Foreword

Since my foreword to the first edition of the Encyclopedia written over three years ago, the field of data mining continued to grow with more researchers coming to the field from a diverse set of disciplines, including statistics, machine learning, databases, mathematics, OR/management science, marketing, biology, physics and chemistry, and contributing to the field by providing different perspectives on data mining for an ever-growing set of topics.

This cross-fertilization of ideas and different perspectives assures that data mining remains a rapidly evolving field with new areas emerging and the old ones undergoing major transformations. For example, the topic of mining networked data witnessed very significant advances over the past few years, especially in the area of mining social networks and communities of practice. Similarly, text and Web mining undergone significant evolution over the past few years and several books and numerous papers have been recently published on these topics.

Therefore, it is important to take periodic "snapshots" of the field every few years, and this is the purpose of the second edition of the Encyclopedia. Moreover, it is important not only to update previously published articles, but also to provide fresh perspectives on them and other data mining topics in the form of new overviews of these areas. Therefore, the second edition of the Encyclopedia contains the mixture of the two—revised reviews from the first edition and new ones written specifically for the second edition. This helps the Encyclopedia to maintain the balanced mixture of the old and the new topics and perspectives.

Despite all the progress made in the data mining field over the past 10–15 years, the field faces several important challenges, as observed by Qiang Yang and Xindong Wu in their presentation "10 Challenging Problems in Data Mining Research" given at the IEEE ICDM Conference in December 2005 (a companion article was published in the *International Journal of Information Technology & Decision Making*, 5(4) in 2006). Therefore, interesting and challenging work lies ahead for the data mining community to address these and other challenges, and this edition of the Encyclopedia remains what it is—a milestone on a long road ahead.

Alexander Tuzhilin
New York
December 2007

Preface

How can a manager get out of a data-flooded "mire"? How can a confused decision maker navigate through a "maze"? How can an over-burdened problem solver clean up a "mess"? How can an exhausted scientist bypass a "myth"?

The answer to all of these is to employ a powerful tool known as data mining (DM). DM can turn data into dollars; transform information into intelligence; change patterns into profit; and convert relationships into resources.

As the *third* branch of operations research and management science (OR/MS) and the *third* milestone of data management, DM can help support the *third* category of decision making by elevating raw data into the *third* stage of knowledge creation.

The term "third" has been mentioned four times above. Let's go backward and look at three stages of knowledge creation. Managers are drowning in data (the first stage) yet starved for knowledge. A collection of data is not information (the second stage); yet a collection of information is not knowledge! Data are full of information which can yield useful knowledge. The whole subject of DM therefore has a synergy of its own and represents more than the sum of its parts.

There are three categories of decision making: structured, semi-structured and unstructured. Decision making processes fall along a continuum that range from highly structured decisions (sometimes called programmed) to much unstructured, non-programmed decision making (Turban et al., 2006).

At one end of the spectrum, structured processes are routine, often repetitive, problems for which standard solutions exist. Unfortunately, rather than being static, deterministic and simple, the majority of real world problems are dynamic, probabilistic, and complex. Many professional and personal problems can be classified as unstructured, semi-structured, or somewhere in between. In addition to developing normative models (such as linear programming, economic order quantity) for solving structured (or programmed) problems, operation researchers and management scientists have created many *descriptive* models, such as simulation and goal programming, to deal with semi-structured tasks. Unstructured problems, however, fall into a gray area for which there is no cut-and-dry solution. The current two branches of OR/MS often cannot solve unstructured problems effectively.

To obtain knowledge, one must understand the patterns that emerge from information. Patterns are not just simple relationships among data; they exist separately from information, as archetypes or standards to which emerging information can be compared so that one may draw inferences and take action. Over the last 40 years, the tools and techniques used to process data and information have continued to evolve from databases (DBs) to data warehousing (DW), to DM. DW applications, as a result, have become business-critical and can deliver even more value from these huge repositories of data.

