregulated or downregulated) between two groups of samples or ones that are coexpressed across a group of samples. Though every gene is measured, many are irrelevant to the phenomenon being studied. Such irrelevant features tend to mask interesting patterns, making gene selection difficult. To overcome this, external information is required to draw meaningful inferences (guided feature selection). Currently, numerous high-throughput techniques exist along with diverse annotation datasets presenting considerable challenges for data mining (Allison, Cui, Page & Sabripour, 2006).

Sources of background knowledge available include metabolic and regulatory pathways, gene ontologies, protein localization, transcription factor binding, molecular interactions, protein family and phylogenetic information, and information mined from biomedical literature. Sources of high-throughput data include gene expression microarrays, comparative genomic hybridization (CGH) arrays, single nucleotide polymorphism (SNP) arrays, genetic and physical interactions (affinity precipitation, two-hybrid techniques, synthetic lethality, synthetic rescue) and protein arrays (Troyanskaya, 2005). Each type of data can be richly annotated using clinical data from patients and background knowledge. This article focuses on studies using microarray data for the core analysis combined with other data or background knowledge. This is the most commonly available data at the moment, but the concepts can be applied to new types of data and knowledge that will emerge in the future.

Gene expression data has been widely utilized to study varied things ranging from biological processes and diseases to tumor classification and drug discovery (Carmona-Saez, Chagoyen, Rodriguez, Trelles, Carazo & Pascual-Montano, 2006). These datasets contain information for thousands of genes. However, due to the high cost of these experiments, there are very few samples relative to the thousands of genes. This leads to the curse of dimensionality (Yu & Liu 2004). Let M be the number of samples and N be the number of genes. Computational learning theory suggests that the search space is exponentially large in terms of N and the required number of samples for reliable learning about given phenotypes is on the scale of $O(2^N)$ (Mitchell, 1997; Russell & Norvig, 2002). However, even the minimum requirement (M=10*N) as a statistical "rule of thumb" is patently impractical for such a dataset (Hastie, Tibshirani & Friedman, 2001). With limited samples, analyzing a dataset using a single criterion leads to the selection of many statistically relevant genes that are equally valid in interpreting the data. However, it is commonly observed that statistical significance may not always correspond to biological relevance. Traditionally, additional information is used to guide the selection of biologically relevant genes from the list of statistically significant genes. Using such information during the analysis phase to guide the mining process is more effective, especially when dealing with such complex processes (Liu, Dougherty, Dy, Torkkola, Tuv, Peng, Ding, Long, Berens, Parsons, Zhao, Yu & Forman, 2005; Anastassiou, 2007).

Data integration has been studied for a long time, ranging from early applications in distributed databases (Deen, Amin & Taylor, 1987) to the more recent ones in sensor networks (Qi, Iyengar & Chakrabarty, 2001) and even biological data (Lacroix, 2002; Searls, 2003). However, the techniques we discuss are those using integrative analyses as opposed to those which integrate data or analyze such integrated data. The difference lies in the use of data from multiple sources in an integrated analysis framework. The range of biological data available and the variety of applications make such analyses particularly necessary to gain biological insight from a whole organism perspective.

MAIN FOCUS

With the increase in availability of several types of data, more researchers are attempting integrated analyses. One reason for using numerous datasets is that high-throughput data often sacrifice specificity for scale (Troyanskaya, 2005), resulting in noisy data that might generate inaccurate hypotheses. Replication of experiments can help remove noise but they are costly. Combining data from different experimental sources and knowledge bases is an effective way to reduce the effects of noise and generate more accurate hypotheses. Multiple sources provide additional information that

when analyzed together, can explain some phenomenon that one source cannot. This is commonly observed in data mining and statistical pattern recognition problems (Troyanskaya, 2005; Rhodes & Chinnaiyan, 2005; Quackenbush, 2007). In addition, the systems being studied are inherently complex (Figure 1). One dataset provides only one view of the system, even if it looks at it from a whole organism perspective. As a result, multiple datasets providing different views of the same system are intuitively more useful in generating biological hypotheses.

There are many possible implementation strategies to realize the goals of integrative analysis. One can visualize the use of one dataset after another in a serial model or all the datasets together in a parallel model. A serial model represents classical analysis approaches (Figure 2a). Using all the datasets at once to perform an integrative analysis would be a fully parallel model (Figure 2b). By combining those approaches, we arrive at a semi-parallel model that combines some of the data early on, but adds some in later stages of the analysis. Such an analysis could integrate different groups of data separately and then integratively process the results (Figure 2c).

The fully parallel model combines all the datasets together and performs the analysis without much user intervention. Any application of expert knowledge is done at the preprocessing stage or after the analysis. An algorithm that follows this model allows the use of heterogeneous datasets and can therefore be applied in later studies without need for modification.

The semi-parallel model is used when expert knowledge is needed to guide the analysis towards more specific goals. A model that can be tailored to a study and uses expert knowledge can be more useful than a generic model. An algorithm that follows this model requires tuning specific to each experiment and cannot be applied blindly to diverse datasets. These models represent the basic ways of performing an integrative analysis.

REPRESENTATIVE SELECTION OF ALGORITHMS

Integrative analyses using data from diverse sources have shown promise of uncovering knowledge that is not found when analyzing a single dataset. These studies analyze disparate datasets to study subjects ranging from gene function to protein-protein interaction. Common to all these studies is the use of expert knowledge and an increase in prediction accuracy when executing integrative analysis of varied datasets compared to results obtained when executing classical analysis with a single data source. More specifically these studies use data sources that include both high-throughput and conventional data to perform an analysis and generate inferences. This is in contrast to conventional studies where a high-throughput data source is used for analysis and additional information is later sought to help in drawing inferences. A variety of data mining techniques including decision trees, biclustering, Bayesian networks, kernel methods have been applied to the integrated analysis of biological data.

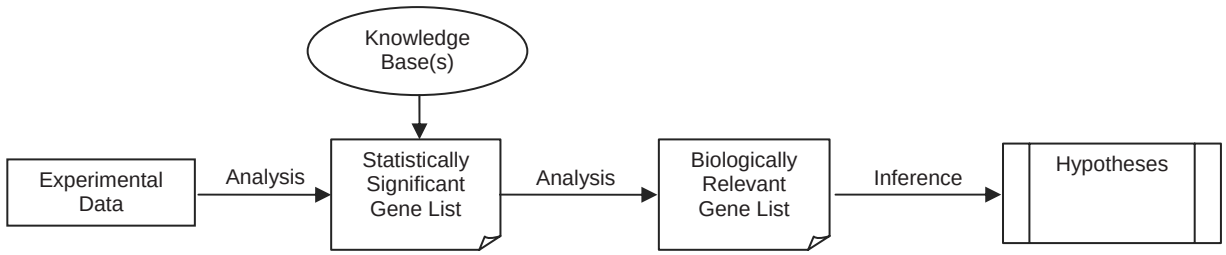
Troyanskaya, Dolinksi, Owen, Altman & Botstein (2003) developed a framework called Multisource Association of Genes by Integration of Clusters (MAGIC) that allows the combination of different biological data with expression information to make predictions about gene function using Bayesian reasoning. The structure of the Bayesian network is created using expert input. The inputs to this network are matrices representing gene-gene relationships resulting in groups of functionally related genes as output. This approach would fall under the fully parallel model with the use of expert knowledge at the preprocessing stage. The data is processed individually to create matrices and all these matrices are analyzed together integratively.

Jansen, Yu, Greenbaum, Kluger, Krogan, Chung, Emili, Snyder, Greenblatt & Gerstein (2003) predicted protein-protein interactions using experimental and annotation data separately. Bayesian networks were used to obtain an experimental probabilistic interactome and a predicted probabilistic interactome respectively. These two were then combined to give a final probabilistic interactome. This experiment would fall under the semi-parallel model.

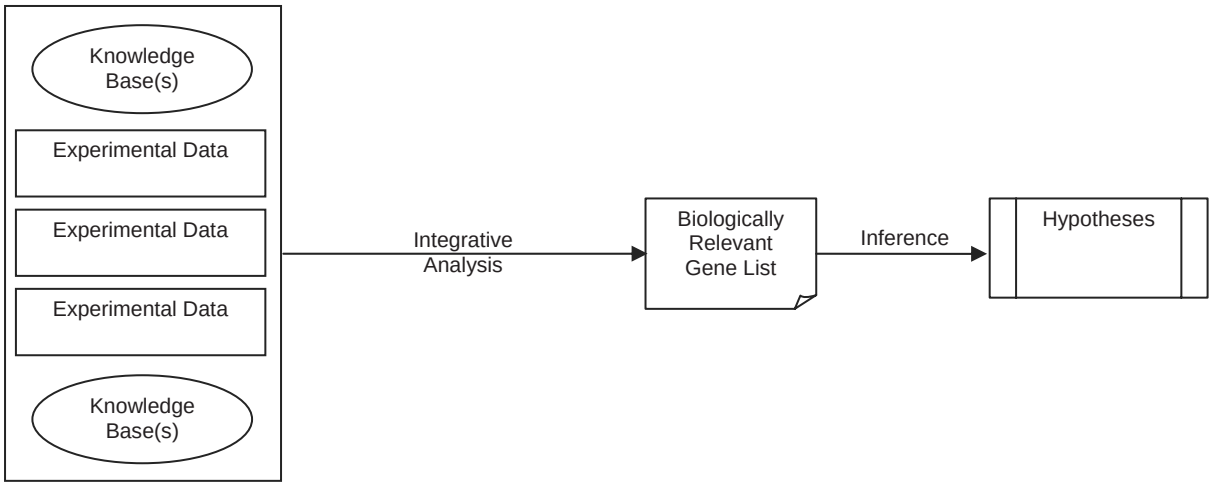
Jiang & Keating (2003) developed a multistage learning framework called Annotation Via Integration of Data (AVID) for prediction of functional relationships among proteins. High-confidence networks are built in which proteins are connected if they are likely to share a common annotation. Functional annotation is treated as a classification problem and annotations are assigned to unannotated proteins based on their neighbors in the network. This method also falls into the fully parallel model but in a multi stage implementation.

Figure 2. Integrative Analysis Models: a. Serial, b. Fully Parallel, c. Semi-Parallel

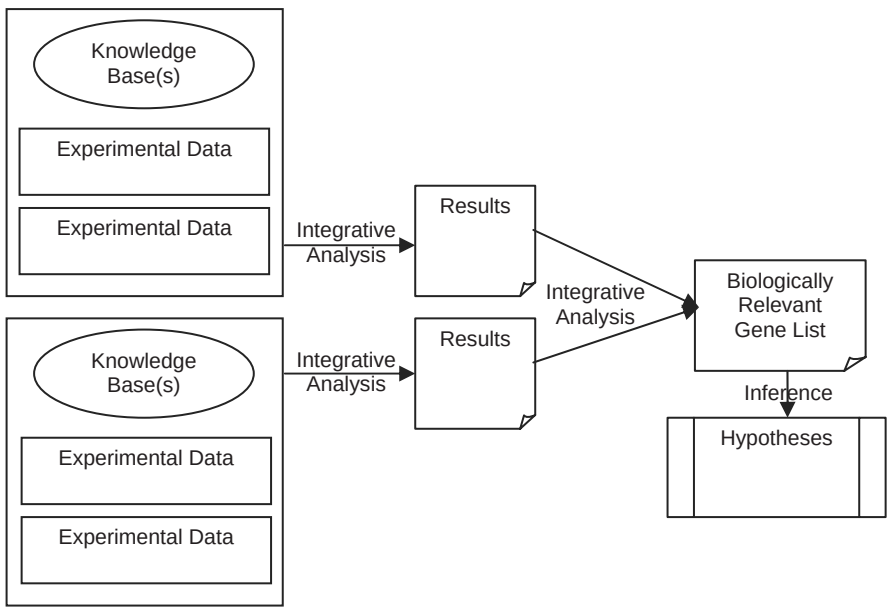
a. Model for analysis of a single high-throughput dataset with the aid of knowledge base(s) (serial analysis)



b. Model for Integrative analysis of multiple high-throughput datasets with the aid of knowledge base(s) (fully parallel analysis)



c. Model for Integrative analysis of multiple high-throughput datasets with the aid of knowledge base(s) (semi-parallel analysis)



Tanay, Sharan, Kupiec & Shamir (2004) proposed Statistical-Algorithmic Method for Bicluster Analysis (SAMBA) to analyze mixed datasets to identify genes that show statistically significant correlation across these sources. The data is viewed as properties of the genes and the underlying biclustering algorithm looks for statistically significant subgraphs from the genes-properties graph to predict functional groupings for various genes. This method again falls under the fully parallel model with some preprocessing.

Lanckriet, Bie, Cristianini, Jordan & Noble (2004) proposed a computational framework where each dataset is represented using a kernel function and these kernel functions are later combined to develop a learning algorithm to recognize and classify yeast ribosomal and membrane proteins. This method also could be categorized as a fully parallel model.

Zhang, Wong, King & Roth (2004) used a probabilistic decision tree to analyze protein-protein interactions from high-throughput methods like yeast two-hybrid and affinity purification coupled with mass spectrometry along with several other protein-pair characteristics to predict co-complexed pairs of proteins. This method again follows a fully parallel model with all the datasets contributing to the analysis.

Carmona-Saez, Chagoyen, Rodriguez, Trelles, Carazo, & Pascual-Montano (2006) developed a method for integrated analysis of gene expression data using association rules discovery. The itemsets used include the genes along with the set of experiments in which the gene is differentially expressed and the gene annotation. The generated rules are constrained to have gene annotation as an antecedent. Since the datasets used were well studied, the generated rules could be compared with the known information to find that they really are insightful.

APPLICATION TO A SPECIFIC DOMAIN: CANCER

Cancer studies provide a particularly interesting application of integrated analysis techniques. Different datasets from studies interrogating common hypotheses can be used to perform meta-analyses enabling the identification of robust gene expression patterns. These patterns could be identified in a single type or across different cancers. Annotation databases and pathway resources can be used for functional enrichment of cancer signatures by reducing large signatures to a smaller number of genes. Such additional knowledge is useful to view the existing information in a new light. Understanding a complex biological process requires us to view such knowledge in terms of complex molecular networks. To understand such networks, protein-protein interactions need to be mapped. Information on such protein interaction networks is limited.

In addition to protein interaction networks, global transcriptional networks can be used to enhance our interpretation of cancer signatures. Knowledge of transcription factor binding site information allows us to identify those that might be involved in particular signatures. Studying model oncogene systems can further enhance our understanding of these signatures (Rhodes & Chinnaiyan, 2005; Hu, Bader, Wigle & Emili, 2007). Examples of studies employing these approaches show the usefulness of integrative analyses in general as well as for their application to cancer.

FUTURE TRENDS

The future trends in this area can be divided into three broad categories: experimental techniques, analysis methods and application areas. Though, we are more interested in the analysis methods, these categories are interlinked and drive each other in terms of change and growth. In addition to existing high-throughput techniques, advancement in newer approaches like SNP arrays, array comparative genome hybridization, promoter arrays, proteomics and metabolomics would provide more high quality information to help us understand complex biological processes (Rhodes & Chinnaiyan, 2005). With such an aggregation of data, integrative analyses techniques would be a key to gaining maximum understanding of these processes.

Apart from experimental techniques, there is tremendous unrealized potential in integrative analysis techniques. A majority of the current methods are fully parallel and generic. They can be applied to different studies using dissimilar datasets but asking the same biological question. Though domain knowledge guides the development of these algorithms to an extent, optimal use of such knowledge is not seen. With the huge amount of diversity in the datasets, the use of expert knowledge is needed to develop a method specific to a domain based on the types of data being used and the questions being asked. This means alternate semi-

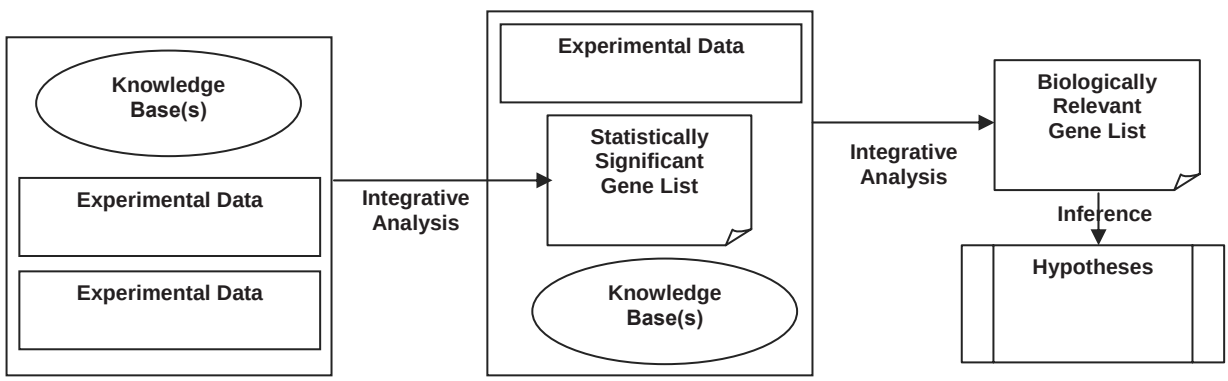
parallel integrative analysis techniques might be seen in the future that are better suited to a specific study. Such methods can then be adapted to other studies using knowledge about that particular domain and those datasets.