Certainly, there are many statistical models that have emerged over time. Earlier, machine learning has marked a milestone in the evolution of computer science (Fayyad, Piatetsky-Shapiro, Smyth & Uthurusamy, 1996). Although DM is still in its infancy, it is now being used in a wide range of industries and for a range of tasks and contexts (Wang, 2006). DM is synonymous with knowledge discovery in databases, knowledge extraction, data/pattern analysis, data archeology, data dredging, data snooping, data fishing, information harvesting, and

business intelligence (Hand et al., 2001; Giudici, 2003; Han & Kamber, 2006). Data warehousing and mining (DWM) is the science of managing and analyzing large datasets and discovering novel patterns within them. In recent years, DWM has emerged as a particularly exciting and relevant area of research. Prodigious amounts of data are now being generated in domains as diverse and elusive as market research, functional genomics, and pharmaceuticals and intelligently analyzing them to discover knowledge is the challenge that lies ahead.

Yet managing this flood of data, and making it useful and available to decision makers has been a major organizational challenge. We are facing and witnessing global trends (e.g. an information/knowledge-based economy, globalization, technological advances etc.) that drive/motivate data mining and data warehousing research and practice. These developments pose huge challenges (eg. need for faster learning, performance efficiency/effectiveness, new knowledge and innovation) and demonstrate the importance and role of DWM in responding to and aiding this new economy through the use of technology and computing power. DWM allows the extraction of "nuggets" or "pearls" of knowledge from huge historical stores of data. It can help to predict outcomes of future situations, to optimize business decisions, to increase the customer relationship management, and to improve customer satisfaction. As such, DWM has become an indispensable technology for businesses and researchers in many fields.

The Encyclopedia of Data Warehousing and Mining (2nd Edition) provides theories, methodologies, functionalities, and applications to decision makers, problem solvers, and data mining professionals and researchers in business, academia, and government. Since DWM lies at the junction of database systems, artificial intelligence, machine learning and applied statistics, it has the potential to be a highly valuable area for researchers and practitioners. Together with a comprehensive overview, *The Encyclopedia of Data Warehousing and Mining* (2nd Edition) offers a thorough exposure to the issues of importance in this rapidly changing field. The encyclopedia also includes a rich mix of introductory and advanced topics while providing a comprehensive source of technical, functional, and legal references to DWM.

After spending more than two years preparing this volume, using a totally peer-reviewed process, I am pleased to see it published. Of the *324* articles, there are *214* brand-new articles and 110 updated ones that were chosen from the *234* manuscripts in the first edition. Clearly, the need to significantly update the encyclopedia is due to the tremendous progress in this ever-growing field. Our selection standards were very high. Each chapter was evaluated by at least three peer reviewers; additional third-party reviews were sought in cases of controversy. There have been numerous instances where this feedback has helped to improve the quality of the content, and guided authors on how they should approach their topics. The primary objective of this encyclopedia is to explore the myriad of issues regarding DWM. A broad spectrum of practitioners, managers, scientists, educators, and graduate students who teach, perform research, and/or implement these methods and concepts, can all benefit from this encyclopedia.

The encyclopedia contains a total of *324* articles, written by an international team of *555* experts including leading scientists and talented young scholars from *over forty* countries. They have contributed great effort to create a source of solid, practical information source, grounded by underlying theories that should become a resource for all people involved in this dynamic new field. Let's take a peek at a few articles:

Kamel presents an overview of the most important issues and considerations for preparing data for DM. Practical experience of DM has revealed that preparing data is the most time-consuming phase of any DM project. Estimates of the amount of time and resources spent on data preparation vary from at least 60% to upward of 80%. In spite of this fact, not enough attention is given to this important task, thus perpetuating the idea that the core of the DM effort is the modeling process rather than all phases of the DM life cycle.

The past decade has seen a steady increase in the number of fielded applications of predictive DM. The success of such applications depends heavily on the selection and combination of suitable pre-processing and modeling algorithms. Since the expertise necessary for this selection is seldom available in-house, users must either resort to trial-and-error or consultation of experts. Clearly, neither solution is completely satisfactory for the non-expert end-users who wish to access the technology more directly and cost-effectively. Automatic and systematic guidance is required. Giraud-Carrier, Brazdil, Soares, and Vilalta show how meta-learning can be leveraged to provide such guidance through effective exploitation of meta-knowledge acquired through experience.

Ruqian Lu has developed a methodology of acquiring knowledge automatically based on pseudo-natural language understanding. He has won two first class awards from the Academia Sinica and a National second class prize. He has also won the sixth Hua Loo-keng Mathematics Prize.

Wu, McGinnity, and Prasad present a general self-organizing computing network, which have been applied to a hybrid of numerical machine learning approaches and symbolic AI techniques to discover knowledge from databases with a diversity of data types. The authors have also studied various types of bio-inspired intelligent computational models and uncertainty reasoning theories. Based on the research results, the IFOMIND robot control system won the 2005 Fourth British Computer Society's Annual Prize for Progress towards Machine Intelligence.

Zhang, Xu, and Wang introduce a class of new data distortion techniques based on matrix decomposition. They pioneer use of *Singular Value Decomposition* and *Nonnegative Matrix Factorization* techniques for perturbing numerical data values in privacy-preserving DM. The major advantage of this class of data distortion techniques is that they perturb the data as an entire dataset, which is different from commonly used data perturbation techniques in statistics.

There are often situations with large amounts of "unlabeled data" (where only the explanatory variables are known, but the target variable is not known) and with small amounts of labeled data. As recent research in machine learning has shown, using only labeled data to build predictive models can potentially ignore useful information contained in the unlabeled data. Yang and Padmanabhan show how learning patterns from the entire data (labeled plus unlabeled) can be one effective way of exploiting the unlabeled data when building predictive models.

Pratihar explains the principles of some of the non-linear *Dimensionality Reduction* (DR) techniques, namely Sammon's *Non-Linear Mapping* (NLM), *VISOR algorithm*, *Self-Organizing Map* (SOM) and *Genetic Algorithm* (GA)-Like Technique. Their performances have been compared in terms of accuracy in mapping, visibility and computational complexity on a test function – Schaffer's F1. The author had proposed the above GA-like Technique, previously.

A lot of projected clustering algorithms that focus on finding specific projection for each cluster have been proposed very recently. Deng and Wu found in their study that, besides distance, the closeness of points in different dimensions also depends on the distributions of data along those dimensions. Based on this finding, they propose a projected clustering algorithm, IPROCLUS (Improved PROCLUS), which is efficient and accurate in handling data in high dimensional space. According to the experimental results on real biological data, their algorithm shows much better accuracy than PROCLUS.

Meisel and Mattfeld highlight and summarize the state of the art in attempts to gain synergies from integrating DM and Operations Research. They identify three basic ways of integrating the two paradigms as well as discuss and classify, according to the established framework, recent publications on the intersection of DM and Operations Research.

Yuksektepe and Turkay present a new data classification method based on *mixed-integer programming*. Traditional approaches that are based on partitioning the data sets into two groups perform poorly for multi-class data classification problems. The proposed approach is based on the use of hyper-boxes for defining boundaries of the classes that include all or some of the points in that set. A *mixed-integer programming* model is developed for representing existence of hyper-boxes and their boundaries.

Reddy and Rajaratnam give an overview of the *Expectation Maximization* (EM) algorithm, deriving its theoretical properties, and discussing some of the popularly used global optimization methods in the context of this algorithm. In addition the article provides details of using the EM algorithm in the context of the finite mixture models, as well as a comprehensive set of derivations in the context of *Gaussian* mixture models. Also, it shows some comparative results on the performance of the EM algorithm when used along with popular global optimization methods for obtaining maximum likelihood estimates and the future research trends in the EM literature.

Smirnov, Pashkin, Levashova, Kashevnik, and Shilov describe usage of an *ontology-based context model* for decision support purposes and document ongoing research in the area of intelligent decision support based on context-driven knowledge and information integration from distributed sources. Within the research the context is used for representation of a decision situation to the decision maker and for support of the decision maker in

solving tasks typical for the presented situation. The solutions and the final decision are stored in the user profile for further analysis via decision mining to improve the quality of the decision support process.

Corresponding to Feng, XML-enabled association rule framework extends the notion of associated items to XML fragments to present associations among trees rather than simple-structured items of atomic values. They are more flexible and powerful in representing both simple and complex structured association relationships inherent in XML data. Compared with traditional association mining in the well-structured world, mining from XML data, however, is confronted with more challenges due to the inherent flexibilities of XML in both structure and semantics. To make XML-enabled association rule mining truly practical and computationally tractable, template-guided mining of association rules from large XML data must be developed.