Apart from the semi-parallel analysis model seen earlier (Figure 2c), there can be other variations of the model. One such model (Figure 3a) uses few datasets together to perform the analysis and uses background knowledge (left out of the analysis phase intentionally based on the nature of the study or unintentionally based on the nature of the data) to further refine hypotheses. Yet another variation of the semi-parallel model (Figure 3b) analyzes some of these datasets individually and uses the generated results to guide the integrative analysis of the other datasets. An example would be to use the results for each gene from an analysis as annotation while analyzing the other datasets. Though many techniques for integrative analysis are seen, a comprehensive evaluation methodology still needs to be adopted to allow for comparisons between techniques and evaluation across varying datasets.

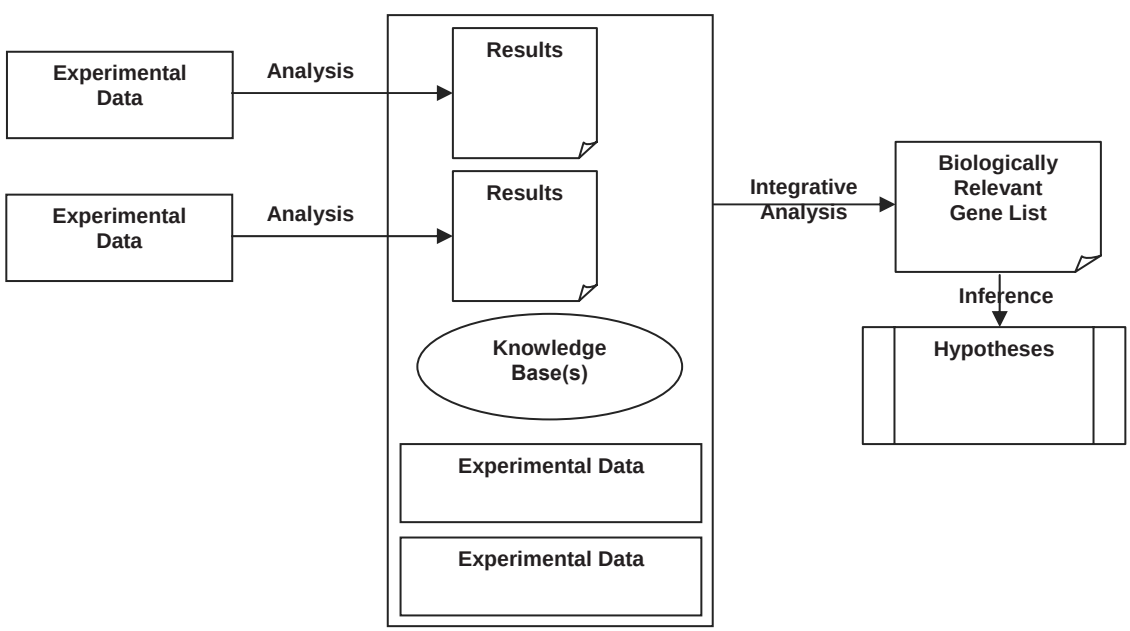
In addition, there is room to expand the application of these techniques in the current domains as well

Figure 3. Alternate semi-parallel analysis models

a. Alternate model 1 for semi-parallel integrative analysis of multiple high-throughput datasets with the aid of knowledge base(s)



b. Alternate model 2 for semi-parallel integrative analysis of multiple high-throughput datasets with the aid of knowledge base(s)



as to apply them to newer domains like personalized medicine. In most of the existing studies, the prominent datasets have been at the gene and protein expression level. In the future, we can foresee other datasets like SNP data and clinical data contributing equally to biological discovery.

CONCLUSION

The field of biological and biomedical informatics has been developing at a searing pace in recent years. This has resulted in the generation of a voluminous amount of data waiting to be analyzed. The field of data mining has been up to the challenge so far, with researchers taking a keen interest and providing impressive solutions to research questions. However, with the generation of heterogeneous datasets, the scope for analysis from a systems biology perspective has increased. This has stimulated the move from conventional independent analyses to novel integrated analyses.

Integrative analysis of biological data has been employed for a short while with some success. Different techniques for such integrative analyses have been developed. We have tried to summarize these techniques in the framework of the models described in Figure 2 and Figure 3. However, varied research questions and applications still exist and new data is being created continuously. Hence, there is a lot of scope for improvement and development of new techniques in this fledgling area, which could ultimately lead to important biological discoveries.

KEY TERMS

Annotation: Additional information that helps understand and interpret data better.

Biological Relevance: Relevance from a biological perspective as opposed to a statistical perspective.

Data Integration: Integration of multiple datasets from disparate sources.

DNA Microarrays: A technology used to measure the gene expression levels of thousands of genes at once.

Genomics/Proteomics: The study of the complete collection of knowledge encoded by DNA and proteins, respectively, in an organism.

High-throughput techniques: Biological techniques capable of performing highly parallel analyses that generate a large amount of data through a single experiment.

Integrated/Integrative Data Analysis: The analysis of multiple heterogeneous datasets under an integrated framework suitable to a particular application.

Meta-analyses: The combination and analysis of results from multiple independent analyses focusing on similar research questions.

Intelligent Image Archival and Retrieval System

INTRODUCTION

'A visual idea is more powerful than verbal idea', 'A picture is worth more than ten thousand words', 'No words can convey what a picture speaks', 'A picture has to be seen and searched as a picture only' are few of the well-known sayings that imply the certainty for the widespread availability of images. Common sense evidence suggests that images are required for a variety of reasons, like, illustration of text articles, conveying information or emotions that are difficult to describe in words, display of detailed data for analysis (medical images), formal recording of design data for later use (architectural plans) etc.

The advent of digital photography combined with decreasing storage and processing cost, allows more and more people to have their personal collection of photographs and other visual content available on the internet. Organising these digital images into a small number of categories and providing effective indexing is imperative for accessing, browsing and retrieving useful data in "real time". The process of digitization does not in itself make image collections easier to manage. Some form of indexing (cataloguing) is still necessary. People's interest to have their own digital libraries has burgeoned and hence requires a data structure to preserve the images for a long time and also provide easy access to the desired images. These requirements have indeed forced the design of specialized imaging systems/ image databases, such that an access to any image is effective and efficient.

An efficient image archival and retrieval system is characterized by its ability to retrieve relevant images based on their visual and semantic contents rather than using simple attributes or keywords assigned to them. Thus, it is necessary to support queries based on image semantics rather than mere-pixel-to-pixel matching. An image archival and retrieval system should therefore allow adequate abstraction mechanisms for capturing higher level semantics of images in order to support content addressability as far as possible. That is, for two images to be similar, not only the shape, color and texture properties of individual image regions must be similar, but also they must have the same arrangement (i.e., spatial relationships) in both the images. In fact, this is the strategy, which is generally being employed by our vision system most of the times. An effective method of representing images depends on the perception of knowledge embedded in images in terms of objects/components (generally known as elements) present in them along with their topological relationships. The perception of topological relationships, especially spatial relationships existing among the significant elements of an image, helps in making the image database system more intelligent, fast and flexible.

An obvious method to search an image database is sequential scanning. The query is matched with all stored images (i.e., the representation of the query is matched with all representations stored in the image database) one by one. Retrievals may become extremely slow, especially when database search involves time consuming image matching operations. To deal with slow retrieval response times, and high complexity matching, an image database must utilize indexing methods that are faster than sequential scanning methods. In traditional image database systems, the use of indexing to allow database accessing has been well established. Analogously, image indexing techniques have been studied during the last decade to support representation of pictorial information in an image database and also to retrieve information from an image database. The use of significant elements present in images along with their topological relationships as indexes is the basic issue of the indexing methodologies developed to this aim.

BACKGROUND

An image archival and retrieval system is a system in which a large amount of picture data and their related information are stored, retrieved and manipulated. It is indeed necessary to design an image database system that represents images more efficiently. In addition, making the system capable of responding to specified queries to retrieve desired images from the database besides devising robust search techniques to make retrieval process fast and flexible is interesting and more challenging.

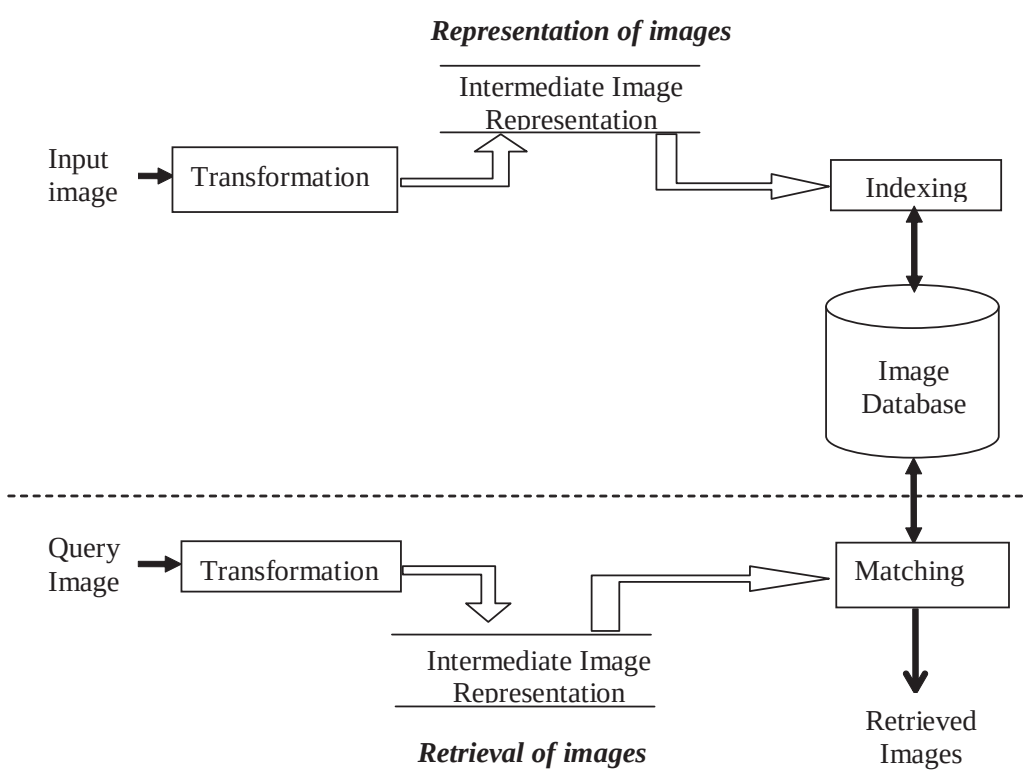
Image Archival and Retrieval System: An Architecture

Crucially, the design of an image database system is a two stage problem. The first stage deals with the representation of images in the image database while the second stage focuses on retrieving images relevant to a given query image as shown in Fig.1 The first stage concentrates on transforming images to intermediate representations through localization and identification of significant elements present in the images and then the mechanism of indexing the intermediate images in the image database. In the second stage, a given query image is subjected to the same transformation process to obtain its intermediate representation which shall subsequently be used in matching.

Image Transformation

Processing of images representing information only at pixel level to have interactive response to high-level user queries is not economically viable if not technologically impossible in a database environment where the number of images tends to be large. Therefore, given an image representing information at pixel level

Figure 1. General architecture of a typical image archival and retrieval system



(lower level), various image processing and understanding techniques are used to identify the domain objects/components and their locations in the image along with their centroid co-ordinates. An image is then obtained by associating a unique name and a meaningful graphic icon with each domain object identified. Intuitively, a domain object is a semantic entity (with respect to an application) contained in an image. For example, in the interior design application, the various furniture and decorative items in an image constitute the domain objects. An image of human face includes eyes, nose, mouth, ears and jaw as the domain objects. As another example, minutiae points with class labels and additional information such as their orientation form domain objects in fingerprint images. Encoding each iconic object present in an image by the respective label produces the corresponding symbolic image/ iconic image/ logical image. Though this task of transforming a physical image into corresponding symbolic image is computationally expensive and difficult, it is performed only once at the time of image insertion into the image database. Moreover this task may be carried out in a semi-automated (human –assisted) scheme or in a fully automated scheme depending upon the domain and complexity of images. However, the transformation of images into corresponding symbolic images, in itself is a challenging research topic.

The storage requirement for representing a symbolic image is relatively negligible when compared to that of representing the image as it is. The decision of arriving at relevant images for a given query is achieved by the usage of symbolic images only. Once the relevant images are identified, only those images are transferred from the central location to a local site.

Image Indexing

To achieve faster retrieval speed and make the retrieval system truly scalable to large size image collection, an effective and efficient indexing is an indispensable part of the whole image database system. The nature of the features extracted from images implies the need for some special purpose storage mechanisms. In order to provide efficient access and retrieval, the data stored in the image database must be organized in some way that enables searching directly based on the extracted features. This ability is often referred to as image indexing. An image database must provide some means of specifying the attributes that should be indexed. Methods should be provided to build these indices automatically. Thus, creation of an image database requires the knowledge of advanced issues in data structures.

Image Database

An image database is a repository of images consisting of a large amount of picture data and their related information. It consists of both symbolic images as well as their corresponding real images. The information stored in an image database can further be referred, retrieved and manipulated.

Image Matching

Once images are stored in an image database, the image database system should provide a means to retrieve images relevant to the specification. Since each image is associated with a feature vector, distance measures that compute distances between these feature vectors are used to find a match between images. Feature vectors usually exist in a very high dimensional space. Due to this high dimensionality, non-parametric approaches, like the nearest neighbor rule, are used for matching purpose. More generally, the matching works on the basis of two well accepted theories i.e., Minimum distance criterion and Maximum likelihood criterion. Minimum distance measure looks for the degree of dissimilarity between the query image and the image being retrieved as a relevant image to the query image, while maximum likelihood works based on the degree of similarity. Since an indexing mechanism based on the features extracted is already framed during representing images in the database, the same can be used to retrieve the images in an efficient way.

Visual Features for Image Retrieval

The area of image retrieval gained its initial attention in the late 70s. Since then, till date, it has attracted many researchers and has become a major focused field of Computer Vision. This is also evident from many special issues of leading journals being dedicated to this topic of research.

A large volume and variety of digital images currently acquired and used in different application domains has given rise to the requirement for intelligent image management and retrieval techniques. In particular,

there is an increased availability of automated image content analysis and description techniques in order to retrieve images efficiently from large collections, based on their visual content such as color, texture and shape information that is present in the images. In the following paragraphs we present a very brief review of the work done on various visual contents. A detailed survey on the approaches proposed and the systems developed in the early years can be found in (Liu et al., 2007; Punitha, 2006).

Color Based

Color not only adds beauty to objects but also gives more information, which can be used as powerful tool in content-based image retrieval. In color based retrieval, given a query image, the goal is to retrieve all the images whose color compositions are similar to the color composition of a given query image. Though the color matching algorithms have their own limitations, such as two semantically different objects possess same color, some researchers are still working in this area to improve the performance of color based retrieval systems (Ozden and Polat, 2007; Sun et al., 2006).

Texture Based

An ability to match on texture similarities can often be more useful in distinguishing between regions of images with same color (such as sky and sea, or leaves and grass). To achieve better performance in measuring texture similarities, a few techniques have been proposed recently (Sastry et al., 2007; Li and Taylor, 2005). Texture queries can be formulated in a similar manner to color queries, by selecting examples of desired textures from a palette, or by supplying an example query image. Similar to color, neither, ability to retrieve images on the basis of only texture similarity does seem very useful.

Shape Based

Shape is a fairly well defined concept compared to color and texture and there is considerable evidence that a natural object is primarily recognized by its shape. The problem of retrieving images containing objects, which are similar to the objects specified in a query image, is transformed into a problem of object recognition, or object classification which is a well known problem in computer vision research. Even recently, a few techniques for image retrieval based on shape were proposed (Chi and Leung, 2007; Alajlan et al., 2006).

Hybridised

A few models, with combined visual features are also explored (Ozden and Polat, 2007; Sun et al., 2006; Hafiane et al., 2006).