With the XML becoming a standard for representing business data, a new trend toward XML DW has been emerging for a couple of years, as well as efforts for extending the XQuery language with near-OLAP capabilities. Mahboubi, Hachicha, and Darmont present an overview of the major XML warehousing approaches, as well as the existing approaches for performing OLAP analyses over XML data. They also discuss the issues and future trends in this area and illustrate this topic by presenting the design of a unified, XML DW architecture and a set of XOLAP operators.

Due to the growing use of XML data for data storage and exchange, there is an imminent need for developing efficient algorithms to perform DM on semi-structured XML data. However, the complexity of its structure makes mining on XML much more complicated than mining on relational data. Ding discusses the problems and challenges in XML DM and provides an overview of various approaches to XML mining.

Pon, Cardenas, and Buttler address the unique challenges and issues involved in personalized online news recommendation, providing background on the shortfalls of existing news recommendation systems, traditional document adaptive filtering, as well as document classification, the need for online feature selection and efficient streaming document classification, and feature extraction algorithms. In light of these challenges, possible machine learning solutions are explored, including how existing techniques can be applied to some of the problems related to online news recommendation.

Clustering is a DM technique to group a set of data objects into classes of similar data objects. While Peer-to-Peer systems have emerged as a new technique for information sharing on Internet, the issues of peer-to-peer clustering have been considered only recently. Li and Lee discuss the main issues of peer-to-peer clustering and reviews representation models and communication models which are important in peer-to-peer clustering.

Users must often refine queries to improve search result relevancy. Query expansion approaches help users with this task by suggesting refinement terms or automatically modifying the user's query. Finding refinement terms involves mining a diverse range of data including page text, query text, user relevancy judgments, historical queries, and user interaction with the search results. The problem is that existing approaches often reduce relevancy by changing the meaning of the query, especially for the complex ones, which are the most likely to need refinement. Fortunately, the most recent research has begun to address complex queries by using semantic knowledge and Crabtree's paper provides information about the developments of this new research.

Li addresses web presence and evolution through web log analysis, a significant challenge faced by electronic business and electronic commerce given the rapid growth of the WWW and the intensified competition. Techniques are presented to evolve the web presence and to produce ultimately a predictive model such that the evolution of a given web site can be categorized under its particular context for strategic planning. The analysis of web log data has opened new avenues to assist the web administrators and designers to establish adaptive web presence and evolution to fit user requirements.

It is of great importance to process the raw web log data in an appropriate way, and identify the target information intelligently. Huang, An, and Liu focus on exploiting web log sessions, defined as a group of requests made by a single user for a single navigation purpose, in web usage mining. They also compare some of the state-of-the-art techniques in identifying log sessions from Web servers, and present some applications with various types of Web log data.

Yang has observed that it is hard to organize a website such that pages are located where users expect to find them. Through web usages mining, the authors can automatically discover pages in a website whose location

is different from where users expect to find them. This problem of matching website organization with user expectations is pervasive across most websites.

The *Semantic Web technologies* provide several solutions concerning the retrieval of *Semantic Web Documents* (SWDs, mainly, ontologies), which however presuppose that the query is given in a structured way - using a formal language - and provide no advanced means for the (semantic) alignment of the query to the contents of the SWDs. Kotis reports on recent research towards supporting users to form semantic queries – requiring no knowledge and skills for expressing queries in a formal language - and to retrieve SWDs whose content is similar to the queries formed.

Zhu, Nie, and Zhang noticed that extracting object information from the Web is of significant importance. However, the diversity and lack of grammars of Web data make this task very challenging. *Statistical Web object extraction* is a framework based on statistical machine learning theory. The potential advantages of statistical Web object extraction models lie in the fact that Web data have plenty of structure information and the attributes about an object have statistically significant dependencies. These dependencies can be effectively incorporated by developing an appropriate graphical model and thus result in highly accurate extractors.

Borges and Levene advocate the use of *Variable Length Markov Chains* (VLMC) models for Web usage mining since they provide a compact and powerful platform for Web usage analysis. The authors review recent research methods that build VLMC models, as well as methods devised to evaluate both the prediction power and the summarization ability of a VLMC model induced from a collection of navigation sessions. Borges and Levene suggest that due to the well established concepts from Markov chain theory that underpin VLMC models, they will be capable of providing support to cope with the new challenges in Web mining.