Image retrieval systems cited above mainly perform extraction of visual features typically color, shape and texture as a set of uncorrelated characteristics. Such features no doubt provide a global description of images but fail to consider the meanings of portrayed objects and the semantics of images. At a more abstract level of knowledge about the content of images, extraction of object descriptions and their relative positions provide a spatial configuration and a logical representation of images. An image retrieval system should perform similarity matching based on the representation of visual features conveying the content of segmented regions. Besides, it should capture the spatial relationship among the components, in order to face the user expectations. Indeed, we measure the similarity of images solely on the basis of the components' locations, relative to the locations of other known components present in images. For example, a door image may be of any color and with any design and still can be recognized immediately as a door image on the basis of the relative locations of the lock, doorknob and the handle on the door. Based on the spatial scattering of minutiae points, fingerprint image could be better archived and indexed for faster retrieval. Also, functions for retrieval by spatial similarity based on symbolic images are useful in distributed environments where physical images are stored only at a central location while the symbolic images are stored at each local site. Hence, the most appreciated, acclaimed and currently existing way of representing an image is through the perception of spatial relationships existing amongst the components present in it (Lee et al., 2007; Pham and Smeulders, 2006; Bloch et al., 2006, 2005; Punitha and Guru, 2006, 2005(a); Dehak et al., 2005; Castagliola et al., 2005; Maitre, 2005; Guru and Punitha, 2004(a)).

MAJOR FOCUS

Retrieval by spatial similarity has received considerable attention with many applications viz., object recognition (Pham and Smeulders, 2006), GIS (Hafiane et al., 2006), floor planning (Choi et al., 2006). Retrieval by spatial similarity deals with a class of queries that is based on spatial/topological relations (Punitha, 2006) among domain objects. The insinuated methodologies can be broadly classified into two categories, the value oriented which are shown to be insufficient to deal with complicated operations in an intelligent, fast and flexible manner as they work on low level image features, while other alternative object oriented models receive considerable attention. The object oriented methodologies can be further classified as string based approaches, matrix based approaches, hash table based approaches, graph based approaches.

2D string which is the foremost object oriented method brought a significant turn in the field of image retrieval offering many advantages. It used longest common subsequence matching for retrieval of similar images. Although, many string based representations, were inspired by 2D string, the linear string representation given to the spatial relations existing among the components takes nondeterministic-polynomial time complexity during the process of string matching, in addition to being not invariant to image transformations, especially to rotation. In order to reduce the search time and to avoid string matching, hash-oriented methodologies for similarity retrieval based upon the variations of string based approaches were explored. However, hash function-based algorithms require $O(m^2)$ retrieval time in the worst case, where m is the number of iconic objects. Most of the string based and hash based methodologies are not invariant to image transformations. Many matrix based approaches were proposed which tried to satisfy image invariance property to some extent. However, the matrix matching still increased the matching complexity. The graph based algorithms are again not very suitable as similarity matching in graph itself is a research topic.

In order to achieve fast retrieval, indexing search are learnt to be the best. Indexed search is faster than any other ways even for large collections (with more than 100 thousand images) (Lin et al., 2007; Saha et al., 2007; Manolopoulos et al., 2006; Punitha, 2006; Kwok and Leon, 2006; Alajlan et al., 2006; Guru et al., 2003). In addition to effectiveness and efficiency, an important characteristic of an image retrieval system should be that they are invariant to scene conditions, such as changes in viewpoint or image orientation. The formulation of invariant features have been recently addressed by a number of researchers in the field of image databases (Sastry et al., 2007; Shao and Brady, 2006; Punitha and Guru, 2006). To add to these, dynamic databases which support insertion and deletion of images is also gaining interest (Punitha, 2006; Dong and Bhanu, 2003). Most of the currently existing methods also restrict themselves to handle only ones instance of a particular object in the images. Due to its complexity, a very little research, is done in handling multiple instances of objects in images (Punitha and Guru, 2005(b); Guru and Punitha, 2004(b)). Many researchers are also working on identifying/segmenting and labeling objects by the study of low level visual features, which is an essential step for the design of an highly intelligent image archival and retrieval system (Pham and Smeulders, 2006; Shao and Brady, 2006).

FUTURE TRENDS

Despite the fact that semantic web technologies like ontology and semantic search, ostensive search which work on the basis of relevance feedback have received high appreciation, an intelligent IARS, which would retrieve images solely based on the visual features, without human intervention would be always foreseen and will be the most preferred. To assist this goal, efficient and robust techniques for the transformation of physical image into its corresponding logical image will have to be investigated. To achieve this, the possibility of incorporation of image segmentation and labeling techniques must be studied. To make the system intelligent enough to identify objects and also the semantics embedded in images, solely on the visual features, fuzzy theory based approaches could be explored. Moreover, in order to capture the reality being embedded in the physical image, an attempt to make use of unconventional data types viz., interval, range with weightage, multiple etc., in transforming a physical image into a logical image can also be made. Furthermore, discovering altogether a different method to represent logical image obtained through unconventional data analysis is very challenging. Of course, the corresponding retrieval schemes should also be devised. In order to further speed up the task of retrieval and

also to make it best suitable for online/real time applications, the parallel processing techniques may be incorporated. The parallelism can certainly be achieved as the elements present in images could concurrently be located and labeled to obtain logical images.

CONCLUSION

In this chapter, the state-of-art image retrieval specific to spatial reasoning has been highlighted. A very brief literature survey, especially on the recent contributions is made. Some open avenues and few directions are also figured out. In summary, there is a need for an efficient intelligent IARS. The developed IARS is expected to be intelligent enough to represent the images in a realistic manner. The system is intelligent in the sense that it supports knowledge driven image retrieval schemes, not simply based on similarity match but based on image induction too. That is, the algorithms are expected to mine the required knowledge, sometimes if possible, out of the raw data available about images in the image database. This capability would make the system useful in semantic based image retrieval.

KEY TERMS

2D String: An ordered pair *(u, v)*, where *u* and *v* denote a 1-dimensional string containing spatial relations between symbolic objects along the X and Y axes respectively.

Digital Photography: Corresponds to the images captured by digital sensors.

Image Archival and Retrieval System (IARS): A system in which a large amount of picture data and their related information are stored, retrieved and manipulated.

Image Indexing: A way of organizing the data to be stored in the image database in a way that enables searching directly based on the extracted features.

Intelligent IARS: A IARS which performs knowledge driven retrieval.

Symbolic Image: An abstract representation of the physical image with the objects in the image been segmented and labeled.

Texture: Refers to the patterns in an image that has the properties of homogeneity that do not result from the presence of single color or intensity value.

Intelligent Query Answering

Zbigniew W. Ras
University of North Carolina, Charlotte, USA

Agnieszka Dardzinska
Bialystok Technical University, Poland

INTRODUCTION

One way to make Query Answering System (QAS) intelligent is to assume a hierarchical structure of its attributes. Such systems have been investigated by (Cuppens & Demolombe, 1988), (Gal & Minker, 1988), (Gaasterland et al., 1992) and they are called cooperative. Any attribute value listed in a query, submitted to cooperative QAS, is seen as a node of the tree representing that attribute. If QAS retrieves no objects supporting query q, from a queried information system S, then any attribute value listed in q can be generalized and the same the number of objects supporting q in S can increase. In cooperative systems, these generalizations are controlled either by users (Gal & Minker, 1988), or by knowledge discovery techniques (Muslea, 2004).

If QAS for S collaborates and exchanges knowledge with other systems, then it is also called intelligent. In papers (Ras & Dardzinska, 2004, 2006), a guided process of rules extraction and their goal-oriented exchange among systems is proposed. These rules define foreign attribute values for S and they are used to construct new attributes and/or impute null or hidden values of attributes in S. By enlarging the set of attributes from which queries for S can be built and by reducing the incompleteness of S, we not only enlarge the set of queries which QAS can successfully handle but also we increase the overall number of retrieved objects.

So, QAS based on knowledge discovery has two classical scenarios which need to be considered:

- **System is standalone and incomplete.**

Classification rules are extracted and used to predict what values should replace null values before any query is answered.

- **System is distributed with autonomous sites (including site S). User needs to retrieve objects from S satisfying query q containing nonlocal attributes for S.**

We search for definitions of these non-local attributes at remote sites for S and use them to approximate q (Ras & Zytkow, 2000), (Ras & Dardzinska, 2004, 2006).

The goal of this article is to provide foundations and basic results for knowledge-discovery based QAS.

BACKGROUND

Modern query answering systems area of research is related to enhancements of query-answering systems into intelligent systems. The emphasis is on problems in users posing queries and systems producing answers. This becomes more and more relevant as the amount of information available from local or distributed information sources increases. We need systems not only easy to use but also intelligent in handling the users' needs. A query-answering system often replaces human with expertise in the domain of interest, thus it is important, from the user's point of view, to compare the system and the human expert as alternative means for accessing information.

A knowledge system is defined as an information system S coupled with a knowledge base KB which is simplified in (Ras & Zytkow, 2000), (Ras & Dardzinska, 2004, 2006) to a set of rules treated as definitions of attribute values. If information system is distributed with autonomous sites, these rules can be extracted either locally from S (query was submitted to S) or from its remote sites. The initial alphabet of QAS associated with S contains all values of attributes in *S*, called local, and all decision values used in rules from KB. When KB is updated (new rules are added or some deleted), the alphabet for the local query answering

system is automatically changed. It is often assumed that knowledge bases for all sites are initially empty. Collaborative information system (Ras & Dardzinska, 2004, 2006) learns rules describing values of incomplete attributes and attributes classified as foreign for its site called a client. These rules can be extracted at any site but their condition part should use, if possible, only terms which can be processed by the query answering system associated with the client. When the time progresses more and more rules can be added to the local knowledge base which means that some attribute values (decision parts of rules) foreign for the client are also added to its local alphabet. The choice of which site should be contacted first, in search for definitions of foreign attribute values, is mainly based on the number of attribute values common for the client and server sites. The solution to this problem is given in (Ras & Dardzinska, 2006).

MAIN THRUST

The technology dimension will be explored to help clarify the meaning of intelligent query answering based on knowledge discovery and chase.

Intelligent Query Answering for Standalone Information System

QAS for an information system is concerned with identifying all objects in the system satisfying a given description. For example an information system might contain information about students in a class and classify them using four attributes of "hair color", "eye color", "gender" and "size". A simple query might be to find all students with brown hair and blue eyes. When information system is incomplete, students having brown hair and unknown eye color can be handled by either including or excluding them from the answer to the query. In the first case we talk about optimistic approach to query evaluation while in the second case we talk about pessimistic approach. Another option to handle such a query would be to discover rules for eye color in terms of the attributes hair color, gender, and size. These rules could then be applied to students with unknown eye color to generate values that could be used in answering the query. Consider that in our example one of the generated rules said:

(hair, brown) $\wedge$ (size, medium) $\rightarrow$ (eye,brown).

Thus, if one of the students having brown hair and medium size has no value for eye color, then the query answering system should not include this student in the list of students with brown hair and blue eyes. Attributes hair color and size are classification attributes and eye color is the decision attribute.

We are also interested in how to use this strategy to build intelligent QAS for incomplete information systems. If query is submitted to information system S, the first step of QAS is to make S as complete as possible. The approach proposed in (Dardzinska & Ras, 2005) is to use not only functional dependencies to chase S (Atzeni & DeAntonellis, 1992) but also use rules discovered from a complete subsystem of S to do the chasing.

In the first step, intelligent QAS identifies all incomplete attributes used in a query. An attribute is incomplete in S if there is an object in S with incomplete information on this attribute. The values of all incomplete attributes are treated as concepts to be learned (in a form of rules) from S.

Incomplete information in S is replaced by new data provided by Chase algorithm based on these rules. When the process of removing incomplete vales in the local information system is completed, QAS finds the answer to query in a usual way.

Intelligent Query Answering for Distributed Autonomous Information Systems

Semantic inconsistencies are due to different interpretations of attributes and their values among sites (for instance one site can interpret the concept "young" differently than other sites). Different interpretations are also due to the way each site is handling null values. Null value replacement by values suggested either by statistical or knowledge discovery methods is quite common before user query is processed by QAS.

Ontology (Guarino, 1998), (Van Heijst et al., 1997) is a set of terms of a particular information domain and the relationships among them. Currently, there is a great deal of interest in the development of ontologies to facilitate knowledge sharing among information systems.

Ontologies and inter-ontology relationships between them are created by experts in corresponding domain,

but they can also represent a particular point of view of the global information system by describing customized domains. To allow intelligent query processing, it is often assumed that an information system is coupled with some ontology. Inter-ontology relationships can be seen as semantical bridges between ontologies built for each of the autonomous information systems so they can collaborate and understand each other.

In (Ras and Dardzinska, 2004), the notion of optimal rough semantics and the method of its construction have been proposed. Rough semantics can be used to model semantic inconsistencies among sites due to different interpretations of incomplete values of attributes. Distributed chase (Ras and Dardzinska, 2006) is a chase-type algorithm, driven by a client site of a distributed information system DIS, which is similar to chase algorithms based on knowledge discovery and presented in (Dardzinska and Ras, 2005). Distributed chase has one extra feature in comparison to other chase-type algorithms: the dynamic creation of knowledge bases at all sites of DIS involved in the process of solving a query submitted to the client site of DIS.

The knowledge base at the client site may contain rules extracted from the client information system and also rules extracted from information systems at remote sites in DIS. These rules are dynamically updated through the incomplete values replacement process (Ras and Dardzinska, 2004, 2006).

Although the names of attributes are often the same among sites, their semantics and granularity levels may differ from site to site. As the result of these differences, the knowledge bases at the client site and at remote sites have to satisfy certain properties in order to be applicable in a distributed chase.

So, assume that system S = (X,A,V), which is a part of DIS, is queried be user.

Chase algorithm, to be applicable to S, has to be based on rules from the knowledge base D associated with S which satisfies the following conditions:

1. Attribute value used in decision part of a rule from D has the granularity level either equal to or finer than the granularity level of the corresponding attribute in S.
2. The granularity level of any attribute used in the classification part of a rule from D is either equal or softer than the granularity level of the corresponding attribute in S.
3. Attribute used in the decision part of a rule from D either does not belong to A or is incomplete in S.

Assume again that S=(X,A,V) is an information system (Pawlak, 1991), where X is a set of objects, A is a set of attributes (seen as partial functions from X into $2^{(V\times[0,1])}$ and, V is a set of values of attributes from A. By [0,1] we mean the set of real numbers from 0 to 1. Let $L(D)=\{[t \rightarrow v_c] \in D: c \in In(A)\}$ be a set of all rules (called a knowledge-base) extracted initially from the information system S by ERID (Dardzinska and Ras, 2006), where In(A) is a set of incomplete attributes in S.

Assume now that query q(B) is submitted to system S=(X,A,V), where B is the set of all attributes used in q(B) and that $A \cap B \neq \emptyset$. All attributes in $B - [A \cap B]$ are called foreign for S. If S is a part of a distributed information system, definitions of foreign attributes for S can be extracted at its remote sites. Clearly, all semantic inconsistencies and differences in granularity of attribute values among sites have to be resolved first. In (Ras and Dardzinska, 2004) only different granularity of attribute values and different semantics related to different interpretations of incomplete attribute values among sites have been considered.

In (Ras and Dardzinska, 2006), it was shown that query q(B) can be processed at site S by discovering definitions of values of attributes from $B - [A \cap B]$ at the remote sites for S and next use them to answer q(B).

Foreign attributes for S in B, can be also seen as attributes entirely incomplete in S, which means values (either exact or partially incomplete) of such attributes should be ascribed by chase to all objects in S before query q(B) is answered. The question remains, if values discovered by chase are really correct?

Classical approach, to this kind of problems, is to build a simple DIS environment (mainly to avoid difficulties related to different granularity and different semantics of attributes at different sites). As the testing data set we have taken 10,000 tuples randomly selected from a database of some insurance company in Charlotte, NC. This sample table, containing 100 attributes, was randomly partitioned into four subtables of equal size containing 2,500 tuples each. Next, from each of these subtables 40 attributes (columns) have been randomly removed leaving four data tables of the size 2,500×60 each. One of these tables was called a

client and the remaining 3 have been called servers. Now, for all objects at the client site, values of one of the attributes, which was chosen randomly, have been hidden. This attribute is denoted by d. At each server site, if attribute d was listed in its domain schema, descriptions of d using See5 software (data are complete so it was not necessary to use ERID) have been learned. All these descriptions, in the form of rules, have been stored in the knowledge base of the client. Distributed Chase was applied to predict what is the real value of the hidden attribute for each object x at the client site. The threshold value $\lambda = 0.125$ was used to rule out all values predicted by distributed Chase with confidence below that threshold. Almost all hidden values (2476 out of 2500) have been discovered correctly (assuming $\lambda = 0.125$) (Ras & Dardzinska, 2006).

Distributed Chase and Security Problem of Hidden Attributes

Assume now that an information system S=(X,A,V) is a part of DIS and attribute $b \in A$ has to be hidden. For that purpose, we construct S_b=(X,A,V) to replace S, where:

1. $a_S(x) = a_{Sb}(x)$, for any $a \in A-\{b\}$, $x \in X$,
2. $b_{Sb}(x)$ is undefined, for any $x \in X$,
3. $b_S(x) \in V_b$.

Users are allowed to submit queries to S_b and not to S. What about the information system Chase(S_b)? How it differs from S?

If $b_S(x) = b_{Chase(Sb)}(x)$, where $x \in X$, then values of additional attributes for object x have to be hidden in S_b to guarantee that value $b_S(x)$ can not be reconstructed by Chase. Algorithm SCIKD for protection of sensitive data against Chase was proposed in (Im & Ras, 2007).

FUTURE TRENDS

One of the main problems related to semantics of an incomplete information system S is the freedom how new values are constructed to replace incomplete values in S, before any rule extraction process begins. This replacement of incomplete attribute values in some of the slots in S can be done either by chase or/and by a number of available statistical methods. This implies that semantics of queries submitted to S and driven (defined) by query answering system QAS based on chase may often differ. Although rough semantics can be used by QAS to handle this problem, we still have to look for new alternate methods.

Assuming different semantics of attributes among sites in DIS, the use of global ontology or local ontologies built jointly with inter-ontology relationships among them seems to be necessary for solving queries in DIS using knowledge discovery and chase. Still a lot of research has to be done in this area.

CONCLUSION

Assume that the client site in DIS is represented by partially incomplete information system S. When a query is submitted to S, its query answering system QAS will replace S by Chase(S) and next will solve the query using, for instance, the strategy proposed in (Ras and Dardzinska, 2004). Rules used by Chase can be extracted from S or from its remote sites in DIS assuming that all differences in semantics of attributes and differences in granularity levels of attributes are resolved first. We can argue here why the resulting information system obtained by Chase can not be stored aside and reused when a new query is submitted to S? If system S is not frequently updated, we can do that by keeping a copy of Chase(S) and next reusing that copy when a new query is submitted to S. But, the original information system S still has to be kept so when user wants to enter new data to S, they can be stored in the original system. System Chase(S), if stored aside, can not be reused by QAS when the number of updates in the original S exceeds a given threshold value. It means that the new updated information system S has to be chased again before any query is answered by QAS.

KEY TERMS

Autonomous Information System: Information system existing as an independent entity.

Chase: Kind of a recursive strategy applied to a database V, based on functional dependencies or rules extracted from V, by which a null value or an incomplete value in V is replaced by a new more complete value.

Distributed Chase: Kind of a recursive strategy applied to a database V, based on functional dependencies or rules extracted both from V and other autonomous databases, by which a null value or an incomplete value in V is replaced by a new more complete value. Any differences in semantics among attributes in the involved databases have to be resolved first.

Intelligent Query Answering: Enhancements of query-answering systems into sort of intelligent systems (capable or being adapted or molded). Such systems should be able to interpret incorrectly posed questions and compose an answer not necessarily reflecting precisely what is directly referred to by the question, but rather reflecting what the intermediary understands to be the intention linked with the question.

Knowledge Base: A collection of rules defined as expressions written in predicate calculus. These rules have a form of associations between conjuncts of values of attributes.

Ontology: An explicit formal specification of how to represent objects, concepts and other entities that are assumed to exist in some area of interest and relationships holding among them. Systems that share the same ontology are able to communicate about domain of discourse without necessarily operating on a globally shared theory. System commits to ontology if its

observable actions are consistent with the definitions in the ontology.

Query Semantics: The meaning of a query with an information system as its domain of interpretation. Application of knowledge discovery and Chase in query evaluation makes semantics operational.

Semantics: The meaning of expressions written in some language, as opposed to their syntax which describes how symbols may be combined independently of their meaning.

On Interacting Features in Subset Selection

INTRODUCTION

The high dimensionality of data poses a challenge to learning tasks such as classification. In the presence of many irrelevant features, classification algorithms tend to overfit training data (Guyon & Elisseeff, 2003). Many features can be removed without performance deterioration, and feature selection is one effective means to remove irrelevant features (Liu & Yu, 2005). Feature selection, also known as variable selection, feature reduction, attribute selection or variable subset selection, is the technique of selecting a subset of relevant features for building robust learning models. Usually a feature is relevant due to two reasons: (1) it is strongly correlated with the target concept; or (2) it forms a feature subset with other features and the subset is strongly correlated with the target concept. Optimal feature selection requires an exponentially large search space ($O(2^n)$, where n is the number of features) (Almual-lim & Dietterich, 1994). Researchers often resort to various approximations to determine relevant features, and in many existing feature selection algorithms, feature relevance is determined by correlation between individual features and the class (Hall, 2000; Yu & Liu, 2003). However, a single feature can be considered irrelevant based on its correlation with the class; but when combined with other features, it can become very relevant. Unintentional removal of these features can result in the loss of useful information and thus may cause poor classification performance, which is studied as attribute interaction in (Jakulin & Bratko, 2003). Therefore, it is desirable to consider the effect of feature interaction in feature selection.

BACKGROUND

The goal of feature selection is to remove irrelevant features and retain relevant ones. We first give the definition of feature relevance as in (John et al., 1994).

Definition 1 (Feature Relevance):

Let F be the full set of features, F_i be a feature and $S_i = F - \{F_i\}$. Let $P(C|S)$ denote the conditional probability of class C given a feature sets. A feature F_i is relevant *iff*

$$\exists S_i' \in S_i, \text{ such that } P(C \mid F_i, S_i') \neq P(C \mid S_i') \qquad (1)$$

Definition 1 suggests that a feature can be relevant, if its removal from a feature set reduces the prediction power of the feature set. A feature, whose removal does not reduce the prediction power of any feature set, is an irrelevant feature and can be removed from the whole feature set without any side-effect. From Definition 1, it can be shown that a feature can be relevant due to two reasons: (1) it is strongly correlated with the target concept; or (2) it forms a feature subset with other features and the subset is strongly correlated with the target concept. If a feature is relevant because of the second reason, there exists feature interaction. Feature interaction is characterized by its irreducibility (Jakulin & Bratko, 2004). We give the definition of *k*th-order below.

Definition 2 (*k*th order Feature Interaction):

Let F be a feature subset with k features $F_1, F_2, ..., F_k$. Let $\Im$ denote a metric that measures the relevance of a feature or a feature subset with the class label. Features $F_1, F_2, ... F_k$ are said to interact with each other *iff*: for an arbitrary partition $S = \{S_1, S_2, S_3, ... , S_l\}$ of F, where $2 \leq l \leq k$ and $S_i \neq \phi$, we have $\forall i \in [1, l]$, $\Im(F) > \Im(S_i)$.

It is clear that identifying either relevant features or *k*th-order feature interaction requires exponential time. Therefore Definitions 1 and 2 cannot be directly applied to identify relevant or interacting features when the dimensionality of a data set is huge. Many efficient feature selection algorithms identify relevant features based on the evaluation of the correlation between the

class and a feature (or a current, selected feature subset). Representative measures used for evaluating feature relevance includes (Liu & Motoda, 1998): distance measures (Kononenko, 1994; Robnik-Sikonja & Kononenko, 2003), information measures (Fleuret, 2004), and consistency measures (Almuallim & Dietterich, 1994), to name a few. Using these measures, feature selection algorithms usually start with an empty set and successively add "good" features to the selected feature subset, the so-called sequential forward selection (SFS) framework. Under this framework, features are deemed relevant mainly based on their individually high correlations with the class, and relevant interacting features of high order may be removed (Hall, 2000; Bell & Wang, 2000), because the irreducible nature of feature interaction cannot be attained by SFS. This motivates the necessity of handling feature interaction in feature selection process.

MAIN FOCUS

Finding high-order feature interaction using Definitions 1 and 2 entails exhaustive search of all feature subsets. Existing approaches often determine feature relevance using the correlation between individual features and the class, thus cannot effectively detect interacting features. Ignoring feature interaction and/or unintentional removal of interacting features might result in the loss of useful information and thus may cause poor classification performance. This problem arouses the research attention to the study of interacting features. There are mainly two directions for handling feature interaction in the process of feature selection: using *information theory* or through *margin maximization*.

Detecting Feature Interaction via Information Theory

Information theory can be used to detect feature interaction. The basic idea is that we can detect feature interaction by measuring the information loss of removing a certain feature. The measure of information loss can be achieved by calculating *interaction information* (McGill, 1954) or McGill's multiple mutual information (Han, 1980). Given three variables, *A*, *B* and *C*, the interaction information of them is defined as:

$$I(A;B;C) = H(AB) + H(BC) + H(AC) - H(A) - H(B) - H(C) - H(ABC)$$
$$= I(A,B;C) - I(A;C) - I(B;C) \quad (2)$$

Here $H(\cdot)$ denotes the entropy of a feature or a feature set. $I(X; Y)$ is the mutual information between X and Y, where X can be a feature set, such as $\{X_1, X_2\}$. Interaction information among features can be understood as the amount of information that is common to all the attributes, but not present in any subset. Like mutual information, interaction information is symmetric, meaning that I(A;B;C) = I(A;C;B) = I(C;B;A) = …. However, interaction information can be negative.

If we set one of the features in the interaction information to be the class, then the interaction information can be used to detect the *2*-way feature interaction as defined in Definition 2. $\Im$, the metric that measures the relevance of a feature or a feature subset with the class label, is defined as the mutual information between a feature or a feature set and the class. Positive interaction information indicates the existence of interaction between features.

Using the interaction information defined in Formula (2), we can only detect *2*-way feature interaction. To detect high order feature interaction, we need to generalize the concept to interactions involving an arbitrary number of attributes. In (Jakulin, 2005) the *k-way interaction information* is defined as:

$$I(S) = -\sum_{T \subseteq S} (-1)^{|S \setminus T|} H(T) \quad (3)$$

Where S is a feature set with k features in it, T is a subset of S and "\" is the set difference operator. $|\cdot|$ measures the cardinality of the input feature set, and $H(T)$ is the entropy for the feature subset T and is defined as:

$$H(T) = -\sum_{v \in T} P(v) \log_2 P(v) \quad (4)$$

According to Definition 3, the bigger the $I(S)$ is, the stronger the interaction between the features in S is. The *k*-way multiple mutual information defined in (Jakulin, 2005) is closely related to the lattice-theoretic derivation of multiple mutual information (Han, 1980), $\Delta h(S) = -I(S)$, and to the set-theoretic derivation of multiple mutual information (Yeung, 1991) and co-information (Bell, 2003) as $I'(S) = (-1)^{|S|} \times I(S)$.

Handling Feature Interaction via Margin Maximization

Margin plays an important role in current research of machine learning. It measures the confidence of a classifier with respect to its predictions. The margin of a classifier can be defined by two ways: sample-margin and hypothesis-margin. Sample-margin, as defined in Support Vector Machine (SVM) (Vapnik 1995), measures the distance between an instance and the decision boundary obtained from the classifier. While, the hypothesis-margin measures the "distance" between two alternative hypotheses (or predictions) which may be derived by a classifier on a certain instance. For classifiers, such as SVM (sample margin) and Adaboost (Freund & Schapire 1997) (hypothesis margin), a large margin ensures high accuracy as well as good generalization capability. Recall the fact that the removal of interacting features results in the loss of useful information and thus cause poor classification performance. It is quite straightforward that we can (explicitly) handle the feature interaction problem by selecting a subset of features that ensure the acquisition of large margin for classifiers. Apparently wrapper model (Koha & John 1997) can be utilized to achieve the margin maximization in feature selection. However, because of the high computation expense and its nature of inheriting bias from the classifier used in the wrapper model, a filter model is usually more preferable for feature selection algorithm design (Blum & Langley 1997).

Mostly, hypothesis margin is used to design selection algorithms in this category. Comparing with sample margin, the advantages of hypothesis margin are: first hypothesis margin is easier for computation, and second, hypothesis margin lower bounds the sample margin. In (Bachrach-et al. 2004), the hypothesis-margin of an instance x with respect to a set of points P is defined as:

$$\theta_P(x) = \frac{1}{2}(\|x - nearmiss(x)\| - \|x - nearhit(x)\|) \quad (5)$$

Here *nearhit(x)* and *nearmiss(x)* denote the nearest point to x in P with the same and different label respectively, and $\|\cdot\|$ is a distance measurement. On an instance x, the hypothesis margin measures the robustness of the prediction of the Nearest Neighbor classifier on the instance. It is clear-cut that a negative or small positive margin means an error or an unstable prediction, and a large positive margin means a correct and stable prediction. Therefore, as the sum of the hypothesis margins on each points, a large positive hypothesis margin on the whole dataset ensures the small error rate as well as the robustness of prediction. Based on this definition, a family of algorithms for feature selection using filter model can be developed (Robnik-Sikonja & Kononenko, 2003; Bachrach-et al. 2004; Navot-et al. 2005). RELIEF (Kira & Rendell, 1992; Robnik-Sikonja & Kononenko, 2003), one of the most successful feature selection algorithms, can be shown to be in this category. Figure 1 shows the RELIEF algorithm.

In Figure 1, w is an N dimension vector whose i-th element corresponding to the i-th feature. T is the total sampling times and N is the number of features. RELIEF tries to update the weight of features according to their contribution of the hypothesis margin on points of S. Therefore measured on the feature subset selected

Figure 1. the RELIEF algorithm

1. initialize the weight vector to zero: $w = 0$
2. for $t = 1 \ldots T$,
   (a) pick randomly an instance x from S
   (b) for $i = 1 \ldots N$,
   $$w_i = w_i + (x_i - nearmiss(x)_i)^2 - (x_i - nearhit(x)_i)^2$$
3. the chosen feature set is $\{i | w_i > \tau\}$ where τ is a threshold

by RELIEF, the hypothesis margin on the dataset S is big. Obviously, in RELIEF, the hypothesis margin maximization is achieved by online optimization (Krumke, 2002).

FUTURE TRENDS

Though feature interaction can be detected by interaction information, detecting high-order feature interactions is still a daunting task, especially when the dimensionality of the data is huge. In the framework of feature selection via margin maximization, feature interaction is handled efficiently, but its detection is implicit. Hence, it is highly desirable to investigate and develop efficient algorithms and new measurements that can effectively detect high-order feature interaction. One possible way is to combine the two frameworks into one, in which a margin-based feature selection algorithm, such as RELIEF, is first used to reduce the original input space to a tractable size, and then using the interaction information to detect feature interaction in the reduced feature space. In real world applications, the detection of interacting features goes beyond accurate classification. For example, in discriminant gene identification, finding interactions between genes involved in common biological functions is a way to get a broader view of how they work cooperatively in a cell. Therefore, it is promising to use feature interaction detection approaches to assist people to acquire better an understanding about the real-world problems in which interacting features exist.

CONCLUSION

Interacting features usually carry important information that is relevant to learning tasks. Unintentional removal of these features can result in the loss of useful information, and eventuate poor classification performance. Detecting feature interaction especially for data with huge dimensionality is computationally expensive. The challenge is to design efficient algorithms to handle feature interaction. In this short article, we present a brief review of the current status and categorize the existing approaches into two groups: *feature interaction detecting via information theory* and *handling feature interaction via margin maximization*. As the demand for finding interacting features intensifies, we anticipate the burgeoning efforts in search of effective and efficient approaches to answer pressing issues arising from many new data-intensive applications.

KEY TERMS

Feature Selection: An important data preprocessing technique for data mining, helps reduce the number of features, remove irrelevant, redundant, or noisy data, and bring the immediate effects for applications: speeding up a data mining algorithm, improving mining performance such as predictive accuracy and result comprehensibility.

Filter Model: The model relies on general characteristics of the data to evaluate the quality of select features without involving any mining algorithm.

Information Entropy: Information entropy, which is alsocalled Shannon's entropy, is the information-theoretic formulation of entropy. It measures how much information there is in a signal or event. An intuitive understanding of information entropy relates to the amount of uncertainty about an event associated with a given probability distribution. In thermodynamics, entropy is a measurement of the disorder of an isolated system.

Mutual Information: A quantity measures the mutual dependence of variables. It is nonnegative and symmetric.

Margin Maximization: It is a process to find the optimal decision boundary for a classifier, such that the margin (either the hypothesis margin or the sample margin) is maximized.

Support Vector Machines (SVMs): A type of supervised learning methods learns classification boundary through finding optimal hyper-planes between classes.