With the rapid growth of online information (i.e. web sites, textual document) *text categorization* has become one of the key techniques for handling and organizing data in textual format. First fundamental step in every activity of text analysis is to transform the original file in a classical database, keeping the single words as variables. Cerchiello presents the current state of the art, taking into account all the available classification methods and offering some hints on the more recent approaches. Also, Song discusses issues and methods in automatic *text categorization*, which is the automatic assigning of pre-existing category labels to a group of documents. The article reviews the major models in the field, such as *naïve Bayesian classifiers*, *decision rule classifiers*, the *k-nearest neighbor algorithm*, and *support vector machines*. It also outlines the steps requires to prepare a text classifier and touches on related issues such as dimensionality reduction and machine learning techniques.

Sentiment analysis refers to the classification of texts based on the sentiments they contain. It is an emerging research area in text mining and computational linguistics, and has attracted considerable research attention in the past few years. Leung and Chan introduce a typical sentiment analysis model consisting of three core steps, namely data preparation, review analysis and sentiment classification, and describes representative techniques involved in those steps.

Yu, Tungare, Fan, Pérez-Quiñones, Fox, Cameron, and Cassel describe text classification on a specific information genre, one of the text mining technologies, which is useful in genre-specific information search. Their particular interest is on course syllabus genre. They hope their work is helpful for other genre-specific classification tasks.

Hierarchical models have been shown to be effective in content classification. However, an empirical study has shown that the performance of a hierarchical model varies with given taxonomies; even a semantically sound taxonomy has potential to change its structure for better classification. Tang and Liu elucidate why a given semantics-based hierarchy may not work well in content classification, and how it could be improved for accurate hierarchical classification.

Serrano and Castillo present a survey on the most recent methods to index documents written in natural language to be dealt by text mining algorithms. Although these new indexing methods, mainly based of hyperspaces of word semantic relationships, are a clear improvement on the traditional “bag of words” text representation, they are still producing representations far away from the human mind structures. Future text indexing methods should take more aspects from human mind procedures to gain a higher level of abstraction and semantic depth to success in free-text mining tasks.

Pan presents recent advances in applying machine learning and DM approaches to extract automatically explicit and implicit temporal information from natural language text. The extracted temporal information includes, for example, events, temporal expressions, temporal relations, (vague) event durations, event anchoring, and event orderings.

Saxena, Kothari, and Pandey present a brief survey of various techniques that have been used in the area of *Dimensionality Reduction* (DR). In it, evolutionary computing approach in general, and *Genetic Algorithm* in particular have been used as approach to achieve DR.

Huang, Krneta, Lin, and Wu describe the notion of *Association Bundle Identification*. Association bundles were presented by Huang et al. (2006) as a new pattern of association for DM. On applications such as the *Market Basket Analysis*, association bundles can be compared to, but essentially distinguished from the well-established association rules. Association bundles present meaningful and important associations that association rules unable to identify.

Bartík and Zendulka analyze the problem of association rule mining in relational tables. Discretization of quantitative attributes is a crucial step of this process. Existing discretization methods are summarized. Then, a method called *Average Distance Based Method*, which was developed by the authors, is described in detail. The basic idea of the new method is to separate processing of categorical and quantitative attributes. A new measure called average distance is used during the discretization process.

Leung provides a comprehensive overview of *constraint-based association rule mining*, which aims to find interesting relationships—represented by association rules that satisfy user-specified constraints—among items in a database of transactions. The author describes *what* types of constraints can be specified by users and discusses *how* the properties of these constraints can be exploited for efficient mining of interesting rules.

Pattern discovery was established for second order event associations in early 90's by the authors' research group (Wong, Wang, and Li). A higher order pattern discovery algorithm was devised in the mid 90s for discrete-valued data sets. The discovered high order patterns can then be used for classification. The methodology was later extended to continuous and mixed-mode data. Pattern discovery has been applied in numerous real-world and commercial applications and is an ideal tool to uncover subtle and useful patterns in a database.