Wrapper Model: The model requires one predetermined mining algorithm and uses its performance as the evaluation criterion of the quality of selected features. It searches for features better suited to the mining algorithm aiming to improve mining performance

INTRODUCTION

Exploring and extracting knowledge from data is one of the fundamental problems in science. Data mining consists of important tasks, such as description, prediction and explanation of data, and applies computer technologies to nontrivial calculations. Computer systems can maintain precise operations under a heavy information load, and also can maintain steady performance. Without the aid of computer systems, it is very difficult for people to be aware of, to extract, to search and to retrieve knowledge in large and separate datasets, let alone interpreting and evaluating data and information that are constantly changing, and then making recommendations or predictions based on inconsistent and/or incomplete data.

On the other hand, the implementations and applications of computer systems reflect the requests of human users, and are affected by human judgement, preference and evaluation. Computer systems rely on human users to set goals, to select alternatives if an original approach fails, to participate in unanticipated emergencies and novel situations, and to develop innovations in order to preserve safety, avoid expensive failure, or increase product quality (Elm, *et al*., 2004; Hancock & Scallen, 1996; Shneiderman, 1998).

Users possess varied skills, intelligence, cognitive styles, and levels of tolerance of frustration. They come to a problem with diverse preferences, requirements and background knowledge. Given a set of data, users will see it from different angles, in different aspects, and with different views. Considering these differences, a universally applicable theory or method to serve the needs of all users does not exist. This motivates and justifies the co-existence of numerous theories and methods of data mining systems, as well as the exploration of new theories and methods.

According to the above observations, we believe that interactive systems are required for data mining tasks. Generally, interactive data mining is an integration of human factors and artificial intelligence (Maanen, Lindenberg and Neerincx, 2005); an interactive system is an integration of a human user and a computer machine, communicating and exchanging information and knowledge. Through interaction and communication, computers and users can share the tasks involved in order to achieve a good balance of automation and human control. Computers are used to retrieve and keep track of large volumes of data, and to carry out complex mathematical or logical operations. Users can then avoid routine, tedious and error-prone tasks, concentrate on critical decision making and planning, and cope with unexpected situations (Elm, *et al*., 2004; Shneiderman, 1998). Moreover, interactive data mining can encourage users' learning, improve insight and understanding of the problem to be solved, and stimulate users to explore creative possibilities. Users' feedback can be used to improve the system. The interaction is mutually beneficial, and imposes new coordination demands on both sides.

BACKGROUND

The importance of human-machine interaction has been well recognized and studied in many disciplines. One example of interactive systems is an information retrieval system or a search engine. A search engine connects users to Web resources. It navigates searches, stores and indexes resources and responses to users' particular queries, and ranks and provides the most relevant results to each query. Most of the time, a user initiates the interaction with a query. Frequently, feedback will arouse the user's particular interest, causing the user to refine the query, and then change or adjust further interaction. Without this mutual connection, it would be hard, if not impossible, for the user to access these resources, no matter how important and how relevant

they are. The search engine, as an interactive system, uses the combined power of the user and the resources, to ultimately generate a new kind of power.

Though human-machine interaction has been emphasized for a variety of disciplines, until recently it has not received enough attention in the domain of data mining (Ankerst, 2001; Brachmann & Anand, 1996; Zhao & Yao, 2005). In particular, the human role in the data mining processes has not received its due attention. Here, we identify two general problems in many of the existing data mining systems:

1. Overemphasizing the automation and efficiency of the system, while neglecting the adaptiveness and effectiveness of the system. Effectiveness includes human subjective understanding, interpretation and evaluation.
2. A lack of explanations and interpretations of the discovered knowledge. Human-machine interaction is always essential for constructing explanations and interpretations.

To study and implement an interactive data mining system, we need to pay more attention to the connection between human users and computers. For cognitive science, Wang and Liu (2003) suggest a relational metaphor, which assumes that relations and connections of neurons represent information and knowledge in the human brain, rather than the neurons alone. Berners-Lee (1999) explicitly states that "in an extreme view, the world can be seen as only connections, nothing else." Based on this statement, the World Wide Web was designed and implemented. Following the same way of thinking, we believe that interactive data mining is sensitive to the capacities and needs of both humans and machines. A critical issue is not how intelligent a user is, or how efficient an algorithm is, but how well these two parts can be connected and communicated, adapted, stimulated and improved.

MAIN THRUST

The design of interactive data mining systems is highlighted by the process, forms and complexity issues of interaction.

Processes of Interactive Data Mining

The entire knowledge discovery process includes data preparation, data selection and reduction, data pre-processing and transformation, pattern discovery, pattern explanation and evaluation, and pattern presentation (Brachmann & Anand, 1996; Fayyad, *et al*., 1996; Mannila, 1997; Yao, Zhao & Maguire, 2003; Yao, Zhong & Zhao, 2004). In an interactive system, these phases can be carried out as follows:

- Interactive data preparation observes raw data with a specific format. Data distribution and relationships between attributes can be easily observed.
- Interactive data selection and reduction involves the reduction of the number of attributes and/or the number of records. A user can specify the attributes of interest and/or data area, and remove data that is outside of the area of concern.
- Interactive data pre-processing and transformation determines the number of intervals, as well as cut-points for continuous datasets, and transforms the dataset into a workable dataset.
- Interactive pattern discovery interactively discovers patterns under the user's guidance, selection, monitoring and supervision. Interactive controls include decisions made on search strategies, directions, heuristics, and the handling of abnormal situations.
- Interactive pattern explanation and evaluation explains and evaluates the discovered pattern if the user requires it. The effectiveness and usefulness of this are subject to the user's judgement.
- Interactive pattern presentation visualizes the patterns that are perceived during the pattern discovery phase, and/or the pattern explanation and evaluation phase.

Practice has shown that the process is virtually a loop, which is iterated until satisfying results are obtained. Most of the existing interactive data mining systems add visual functionalities into some phases, which enable users to invigilate the mining process at various stages, such as raw data visualization and/or final results visualization (Brachmann & Anand, 1996; Elm, *et al*., 2004). Graphical visualization makes it easy to identify and distinguish the trend and distribution. This is a necessary feature for human-machine interaction,

but is not sufficient on its own. To implement a good interactive data mining system, we need to study the types of interactions users expect, and the roles and responsibilities a computer system should take.

Forms of Interaction

Users expect different kinds of human-computer interactions: proposition, information/guidance acquisition, and manipulation. These interactions proceed with the entire data mining process we mentioned above to arrive at desirable mining results.

Users should be allowed to make propositions, describe decisions and selections based on their preference and judgement. For example, a user can state an interested class value for classification tasks, express a target knowledge representation, indicate a question, infer features for explanation, describe a preference order of attributes, set up the constraints, and so on. Subjects of propositions differ among the varying views of individuals. One may initiate different propositions at different times based on different considerations at different cognitive levels. The potential value consideration enters in to the choice of proposition.

Information acquisition is a basic form of interaction associated with information analysis. Information might be presented in various fashions and structures. Raw data is raw information. Mined rules are extracted knowledge. Numerous measurements show the information of an object from different aspects. Each data mining phase contains and generates much information. An object might be changed; the information it holds might be erased, updated or manipulated by the user in question. Benchmarks, official standards and de facto standards are valuable reference knowledge, which can make it easier to learn and evaluate new applications. In general, information acquisition can be conducted by granular computing and hierarchy theory. A granule in a higher level can be decomposed into many granules in a lower level, and conversely, some granules in a lower level can be combined into a granule in a higher level. A granule in a lower level provides a more detailed description than that of a parent granule in the higher level, and a granule in a higher level has a more abstract description than a child granule in the lower level. Users need to retrieve the information in an interactive manner, namely, "show it correctly when I want to or need to see it, and in an understandable format."

Guidance acquisition is another form of interaction. A consultant role that an interactive system can play is to provide knowledge or skills that the user does not have in-house, for example, doing an evaluation or providing an analysis of the implications of environmental trends. To achieve this expert role, the interactive system must be able to "understand" the human proposition, and be able to make corresponding inferences. Guidance is especially useful while the domain is complex and the search space is huge. To achieve guidance, the system needs to store an extra rule base (usually serving as a standard or a reference), and be context aware. The inference function helps users to pay attention to items that are easily ignored, considered as "boundary" issues, or are important but not part of the current focus. The inference function takes the role and responsibility of a consultant. It ensures the process develops in a more balanced manner.

Manipulation is the form of interaction that includes selecting, retrieving, combining and changing objects, using operated objects to obtain new objects. Different data mining phases require different kinds of manipulations. Interactive manipulations obligate the computer system to provide necessary cognitive supports, such as: a systematic approach that uses an exhaustive search or a well-established, recursive search for solving a problem in a finite number of steps; a heuristic approach that selectively searches a portion of a solution space, a sub-problem of the whole problem, or a plausible solution according to the user's special needs; and an analogy approach that uses known solutions to solve an existing problem (Chiew & Wang, 2004; Matlin, 1998; Mayer, 1992; Ormrod, 1999). In addition, interactive systems should allow users to build their own mental buildings using the standard blocks. The blocks can be connected by functions similar to the pipe command in UNIX systems. What this means is that the standard output of the command to the left of the pipe is sent as standard input of the command to the right of the pipe. A result of this interaction is that users can define their own heuristics and algorithms.

The interaction should be directed to construct a reasonable and meaningful cognitive structure to each user. To a novice, the constructive operation is the psychological paradigm in which one constructs his/her own mental model of a given domain; to an expert, the constructive operation is an experienced practice containing anticipation, estimation, understanding and management of the domain.

Figure 1 illustrates the process and the forms of interactive data mining. A particular interactive data mining system can involve interactions of all four forms at six different phases.

Complexity of Interactive Data Mining Systems

Because of the special forms of interaction, complexity issues often raise concerns during implementation. Weir (1991) identified three sources of complexity in interactive applications.

Complexity of the domain: The domain can be very complex because of the size and type of data, the high dimensionality and high degree of linkage that exist in the data. Modelling the domain to a particular search space is essential. Some search spaces may embody a larger number of possible states than others. Knowledge may be not determined by a few discrete factors but by a compound of interrelated factors.

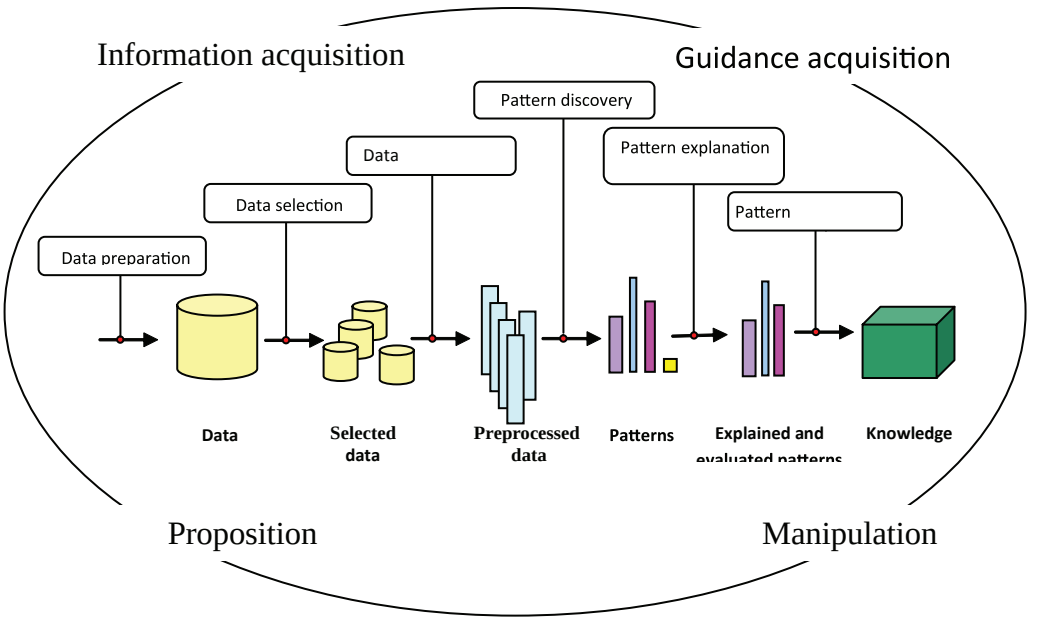
Complexity of control: The complexity of a specific control studies how much time and memory space a chosen computer routine/algorithm may take. It is characterized by its search direction, heuristic, constraint and threshold. Different routines/algorithms have different complexities of control. Normally, a complex domain yields a complex search space, and requires a complex control for searching solutions in the search space.

Complexity of interaction: Complexity of interaction concerns the execution issues of the four interaction forms, some of which are: deciding the degree of involvement of a specific form, scheduling process, doing, undoing, iteration and rollback of a specific control, goal setting and resetting, visualization and recommendation. The greater user demand is, the more complex the overall system becomes.

Implementation Examples

We have implemented an interactive classification system using a granule network (Zhao & Yao, 2005). A granule network systematically organizes all the subsets of the universe and formulas that define the subsets. A consistent classification task can be understood as a search for the distribution of classes in a granule network defined by the descriptive attribute set. Users can freely decide to use a partition-based method, a covering-based method, or a hybrid method for facilitating the search. Classification information can be easily retrieved in the form of a tree-view, a pie chart, a bar chart and/or a pivot table representation. The measurements of attribute and attribute-values are listed. These help the user to judge and select one for

Figure 1. Interactive data mining



splitting. Measures can be chosen from the pre-defined measurement set, or can be composed by the user. Users can validate the mined classification rules at any given time, continue or cease the training process according to the evaluation, split the tree node for higher accuracy, or remove one entire tree branch for simplicity.

Another implementation for interactive attribute selection is currently under construction. In order to keep the original interdependency and distribution of the attribute, the concept of reduct in rough set theory is introduced (Pawlak, 1991). Therefore, the selected attribute set is individually necessary and jointly sufficient for retaining all the information contained in the original attribute set. In this system, users can state a preference order of attributes, satisfying a weak order. Based on this order, a reduct that is most consistent, instead of a random reduct among many, can be computed and presented. Different construction strategies, such as add, add-delete and delete approaches, can be selected. Users can set their preferred attribute order once, or change the order dynamically in order to evaluate different results. In this case, users are allowed to choose a target reduct that is able to preserve accuracy, cost and utility, or distribution property. When a certain reduct is too complicated or too expensive to obtain, an approximate reduct can be constructed.

An interactive explanation-oriented system is our third implementation. The subjects selected for explanation, the explanation context, the explanation construction methods, as well as the explanation evaluation methods all highly dependent upon the preference of an individual user. Please refer to another paper (Yao, Zhao & Maguire, 2003) for further details on this topic.

FUTURE TRENDS

Interactive analysis and mining combines the power of both human users and computer systems. It relies on powerful intuition, analytical skills, insight, and creativity of humans, and fast processing speed, huge storage, and massive computational power of computers. Prototype systems will be implemented to demonstrate the usefulness of the proposed theoretical framework. The seamless integration of humans and computer systems may require the development of multilevel interactive systems, i.e., interaction applied from a low level to a high level, or from fully manual to fully automatic.

From the application point of view, interactive data analysis and mining plays a supporting role for a user. This enables us to design and implement next generation systems that support effective usage of data, for example, decision support systems, business support systems, research support systems and teaching support systems. Considerable research remains to be done.

CONCLUSION

The huge volume of raw data is far beyond a user's processing capacity. One goal of data analysis and mining is to discover, summarize and present information and knowledge from data in concise and human-understandable forms. It should be realized that, at least in the near future, insight about data, as well as its semantics, may not be achieved by a computer system alone. Users, in fact, need to interact with and utilize computer systems as research tools to browse, explore and understand data, and to search for knowledge and insight from data.

Implementing interactive computer systems is an emerging trend in the field of data mining. It aims to have human involvement in the entire data mining process in order to achieve an effective result. This interaction requires adaptive, autonomous systems and adaptive, active users. The performance of these interactions depends upon the complexities of the domain, control, and the available interactive approaches.

KEY TERMS

Complexity of Interactive Data Mining: Complexity of the domain, complexity of control and complexity of interaction. The greater user demand, the more complex the overall system becomes.

Forms of Interactive Data Mining: Proposition, information and guidance acquisition, and manipulation.

Interactive Data Mining: An integration of human factors and artificial intelligence. An interactive system thus is an integration of a human user with a computer machine. The study of interactive data mining and interactive systems is directly related to cognitive science.

Process of Interactive Data Mining: Interactive data preparation, interactive data selection and reduction, interactive data pre-processing and transformation, interactive pattern discovery, interactive pattern explanation and evaluation, and interactive pattern presentation.

Interest Pixel Mining

INTRODUCTION

Visual media data such as an image is the raw data representation for many important applications, such as image retrieval (Mikolajczyk & Schmid 2001), video classification (Lin & Hauptmann, 2002), facial expression recognition (Wang & Ahuja 2003), face recognition (Zhao, Chellappa, Phillips & Rosenfeld 2003), etc. Reducing the dimensionality of raw visual media data is highly desirable since high dimensionality may severely degrade the effectiveness and the efficiency of retrieval algorithms. To obtain low-dimensional representation of visual media data, we can start by selecting good low-level features, such as colors, textures, and interest pixels (Swain & Ballard 1991; Gevers & Smeulders 1998; Schmid, Mohr & Bauckhage 2000).

Pixels of an image may hold different interest strengths according to a specific filtering or convolution technique. The pixels of high interest strengths are expected to be more repeatable and stable than the pixels of low interest strengths across various imaging conditions, such as rotations, lighting conditions, and scaling. Interest pixel mining aims to detect a set of pixels that have the best repeatability across imaging conditions. (An algorithm for interest pixel mining is called a *detector*.) Interest pixel mining can be formulated into two steps: i) interest strength assignment via a specific filtering technique; and ii) candidate selection. The second step, candidate selection, plays an important role in preventing the output of interest pixels from being jammed in a small number of image regions in order to achieve best repeatability.

Based on interest pixels, various image representations can be derived. A straightforward scheme is to represent an image as a collection of local appearances—the intensities of neighboring pixels—of interest pixels (Schmid & Mohr 1997). By ignoring the spatial relationship of interest pixels, this "unstructured" representation requires no image alignment, i.e., free from establishing pixel-to-pixel correspondence among imaging objects by image transformations such as rotation, translation, and scaling. Furthermore, the unstructured representation is very robust with respect to outlier regions in a retrieval application. However, the retrieval cost under unstructured representation is extremely expensive. In the context of face recognition, feature distribution is introduced to capture both global and local information of faces (Li, Ye & Kambhamettu 2006A). A limitation of feature distribution is the assumption of image alignment. A promising trend on interest pixel based representation is to build graph or tree representation for each image and measure the similarity of two images by the edit distance of their graphs or trees (Zhang & Shasha 1989). But as we will see in the later section, this trend is strongly supported by a recently proposed interest pixel mining method (Li, Ye & Kambhamettu 2008).

BACKGROUND

Most previous studies on interest pixel mining focus on exploring filtering techniques, i.e., the first step of an interest pixel detector, which leads to several widely-used filtering techniques such as gradient autocorrelation (Harris & Stephens 1988), and Difference of Gaussian (Lowe 2004). For the second step, previous studies usually adopt the so-called non-maximum suppression as the candidate selection scheme (Harris & Stephens 1988; Schmid, Mohr & Bauckhage 2000; Lowe 2004). Assume each image pixel has been assigned an interest strength. Non-maximum suppression

resets the strength of a pixel to zero, i.e., eliminates its candidacy, if it is not a local maximum. Non-maximum suppression is very effective in preventing interest pixels from being jammed in a small number of image regions. However, studies also show that non-maximum suppression over-suppresses good candidates of interest pixels if an image is weakly-textured, e.g., a face image. Besides the issue of over-suppression, non-maximum suppression may also destroy local geometry information (Li, Ye & Kambhamettu 2008). Brown et. al. proposed adaptive non-maximum suppression to obtain spatially well distributed interest pixels over images (Brown Szeliski & Winder 2005). Instead of using a fixed-size suppression window, adaptive non-maximum suppression dynamically decreases the size of the suppression window. Adaptive non-maximum suppression has been shown to be competitive to the standard one in image mosaicing.

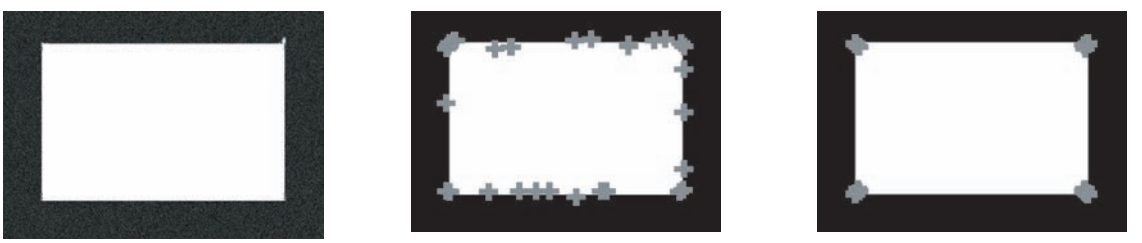
MAIN FOCUS

Li, Ye & Kambhamettu (2008) proposed a novel candidate selection scheme, called imbalance oriented selection that chooses image pixels whose zero-/first-order intensities are clustered into two imbalanced classes (in size), for interest pixel mining. The basic motivation for imbalance oriented selection is to minimize the occurrences of edge pixels. (An edge pixel is a pixel on the boundary of an object or a scene.) It is worth noting that edge pixels are usually not good features in the context of image retrieval. This is because they have similar local appearances, which increases uncertainty in matching local appearances. Besides the issue of ambiguity, the existence of large numbers of edge pixels can also result in high computational cost in high-level applications. Figure 1 shows the key difference between non-maximum suppression and imbalance oriented selection, with a simple image: a white board with a black background. In this circumstance, the edge pixels on the four boundaries of the white board are expected to have distinctly larger strength than other pixels. Furthermore, due to the reality of the existence of noise, the strength of an edge pixel may be slightly different from the strength of its neighboring edge pixels. (The image of a white board in Figure 1 contains 0.1% noise.) So, after non-maximum suppression, the output of interest pixels consists of some edge pixels scattered around the four boundaries. However, with an imbalance oriented scheme, the output of interest pixels only consists of a few image pixels around the four corners of the white board, due to the stronger ability of the scheme in suppressing edge pixels.

FEATURE DISTRIBUTION

A feature distribution of an image represents the number of occurrences of interest pixels in regular grids of an image plane. Figure 2 shows the flow of generating a feature distribution for a simple input image. Feature distribution has been shown a good representation

Figure 1. 30 interest pixels in the image of a white board with a black background

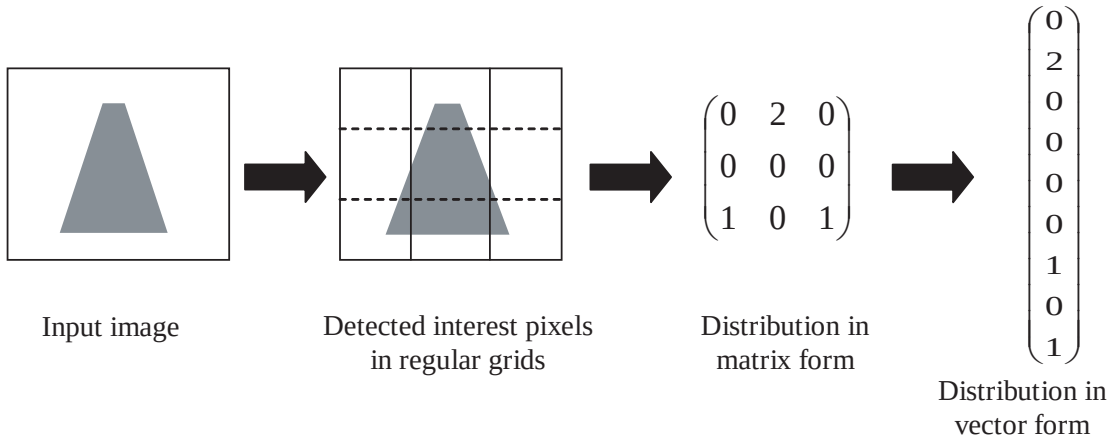


Input image

Non-maximum suppression

Imbalance oriented selection

Figure 2. The flow of generating a feature distribution



technique for face recognition and facial expression recognition (Li, Ye & Kambhamettu 2006A).

It has also been shown that imbalance oriented selection has stronger ability in preserving local geometry structures than non-maximum suppression and achieves better performance in various recognition tasks. A limitation of feature distribution based image representation is the assumption of image alignment. Automatic alignment of a general object is far from straightforward in many scenarios.

UNSTRUCTURED REPRESENTATION

A scheme to overcome the alignment sensitivity issue of feature distribution is to give up the global structure information, and use the local information only. An image is now represented as a set of local appearances of interest pixels (Schmid & Mohr 1997). A database of images is a collection of local appearances of interest pixels of all images along with a label per local appearance. To retrieve a query image from an image database is basically to inquire a set of local appearances of the query image. With the unstructured representation (no preservation of spatial relationship information among interest pixels), measuring the similarity of two images becomes robust with respect to outlier regions, in addition to the advantage of no alignment requirement. A limitation of the unstructured representation is the expensive retrieval cost. Addressing the application of face recognition, Li, Ye & Kambhamettu (2006B) proposed an adaptive framework to integrate the advantages of the structured and unstructured representation.

Specifically, the framework first determines whether an inquiry face image can be successfully aligned via automatic localization of the centers of two eyes. If the alignment can be achieved successfully, the inquiry face image is then represented as a single vector of the entire facial appearance that is inquired in a database of the structured representation of face images of known identities. Otherwise, the inquiry face image is represented as a set of vectors, each of which is associated with a local facial appearance and is inquired in a database of the unstructured representation of face images of known identities.

FUTURE TRENDS

To relax the requirement of image alignment, we may consider graph and furthermore tree representation. For example, based on a set of interest pixels, we can first build up a directed graph, where a node is associated with an interest pixel. Then we can design a certain

scheme to assign links among nodes by the global appearance information. Furthermore, we may obtain a component graph where a component consists of a subset of interest pixels in the same "object''. The above effort will lead us to a segmentation of an image. Figure 3 presents two toy images: a human face and a car, each of which consists of a hierarchy of objects. For example, a face has two eyes and each eye in turn contains one eyeball. Thus, we may use the enclosure/surrounding relationship among objects (components) to build a tree for an input image. The similarity of two images can then be computed by the tree edit distance, i.e., the number of operations of insertion, deletion or re-labeling in order to convert one tree to the other tree (Zhang & Shasha 1989). The idea of tree representation via interest pixels appears to be simple, it is however very difficult to succeed if interest pixels are mined via non-maximum suppression because of its two limitations. First, those interest pixels may include many edge pixels (as shown in Figure 1), which will result in much more noisy component graphs than interest pixels mined via imbalance oriented selection. Second, non-maximum suppression does not have mechanism to distinguish inner or outer pixel regarding a particular boundary, and so it is not reliable to use those interest pixels for segmentation and the enclosure relationship among components. So, the introduction of imbalance oriented selection becomes significant for this future trend.

CONCLUSION

Interest pixels are effective low-level features for image/video representation. Most existing methods for interest pixel mining apply non-maximum suppression to select good candidates. However non-maximum suppression over-suppresses good candidates of interest pixels if an image is weakly-textured and may also destroy local geometry information. Imbalance oriented selection was introduced to overcome the limitation of non-maximum suppression. Three different image representations via interest pixels are described along with the comparison of their advantage and disadvantage.

KEY TERMS

Detector: An algorithm that finds a number of image pixels of strongest interest strength.

Edge Pixel: A pixel on the boundary of an object or a scene. An edge pixel is also called a boundary pixel.

Feature Distribution: A representation of the number of occurrences of interest pixels in regular grids of an image plane.

Image Alignment: A procedure of establishing pixel-to-pixel correspondence among imaging objects by transformations such as rotation, translation, and scaling.

Imbalance Oriented Selection: A candidate selection scheme that chooses image pixels whose zero-/first-order intensities are clustered into two imbalanced classes (in size), as candidates.

Interest Pixel: A pixel that has stronger interest strength than other pixels in an image. An interest pixel is also called a corner, keypoint, or salient image point.

Interest Strength of a Pixel: The magnitude of the change in pixel values along different 2D directions, e.g., horizontal, vertical.

Local Appearance: The intensities of neighboring pixels centered by a given pixel.

Non-Maximum Suppression: A candidate selection scheme that resets the strength of a pixel to zero, i.e., eliminates its candidacy, if it is not a local maximum.

Repeatability: An interest pixel found in one image can be found in another again if these two images are spatially similar to each other.

An Introduction to Kernel Methods

Gustavo Camps-Valls

José Luis Rojo-Álvarez
Universidad Rey Juan Carlos, Spain

INTRODUCTION

Machine learning has experienced a great advance in the eighties and nineties due to the active research in artificial neural networks and adaptive systems. These tools have demonstrated good results in many real applications, since neither *a priori* knowledge about the distribution of the available data nor the relationships among the independent variables should be necessarily assumed. Overfitting due to reduced training data sets is controlled by means of a regularized functional which minimizes the complexity of the machine. Working with high dimensional input spaces is no longer a problem thanks to the use of kernel methods. Such methods also provide us with new ways to interpret the classification or estimation results. Kernel methods are emerging and innovative techniques that are based on first mapping the data from the original input feature space to a kernel feature space of higher dimensionality, and then solving a linear problem in that space. These methods allow us to geometrically design (and interpret) learning algorithms in the kernel space (which is nonlinearly related to the input space), thus combining statistics and geometry in an effective way. This theoretical elegance is also matched by their practical performance.

Although kernels methods have been considered from a long time ago in pattern recognition from a theoretical point of view (see, e.g., Capon, 1965), a number of powerful kernel-based learning methods emerged in the last decade. Significant examples are Support Vector Machines (SVMs) (Vapnik, 1998), Kernel Fisher Discriminant (KFD), (Mika, Ratsch, Weston, Scholkopf, & Mullers, 1999) Analysis, Kernel Principal Component Analysis (PCA) (Schölkopf, Smola and Müller, 1996), Kernel Independent Component Analysis Kernel (ICA) (Bach and Jordan, 2002), Mutual Information (Gretton, Herbrich, Smola, Bousquet, Schölkopf, 2005), Kernel ARMA (Martínez-Ramón, Rojo-Álvarez, Camps-Valls, Muñoz-Marí, Navia-Vázquez, Soria-Olivas, & Figueiras-Vidal, 2006), Partial Least Squares (PLS) (Momma & Bennet, 2003), Ridge Regression (RR) (Saunders, Gammerman, & Vovk, 1998), Kernel K-means (KK-means) (Camastra, & Verri, 2005), Spectral Clustering (SC) (Szymkowiak-Have, Girolami & Larsen, 2006), Canonical Correlation Analysis (CCA) (Lai & Fyfe, 2000), Novelty Detection (ND) (Schölkopf, Williamson, Smola, & Shawe-Taylor, 1999) and a particular form of regularized AdaBoost (Reg-AB), also known as Arc-GV (Rätsch, 2001). Successful applications of kernel-based algorithms have been reported in various fields such as medicine, bioengineering, communications, data mining, audio and image processing or computational biology and bioinformatics.

In many cases, kernel methods demonstrated results superior to their competitors, and also revealed some additional advantages, both theoretical and practical. For instance, kernel methods (i) efficiently handle large input spaces, (ii) deal with noisy samples in a robust way, and (iii) allow embedding user knowledge about the problem into the method formulation easily. The interest of these methods is twofold. On the one hand, the machine-learning community has found in the kernel concept a powerful framework to develop efficient nonlinear *learning* methods, and thus solving efficiently complex problems (e.g. pattern recognition, function approximation, clustering, source independence, and density estimation). On the other hand, these methods can be easily used and tuned in many research areas, e.g. biology, signal and image processing, communica-

tions, etc, which has also captured the attention of many researchers and practitioners in safety-related areas.

BACKGROUND

Kernel Methods offer a very general framework for machine learning applications (classification, clustering regression, density estimation and visualization) over many types of data (time series, images, strings, objects, etc). The main idea of kernel methods is to embed the data set $S \subseteq X$ into a higher (possibly infinite) dimensional Hilbert space $\mathcal{H}$. The mapping of the data S into the Hilbert Space $\mathcal{H}$ is done through a nonlinear transformation $x \mapsto f(x)$. Thus, there will be a nonlinear relationship between the input data x and its image in $\mathcal{H}$. Then, one can use linear algorithms to detect relations in the embedded data that will be viewed as nonlinear from the point of view of the input data.

This is a key point of the field: using linear algorithms provides many advantages since a well-established theory and efficient methods are available. The mapping is denoted here by $\phi: X \rightarrow \mathcal{H}$, where the Hilbert space $\mathcal{H}$ is commonly known also as *feature space*. Linear algorithms will benefit from this mapping because of the higher dimensionality of the Hilbert space. The computational burden would dramatically increase if one needed to deal with high dimensionality vectors, but there is a useful trick (the *kernel trick*) that allows us to use kernel methods. As a matter of fact, one can express almost any linear algorithm as a function of dot products among vectors. Then, one does not need to work with the vectors once the dot products have been computed. The kernel trick consists of computing the dot products of the data into the Hilbert space $\mathcal{H}$ as a function of the data in the input space. Such a function is called a Mercer's kernel. If it is available, one can implement a linear algorithm into a higher (possibly infinite) Hilbert Space $\mathcal{H}$ without needing to explicitly deal with vectors in these space, but just their dot products. Figure 1 illustrates several kernel methods in the feature spaces. In Figure 1(a), the classical SVM is shown, which basically solves the (linear) optimal separating hyperplane in a high dimensional feature spaces. Figure 1(b) shows the same procedure for the KFD, and Figure 1(c) shows how a novelty detection (known as one-class SVM) can be developed in feature spaces.