Li and Ng discuss the *Positive Unlabelled* learning problem. In practice, it is costly to obtain the class labels for large sets of training examples, and oftentimes the negative examples are lacking. Such practical considerations motivate the development of a new set of classification algorithms that can learn from a set of labeled positive examples P augmented with a set of unlabeled examples U. Four different techniques, S-EM, PEBL, Roc-SVM and LPLP, have been presented. Particularly, LPLP method was designed to address a real-world classification application where the size of positive examples is small.

The classification methodology proposed by Yen aims at using different similarity information matrices extracted from citation, author, and term frequency analysis for scientific literature. These similarity matrices were fused into one generalized similarity matrix by using parameters obtained from a genetic search. The final similarity matrix was passed to an agglomerative hierarchical clustering routine to classify the articles. The work, synergistically integrates multiple similarity information, showed that the proposed method was able to identify the main research disciplines, emerging fields, major contributing authors and their area of expertise within the scientific literature collection.

As computationally intensive experiments are increasingly found to incorporate massive data from multiple sources, the handling of original data, the derived data and all intermediate datasets became challenging. Data provenance is a special kind of Metadata that holds information about who did what and when. Sorathia and Maitra discuss various methods, protocols and system architecture for data provenance. It provides insights about how data provenance can affect decisions for utilization. From recent research perspective, it introduces how grid based data provenance can provide effective solution for data provenance even in *Service Orientation Paradigm*.

The practical usages of *Frequent Pattern Mining* (FPM) algorithms in knowledge mining tasks are still limited due to the lack of interpretability caused from the enormous output size. Conversely, we observed recently a growth of interest in FPM community to summarize the output of an FPM algorithm and obtain a smaller set

of patterns that is non-redundant, discriminative, and representative (of the entire pattern set). Hasan surveys different summarization techniques with a comparative discussion among their benefits and limitations.

Data streams are usually generated in an online fashion characterized by huge volume, rapid unpredictable rates, and fast changing data characteristics. Dang, Ng, Ong, and Lee discuss this challenge in the context of finding frequent sets from transactional data streams. In it, some effective methods are reviewed and discussed, in three fundamental mining models for data stream environments: landmark window, forgetful window and sliding window models.

Research in association rules mining has initially concentrated in solving the obvious problem of finding positive association rules; that is, rules among items that remain in the transactions. It was only several years after that the possibility of finding also negative association rules was investigated, based though on the absence of items from transactions. Ioannis gives an overview of the works having engaged with the subject until now and present a novel view for the definition of negative influence among items, where the choice of one item can trigger the removal of another one.

Lin and Tseng consider mining generalized association rules in an evolving environment. They survey different strategies incorporating the state-of-the-art techniques in dealing with this problem and investigate how to update efficiently the discovered association rules when there is transaction update to the database along with item taxonomy evolution and refinement of support constraint.

Feature extraction/selection has received considerable attention in various areas for which thousands of features are available. The main objective of feature extraction/selection is to identify a subset of feature that are most predictive or informative of a given response variable. Successful implementation of feature extraction/selection not only provides important information for prediction or classification, but also reduces computational and analytical efforts for the analysis of high-dimensional data. Kim presents various feature extraction/selection methods, along with some real examples.

Feature interaction presents a challenge to feature selection for classification. A feature by itself may have little correlation with the target concept, but when it is combined with some other features; they can be strongly correlated with the target concept. Unintentional removal of these features can result in poor classification performance. Handling feature interaction could be computationally intractable. Zhao and Liu provide a comprehensive study for the concept of feature interaction and present several existing feature selection algorithms that apply feature interaction.

François addresses the problem of feature selection in the context of modeling the relationship between explanatory variables and target values, which must be predicted. It introduces some tools, general methodology to be applied on it and identifies trends and future challenges.

Datasets comprising of many features can lead to serious problems, like low classification accuracy. To address such problems, feature selection is used to select a small subset of the most relevant features. The most widely used feature selection approach is the wrapper, which seeks relevant features by employing a classifier in the selection process. Chrysostomou, Lee, Chen, and Liu present the state of the art of the wrapper feature selection process and provide an up-to-date review of work addressing the limitations of the wrapper and improving its performance.

Lisi considers the task of mining multiple-level association rules extended to the more complex case of having an ontology as prior knowledge. This novel problem formulation requires algorithms able to deal actually with ontologies, i.e. without disregarding their nature of logical theories equipped with a formal semantics. Lisi describes an approach that resorts to the methodological apparatus of that logic-based machine learning form known under the name of *Inductive Logic Programming*, and to the expressive power of those knowledge representation frameworks that combine logical formalisms for databases and ontologies.

Arslan presents a unifying view for many sequence alignment algorithms in the literature proposed to guide the alignment process. Guiding finds its true meaning in constrained sequence alignment problems, where constraints require inclusion of known sequence motifs. Arslan summarizes how constraints have evolved from inclusion of simple subsequence motifs to inclusion of subsequences within a tolerance, then to more general regular expression-described motif inclusion, and to inclusion of motifs described by context free grammars.

Xiong, Wang, and Zhang introduce a novel technique to alignment manifolds so as to learn the correspondence relationship in data. The authors argue that it will be more advantageous if they can guide the alignment by relative comparison, which is well defined frequently and easy to obtain. The authors show how this problem can be formulated as an optimization procedure. To make the solution tractable, they further re-formulated it as a *convex semi-definite programming* problem.

Time series data are typically generated by measuring and monitoring applications and plays a central role in predicting the future behavior of systems. Since time series data in its raw form contain no usable structure, it is often segmented to generate a high-level data representation that can be used for prediction. Chundi, and Rosenkrantz discuss the segmentation problem and outline the current state-of-the-art in generating segmentations for the given time series data.

Customer segmentation is the process of dividing customers into distinct subsets (segments or clusters) that behave in the same way or have similar needs. There may exist natural behavioral patterns in different groups of customers or customer transactions. Yang discusses research on using behavioral patterns to segment customers.

Along the lines of Wright and Stashuk, quantization based schemes seemingly discard important data by grouping individual values into relatively large aggregate groups; the use of fuzzy and rough set tools helps to recover a significant portion of the data lost by performing such a grouping. If quantization is to be used as the underlying method of projecting continuous data into a form usable by a discrete-valued knowledge discovery system, it is always useful to evaluate the benefits provided by including a representation of the vagueness derived from the process of constructing the quantization bins.

Lin provides a comprehensive coverage for one of the important problems in DM: sequential pattern mining, especially in the aspect of time constraints. It gives an introduction to the problem, defines the constraints, reviews the important algorithms for the research issue and discusses future trends.

Chen explores the subject of clustering time series, concentrating specially on the area of subsequence time series clustering; dealing with the surprising recent result that the traditional method used in this area is meaningless. He reviews the results that led to this startling conclusion, reviews subsequent work in the literature dealing with this topic, and goes on to argue that two of these works together form a solution to the dilemma.

Qiu and Malthouse summarize the recent developments in cluster analysis for categorical data. The traditional latent class analysis assumes that manifest variables are independent conditional on the cluster identity. This assumption is often violated in practice. Recent developments in latent class analysis relax this assumption by allowing for flexible correlation structure for manifest variables within each cluster. Applications to real datasets provide easily interpretable results.

Learning with Partial Supervision (LPS) aims at combining labeled and unlabeled data to boost the accuracy of classification and clustering systems. The relevance of LPS is highly appealing in applications where only a small ratio of labeled data and a large number of unlabeled data are available. LPS strives to take advantage of traditional clustering and classification machineries to deal with labeled data scarcity. Bouchachia introduces LPS and outlines the different assumptions and existing methodologies concerning it.

Wei, Li, and Li introduce a novel learning paradigm called enclosing machine learning for DM. The new learning paradigm is motivated by two cognition principles of human being, which are cognizing things of the same kind and, recognizing and accepting things of a new kind easily. The authors made a remarkable contribution setting up a bridge that connects the cognition process understanding, with mathematical machine learning tools under the function equivalence framework.

Bouguettaya and Yu focus on investigating the behavior of agglomerative hierarchical algorithms. They further divide these algorithms into two major categories: group based and single-object based clustering methods. The authors choose UPGMA and SLINK as the representatives of each category and the comparison of these two representative techniques could also reflect some similarity and difference between these two sets of clustering methods. Experiment results show a surprisingly high level of similarity between the two clustering techniques under most combinations of parameter settings.