The above procedures are done under the framework of the Theorem of Mercer (Aizerman, Braverman & Rozonoér, 1964). A Hilbert space $\mathcal{H}$ is said to be a Reproducing Kernel Hilbert Space (RKHS) with a Reproducing Kernel Inner Product K (often called RKIP or more commonly, Kernel) if the members of $\mathcal{H}$ are functions on a given interval T and if kernel K is defined on the product $T \times T$ having the properties (Aronszajn, 1950):

- for every $t \in T$, $K(\cdot,t) \in \mathcal{H}$, with value at $s \in T$ equal to $K(s,t)$.
- There is a reproducing kernel inner product defined as $(g, K(\cdot,t))_K = g(t)$ for every g in $\mathcal{H}$.

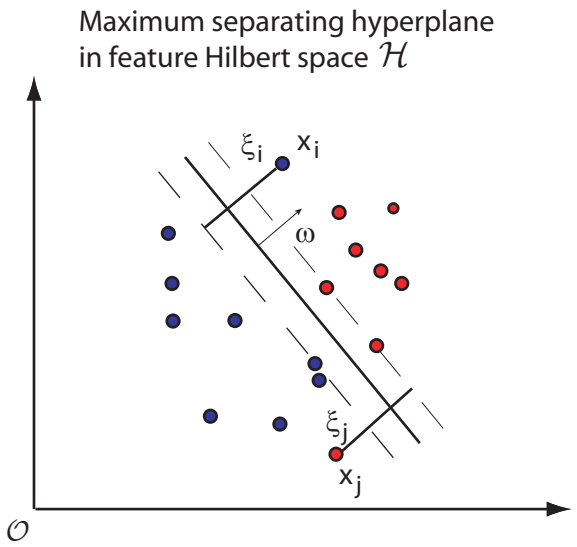
The Mercer's theorem states that there exist a function $\varphi: \mathbb{R}^n \rightarrow \mathcal{H}$ and a dot product $K(s, t) = \langle \varphi(s), \varphi(t) \rangle$ if and only if for any function $g(t)$ for which $\int g(t)dt < \infty$ the inequality $\int K(s, t)g(s)g(t)dsdt \geq 0$ is satisfied.

This condition is not always easy to prove for any function. The first kernels to be proven to fit the Mercer theorem were the polynomial kernel and the Gaussian kernel.

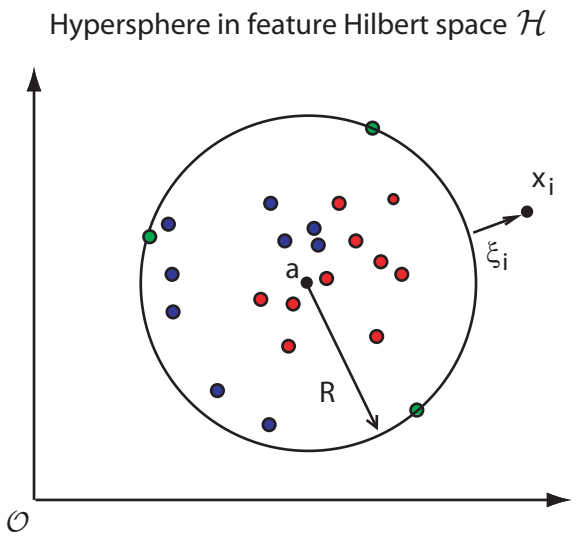
It is worth noting here that mapping ϕ does not require to be explicitly known to solve the problem. In fact, kernel methods work by computing the *similarity* among training samples (the so-called *kernel matrix*) by implicitly measuring distances in the feature space through the pair-wise inner products $\langle \phi(\mathbf{x}), \phi(\mathbf{z}) \rangle$ between mapped samples $\mathbf{x}, \mathbf{z} \in X$. The matrix $K_{ij} = K(\mathbf{x}_i, \mathbf{x}_j)$ (where $\mathbf{x}_i, \mathbf{x}_j$ are data points) is called the *kernel matrix* and contains all necessary information to perform many (linear) classical algorithms in the embedding space. As we said before, a linear algorithm can be transformed into its non-linear version with the so-called *kernel trick*.

The interested reader can find more information about all these methods in (Vapnik, 1998; Cristianini & Shawe-Taylor, 2000; Schölkopf & Smola, 2002; Shawe-Taylor & Cristianini, 2004). Among all good properties revised before, at present the most active area of research is the design of kernels for specific domains, such as string sequences in bioinformatics, image data, text documents, etc. The website www.kernel-machines.org provides free software, datasets, and constantly updated pointers to relevant literature.

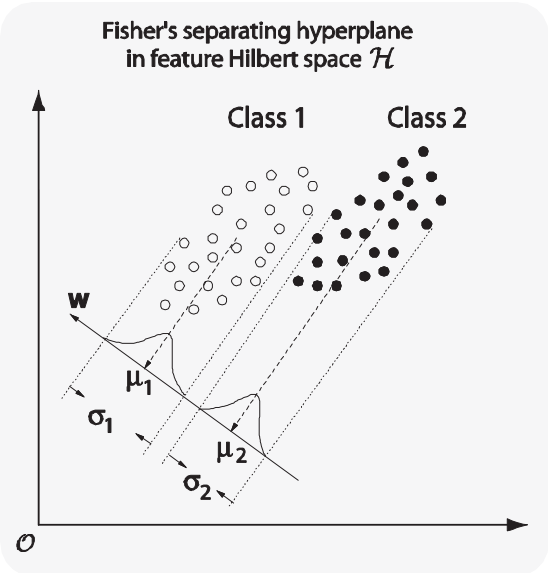
Figure 1.



(a) SVM. Linear decision hyperplane in a non-linearly transformed space, where slack variables ξ_i are included to deal with committed errors.



(b) One-class SVM. The hypersphere containing the (colored) target data is described by the center **a** *and radius* **R,** *in which the samples in the boundary are the support vectors (green) and samples outside the ball are assigned a positive constrained to deal with outliers.*



(c) KFD analysis. Illustration of Fisher's discriminant analysis for two classes. One searches for a direction w such that both the difference between the class means projected onto this directions (μ1, μ2) is large and the variance around these means (μ1, μ2) is small. The kernel Fisher discriminant performs this operation in a kernel space.

FUTURE TRENDS

Despite its few years of conception (early 1990s), the field of kernel methods is a mature enough research area and a huge amount of real-life successful applications have been reported. At present, the field is moving towards more challenging applications, such as working with huge databases, low number of labeled samples, transductive approaches, refined string kernels or the combination and fusion of both different domain knowledge and design of the kernel matrix.

CONCLUSION

This chapter was devoted to the definition of kernel methods and to the revision of the main general methods of application of them. The main feature of kernel methods applied to statistical learning is that they provide nonlinear properties to methods that are formulated in a linear way. This goal is achieved by

the kernel trick, which consists of a mapping of the data from an input space into a RKHS.

RKHS are Hilbert spaces provided with an inner product that is a function of the data in the input space. Therefore, one can compute dot products of the data in the Hilbert space without explicitly knowing the vectors in this space. Using this feature, linear algorithms can be "kernelized", so adding to them nonlinear properties but treating them as linear in these spaces implicitly. A set of references on the most known kernelized methods has been provided in this chapter.

KEYTERMS

Hilbert Space: A Hilbert space is a generalization of the Euclidean space not restricted to finite dimensions, thus being an inner product space.

Kernel Trick: This is a method for converting a linear algorithm into a non-linear one by mapping the samples in the input space to a higher-dimensional (possibly infinite) space so that solving a linear problem is more likely. This linear solution is non-linear in the original input space. This can be done using Mercer's condition, which states that any positive semi-definite kernel $K(x,y)$ can be expressed as a dot product in a high-dimensional space.

Maximum-Margin Hyperplane: In the context of geometry, this is a hyperplane that separates two sets of points, being at the same time at equal and maximum distance from the two.

Positive-Definite Matrix. An $n \times n$ Hermitian matrix M fulfilling that all its eigenvalues λ_i are positive or equivalently, for all non-zero (complex) vectors $\mathbf{z}$, $\mathbf{z}^*\mathbf{Mz} > 0$ where $\mathbf{z}^*$ indicates the conjugate transpose of $\mathbf{z}$.

Quadratic Programming (QP). This is a special type of mathematical optimization problem in which, given a sample $\mathbf{x}$ in $\mathbb{R}^n$, the $n \times n$ matrix Q is symmetric, and an $n \times 1$ vector c, the problem consists of minimizing with respect to $\mathbf{x}$:

$$f(x) = \frac{1}{2}\mathbf{x}^T\mathbf{Q}\mathbf{x} + \mathbf{c}^T\mathbf{x}$$

where superscript T is the transpose operator.

Regularization: In order to provide smoothness to the solution of an inverse problem, the problem must be regularized usually by imposing a bound on the norm of the model weights, inducing a natural trade-off between fitting the data and reducing a norm of the solution.

Reproducing Kernel Hilbert Space is a function space in which point-wise evaluation is a continuous linear functional, i.e. they are spaces that can be defined by reproducing kernels. Formally, given a dataset X and H a Hilbert space of (potentially) complex-valued functions on X, then H is a reproducing kernel Hilbert space if and only if the linear map $x \mapsto f(x)$ from H to the complex numbers is continuous for any x in X. By the Riesz representation theorem, this implies that for given x there exists an element K_x of H with the property that: $f(x) = \langle K_x, f \rangle \; \forall f \in H$. The function $K(x, y) \equiv K_x(y)$ is called a reproducing kernel for the Hilbert space.

Structural Risk Minimization (SRM). In contrast with empirical risk minimization, the SRM is to find the learning machine that yields a good trade-off between low empirical risk and small capacity (*see* regularization).

The Issue of Missing Values in Data Mining

Malcolm J. Beynon
Cardiff University, UK

INTRODUCTION

The essence of data mining is to investigate for pertinent information that may exist in data (often large data sets). The immeasurably large amount of data present in the world, due to the increasing capacity of storage media, manifests the issue of the presence of missing values (Olinsky *et al*., 2003; Brown and Kros, 2003). The presented encyclopaedia article considers the general issue of the presence of missing values when data mining, and demonstrates the effect of when managing their presence is or is not undertaken, through the utilisation of a data mining technique.

The issue of missing values was first exposited over forty years ago in Afifi and Elashoff (1966). Since then it is continually the focus of study and explanation (El-Masri and Fox-Wasylyshyn, 2005), covering issues such as the nature of their presence and management (Allison, 2000). With this in mind, the naïve consistent aspect of the missing value debate is the limited general strategies available for their management, the main two being either the simple deletion of cases with missing data or a form of imputation of the missing values in someway (see Elliott and Hawthorne, 2005). Examples of the specific investigation of missing data (and data quality), include in; data warehousing (Ma *et al*., 2000), and customer relationship management (Berry and Linoff, 2000).

An alternative strategy considered is the retention of the missing values, and their subsequent 'ignorance' contribution in any data mining undertaken on the associated original incomplete data set. A consequence of this retention is that full interpretability can be placed on the results found from the original incomplete data set. This strategy can be followed when using the nascent CaRBS technique for object classification (Beynon, 2005a, 2005b). CaRBS analyses are presented here to illustrate that data mining can manage the presence of missing values in a much more effective manner than the more inhibitory traditional strategies. An example data set is considered, with a noticeable level of missing values present in the original data set. A critical increase in the number of missing values present in the data set further illustrates the benefit from 'intelligent' data mining (in this case using CaRBS).

BACKGROUND

Underlying the necessity to concern oneself with the issue of missing values is the reality that most data analysis techniques were not designed for their presence (Schafer and Graham, 2002). It follows, an external level of management of the missing values is necessary. There is however underlying caution on the ad-hoc manner in which the management of missing values may be undertaken, this lack of thought is well expressed by Huang and Zhu (2002, p. 1613):

Inappropriate treatment of missing data may cause large errors or false results.

A recent article by Brown and Kros (2003) looked at the impact of missing values on data mining algorithms, including; *k*-nearest neighbour, decision trees, association rules and neural networks. For these considered techniques, the presence of missing values is considered to have an impact, with a level external management necessary to accommodate them. Indeed, perhaps the attitude is that it is the norm to have to manage the missing values, with little thought to the consequences of doing this. Conversely, there is also the possibilities that missing values differ in important ways from those that are present.

While common, the specific notion of the management of missing values is not so clear, since firstly it is often necessary to understand the reasons for their presence (De Leeuw, 2001), and subsequently how these reasons may dictate how they should be future described. For example, in the case of large survey data, whether the missing data is (*ibid*.); Missing by design, Inapplicable item, Cognitive task too difficult, Refuse to respond, Don't know and Inadequate score. Whether the data is survey based or from another source, a typi-

cal solution is to make simplifying assumptions about the mechanism that causes the missing data (Ramoni and Sebastiani, 2001). These mechanisms (causes) are consistently classified into three categories, based around the distributions of their presence, namely;

- *Missing Completely at Random (MCAR)*: The fact that an entry is missing is independent of both observed and unobserved values in the data set (e.g. equipment failure).
- *Missing at Random (MAR)*: The fact that an entry is missing is a function of the observed values in the data set (e.g. respondents are excused filling in part of a questionnaire).
- *Missing Not at Random (MNAR)*: An entry will be missing depends on both observed and unobserved values in the data set (e.g. personal demographics of a respondent contribute to the incompleteness of a questionnaire).

Confusion has surrounded the use of these terms (Regoeczi and Riedel, 2003). Further, the type of missing data influences the available methods to manage their presence (Elliott and Hawthorne, 2005). Two most popular approaches to their management are case deletion and imputation (next discussed), in the cases of the missing values being MCAR or MAR then imputation can produce a more complete data set that is not adversely biased (*ibid*.).

The case deletion approach infers cases in a data set are discarded if their required information is incomplete. This, by its nature incurs the loss of information from discarding partially informative case (Shen and Lai, 2001), De Leeuw (2001) describes the resultant loss of information, less efficient estimates and statistical tests. Serious biases may be introduced when missing values are not randomly distributed (Huang and Zhu, 2002). A further problem occurs if there is a small sample so deletion of too many cases may reduce the statistical significance of conclusions. Also associated with this approach is re-weighting, whereby the remaining complete cases can be weighted so that their distribution more closely resembles that of the full sample (Schafer and Graham, 2002; Huang and Zhu, 2002).

Imputation infers an incomplete data set becomes filled-in by the replacement of missing values with surrogates (Olinsky et al., 2003). It is potentially more efficient than case deletion, because no cases are sacrificed, retaining the full sample helps to prevent loss of power resulting from a diminished sample size (Schafer and Graham, 2002). De Leeuw (2001) identifies the availability of modern and user-friendly software encourages the use of imputation, with approaches that include; hot deck imputation, cold deck imputation, multiple imputation, regression and stochastic regression imputation.

Beyond these approaches the commonest is mean imputation, whereby the missing value for a given attribute in a case is filled in with the mean of all the reported values for that attribute (Elliott and Hawthorne, 2005). One factor often highlighted with the utilisation of mean imputation is that the distribution characteristics (including variance) of the completed data set may be underestimated (El-Masri and Fox-Wasylyshyn, 2005). The accompanying danger here is that this approach lulls the user into the plausible state of believing that the data are complete after all. The possible effectiveness of mean imputation, and other approaches, depends of course on the level of incompleteness inherent, with many studies testing results with differing percentages of missing data present (ibid.).

MAIN THRUST

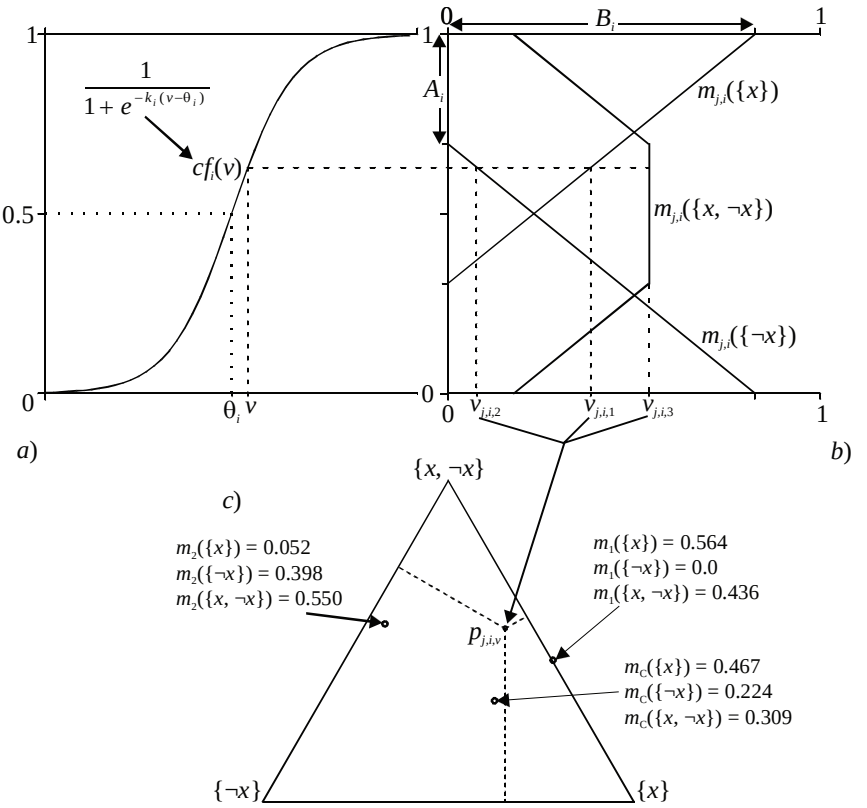
To demonstrate the effect of the management of missing values in data mining, the nascent CaRBS technique is employed (for a detailed elucidation see Beynon, 2005a, 2005b). The aim of the CaRBS technique is to construct a body of evidence (BOE) for each characteristic value that purports levels of exact belief (mass values – $m_{j,i}(\cdot)$) towards the classification of an object to a given hypothesis ($m_{j,i}(\{x\})$), its complement ($m_{j,i}(\{\neg x\})$) and concomitant ignorance ($m_{j,i}(\{x, \neg x\})$). More formally, the mass values come from:

$$m_{j,i}(\{x\}) = \frac{B_i}{1-A_i} cf_i(v) - \frac{A_i B_i}{1-A_i},$$

$$m_{j,i}(\{\neg x\}) = \frac{-B_i}{1-A_i} cf_i(v) + B_i,$$

and $m_{j,i}(\{x, \neg x\}) = 1 - m_{j,i}(\{x\}) - m_{j,i}(\{\neg x\})$, where $cf_i(v)$ is a confidence value (usually sigmoid function). A graphical representation of this process is given in Figure 1.

Figure 1. Stages within the CaRBS technique for a characteristic value $v_{j,i}$



The stages shown in Figure 1 report the construction and final representation in a simplex plot of a characteristic BOE $m_{j,i}(\cdot)$. A series of characteristic BOEs are then combined to form an object BOE that offers the final classification of the respective object (to x or $\neg x$), using Dempster's combination rule. A graphical example of this combination process is shown in Figure 1*c* ($m_1(\cdot)$ and $m_2(\cdot)$ combining to make $m_C(\cdot)$).

Within CaRBS, if a characteristic value is missing its characteristic BOE supports only ignorance, namely $m_{j,i}(\{x, \neg x\}) = 1$ (with $m_{j,i}(\{x\}) = m_{j,i}(\{\neg x\}) = 0$). The consequence is, a missing value is considered an ignorant value and so offers no evidence in the subsequent classification of an object, allowing their retention in the analysis (see Beynon, 2005b).

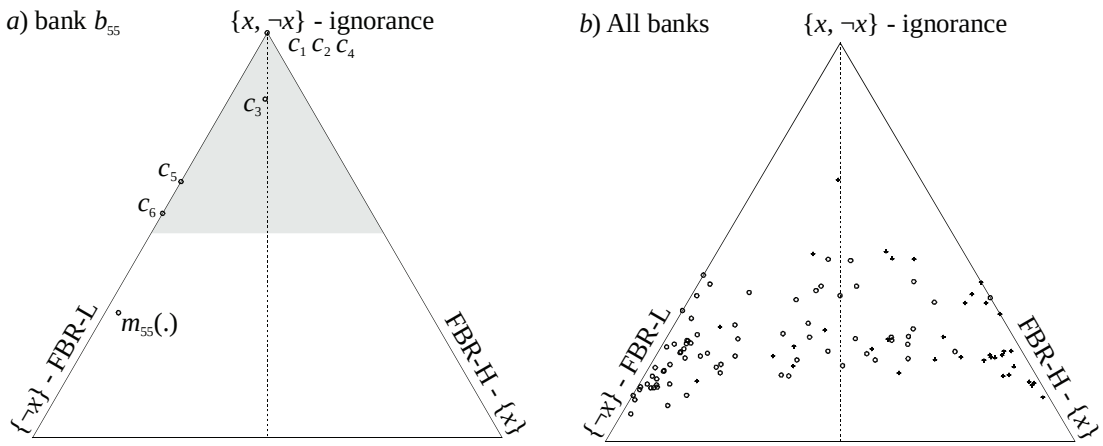
The Fitch Bank Individual Ratings (FBRs) on 108 UK banks is considered (FitchRatings, 2003), partitioned into two groups discerning between 'more than a strong bank' (FBR-H) and 'no more than a strong bank' (FBR-L). The FBR data set was obtained from the Bankscope database (Bankscope, 2005), with 14.35% of the data originally missing. Following Pasiouras *et al*. (2005), six financial characteristics describe the UK banks, briefly abbreviated here to; c_1 (42), c_2 (0), c_3 (7), c_4 (37), c_5 (7) and c_6 (0). The values in brackets indicate the number of missing values of each characteristic within the 108 banks.

The first analysis is undertaken on the original incomplete FBR data set. A configured CaRBS system optimises the classification of the banks through their object BOEs, to either FBR-H or FBR-L, by only minimising ambiguity (see Beynon, 2005b). The defined constrained optimisation problem was solved using trigonometric differential evolution (see Fan and Lampinen, 2003). The results for one bank are next presented, namely b_{55}, known to be classified to FBR-L (its description includes two missing values, c_1 and c_4). Presented in Table 1, are the characteristic BOEs $m_{55,i}(\cdot)$, $i = 1, \ldots, 6$, that describe the evidence from all the characteristics to the bank's FBR classification (for their evaluation see Beynon, 2005a).

Table 1. Characteristic BOEs $m_{55,i}(\cdot)$, $i = 1, \ldots, 6$ for the bank b_{55}

BOEs	c_1	c_2	c_3	c_4	c_5	c_6
Financial values	-	6.65	0.82	-	40.43	6.66
$m_{55,?}$({FBR-H})	0.000	0.000	0.078	0.000	0.000	0.000
$m_{55,?}$({FBR-L})	0.000	0.000	0.086	0.000	0.368	0.446
$m_{55,?}$({FBR-H, FBR-L})	1.000	1.000	0.836	1.000	0.632	0.554

Figure 2. Simplex plots of the FBR classification of the bank b_{55} and all banks



In Table 1 the missing characteristics, c_1 and c_4, offer only ignorant evidence ($m_{55,i}$({FBR-H, FBR-L}) = 1.000), as does c_2 (through the optimisation). For the bank b_{55}, these characteristic BOEs can be combined to construct its object BOE (using Dempster's combination rule), giving; m_{55}({FBR-H}) = 0.029, m_{55}({FBR-L}) = 0.663 and m_{55}({FBR-H, FBR-L}) = 0.309. The evidence towards each bank's FBR classification can be presented using the simplex plot method of data representation, see Figure 2.

In the simplex plot in Figure 2*a*, the base vertices identify certainty in the classification of a bank to either FBR-L (left) or FBR-H (right), and the top vertex is associated with total ignorance. The circles positioned in the grey-shaded region represent characteristic BOEs ($m_{55,i}(\cdot)$), with the resultant object BOE labelled $m_{55}(\cdot)$. The vertical dashed line identifies between where the evidence and final classification are more towards one FBR classification over the other, the bank b_{55} is shown correctly classified to FBR-L. In Figure 2*b*, the final FBR classifications of the 108 banks are reported using their object BOEs (FBR-L and FBR-H banks signified by circles and crosses), indicating 77.778% classification accuracy.

The next CaRBS analysis on the incomplete FBR data set includes when the missing values are managed using mean imputation. Utilising the simplex plot representation of the results, the FBR classification of bank b_{55} and final classification of all banks are given, see Figure 3.

For the bank b_{55} described in Figure 3*a*, the interesting feature is the contribution of c_1, which here offers incorrect evidence towards the bank's classification, even though it was a missing value that has been assigned a surrogate value. From Figure 3*b*, there is 75.926% classification accuracy, lower than that found earlier.

Figure 3. FBR classification of the bank b_{55} and all banks (missing values imputed)

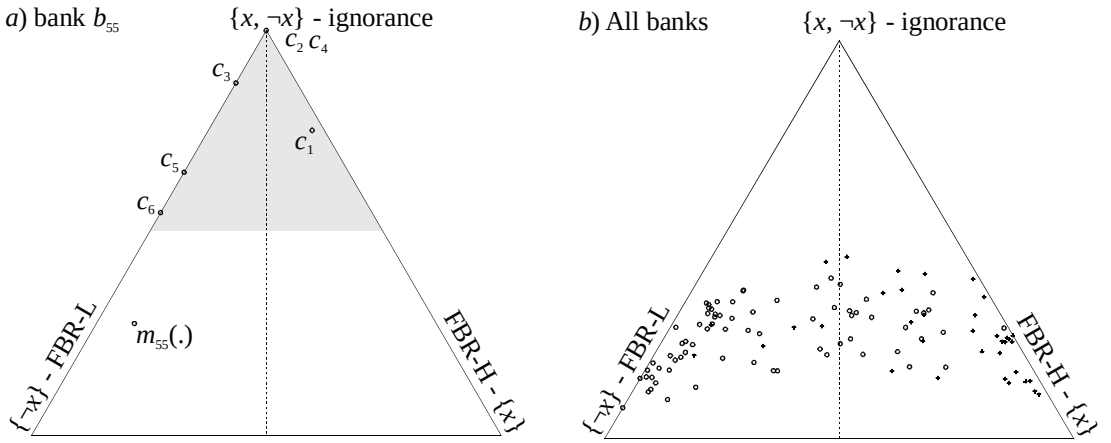


Table 2. Characteristic BOEs $m_{55,i}(\cdot)$, i = 1, …, 6 for the bank b_{55}

BOEs	c_1	c_2	c_3	c_4	c_5	c_6
Financial values	-	6.65	-	-	-	-
$m_{55,?}$({FBR-H})	0.000	0.000	0.000	0.000	0.000	0.000
$m_{55,?}$({FBR-L})	0.000	0.180	0.000	0.000	0.000	0.000
$m_{55,?}$({FBR-H, FBR-L})	1.000	0.820	1.000	1.000	1.000	1.000

The next CaRBS analysis considers a more incomplete FBR data set, with only 25% of the original data retained (no bank has all their characteristics defined missing). This level of incompleteness is critical to effective data mining (see Background section), but a CaRBS analysis can still be performed on it without any concern. For the bank b_{55}, it now only has one characteristic value not missing (c_2), the respective characteristic BOEs associated with it are reported in Table 2.

From Table 2, for the bank b_{55} the resultant object BOE is; $m_{55}(\{x\}) = 0.000$, $m_{55}(\{\neg x\}) = 0.180$ and $m_{55}(\{x, \neg x\}) = 0.820$ (the same as $m_{55,2}(\cdot)$), see also Figure 4.

In Figure 4*a*, the position of the object BOE $m_{55}(\cdot)$ for b_{55} infers more ignorance associated with its classification than in the previous analyses, a direct consequence of the majority of its characteristic values now being missing. In Figure 4*b*, a number of the presented object BOEs are nearer the top vertex than in the previous cases, again due to the large number of missing values present (a 83.333% classification accuracy exists in this case). Importantly, since no transformation of the data set has been undertaken, these results are interpretable. In the next analysis, all missing values are replaced using mean imputation (see Figure 5).

For the bank b_{55}, in Figure 5*a*, the c_1, c_3 and c_6 values contribute evidence even though they are all surrogates for missing values, whereas c_2 that was not missing now contributes only ignorance (Figure 5*b* identifies a 81.481% classification accuracy). This demonstrates how dramatically different results can be found when undertaking a large amount of imputation in a data set.

Figure 4. FBR classification of the bank b_{55} and all banks (25% available data)

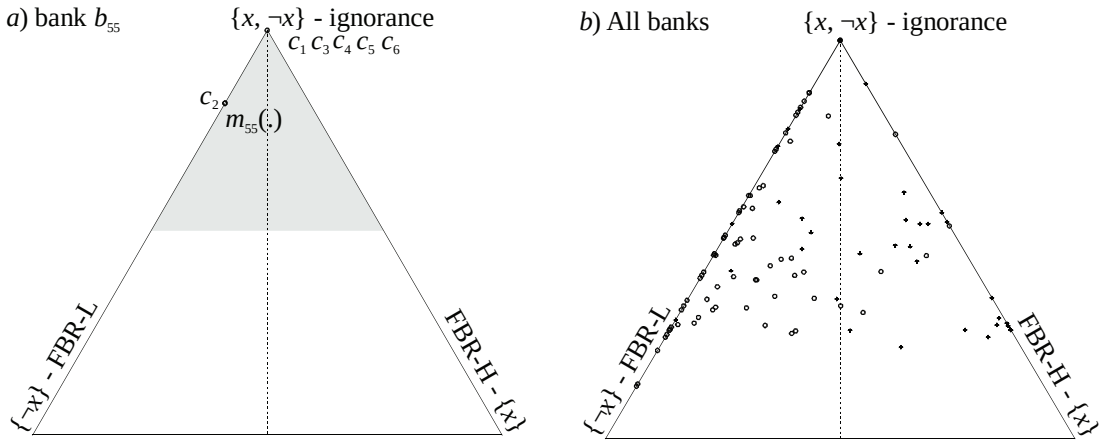

Figure 5. FBR classification of the bank b_{55} and all banks (25% available data the rest imputed)

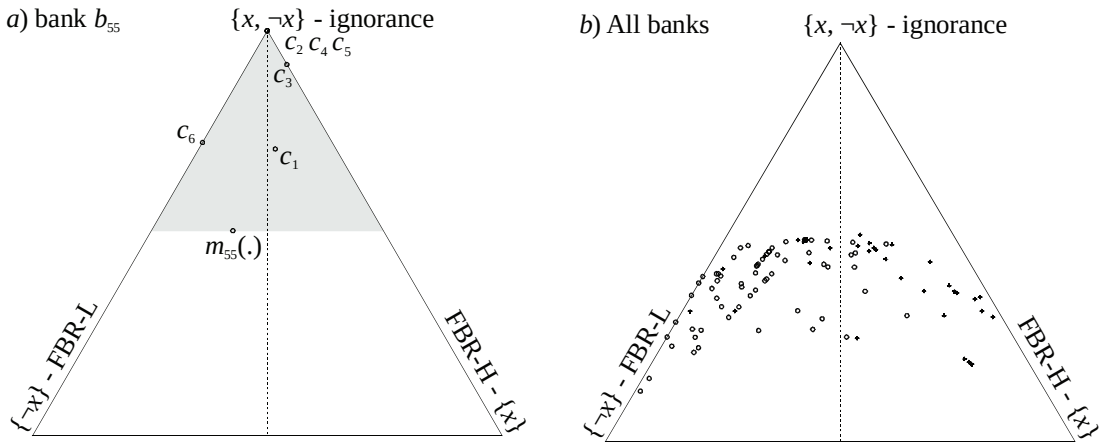

FUTURE TRENDS

Now, and in the future, the issue of missing values in data mining is not going to go away. Indeed, the concomitant literature continually suggests its increased presence, a facet of the increased capacity of computing power and storage media. Consequently, data mining techniques have to continue to offer the most realistic analyses in their presence.

For the most part, their presence is externally managed using approaches that still follow one of two main strategies, namely case deletion or imputation. Modern techniques like CaRBS show the way forward to their internal management. The future may require that the more traditional mining techniques should attempt to follow how the modern techniques work in the presence of missing values.

CONCLUSION

A general view of data mining is that it involves analysing data that the analyst probably had no direct control on its gathering. Moreover, it may be secondary data

accrued from one or more sources. The implication here is that the presence of missing values is similarly out of the control of the analyst, hence the need for their management. However, almost without question, the management has meant the alteration of the considered data set.

The CaRBS technique illustrates one example where it is possible to analyse data with missing values present without any need to incumbently manage them. The level of difference in the analyses when case deletion or imputation are or are not undertaken demonstrates the potential costs that need to be realised when managing missing values. This latter fact is perhaps most concerning since it is probably true that interpretability to data mining results are often undertaken even when missing values have been crudely managed (with the management action performed then soon forgotten).