In an effort to achieve improved classifier accuracy, extensive research has been conducted in classifier ensembles. Cluster ensembles offer a solution to challenges inherent to clustering arising from its ill-posed nature. Domeniconi and Razgan discuss recent developments in ensemble methods for clustering.

Tsoumakas and Vlahavas introduce the research area of *Distributed DM* (DDM). They present the state-of-the-art DDM methods for classification, regression, association rule mining and clustering and discuss the application of DDM methods in modern distributed computing environments such as the Grid, peer-to-peer networks and sensor networks.

Wu, Xiong, and Chen highlight the relationship between the clustering algorithms and the distribution of the "true" cluster sizes of the data. They demonstrate that k-means tends to show the uniform effect on clusters, whereas UPGMA tends to take the dispersion effect. This study is crucial for the appropriate choice of the clustering schemes in DM practices.

Huang describes k-modes, a popular DM algorithm for clustering categorical data, which is an extension to k-means with modifications on the distance function, representation of cluster centers and the method to update the cluster centers in the iterative clustering process. Similar to k-means, the k-modes algorithm is easy to use and efficient in clustering large data sets. Other variants are also introduced, including the fuzzy k-modes for fuzzy cluster analysis of categorical data, k-prototypes for clustering mixed data with both numeric and categorical values, and W-k-means for automatically weighting attributes in k-means clustering.

Xiong, Steinbach, Tan, Kumar, and Zhou describe a pattern preserving clustering method, which produces interpretable and usable clusters. Indeed, while there are strong patterns in the data---patterns that may be a key for the analysis and description of the data---these patterns are often split among different clusters by current clustering approaches, since clustering algorithms have no built in knowledge of these patterns and may often have goals that are in conflict with preserving patterns. To that end, their focus is to characterize (1) the benefits of pattern preserving clustering and (2) the most effective way of performing pattern preserving clustering.

Semi-supervised clustering uses the limited background knowledge to aid unsupervised clustering algorithms. Recently, a kernel method for semi-supervised clustering has been introduced. However, the setting of the kernel's parameter is left to manual tuning, and the chosen value can largely affect the quality of the results. Yan and Domeniconi derive a new optimization criterion to automatically determine the optimal parameter of an RBF kernel, directly from the data and the given constraints. The proposed approach integrates the constraints into the clustering objective function, and optimizes the parameter of a *Gaussian* kernel iteratively during the clustering process.

Vilalta and Stepinski propose a new approach to external cluster validation based on modeling each cluster and class as a probabilistic distribution. The degree of separation between both distributions can then be measured using an information-theoretic approach (e.g., relative entropy or *Kullback-Leibler* distance). By looking at each cluster individually, one can assess the degree of novelty (large separation to other classes) of each cluster, or instead the degree of validation (close resemblance to other classes) provided by the same cluster.

Casado, Pacheco, and Nuñez have designed a new technique based on the metaheuristic strategy *Tabu Search* for variable selection for classification, in particular for discriminant analysis and logistic regression. There are very few key references on the selection of variables for their use in discriminant analysis and logistic regression. For this specific purpose only the Stepwise, Backward and Forward methods, can be found in the literature. These methods are simple and they are not very efficient when there are many original variables.

Ensemble learning is an important method of deploying more than one learning model to give improved predictive accuracy for a given learning problem. Rooney, Patterson, and Nugent describe how regression based ensembles are able to reduce the bias and/or variance of the generalization error and review the main techniques that have been developed for the generation and integration of regression based ensembles.

Dominik, Walczak, and Wojciechowski evaluate performance of the most popular and effective classifiers with graph structures, on two kinds of classification problems from different fields of science: computational chemistry, chemical informatics (chemical compounds classification) and information science (web documents classification).

Tong, Koren, and Faloutsos study asymmetric proximity measures on directed graphs, which quantify the relationships between two nodes. Their proximity measure is based on the concept of escape probability. This way, the authors strive to summarize the multiple facets of nodes-proximity, while avoiding some of the pitfalls to which alternative proximity measures are susceptible. A unique feature of the measures is accounting for the underlying directional information. The authors put a special emphasis on computational efficiency, and develop fast solutions that are applicable in several settings and they show the usefulness of their proposed direction-aware proximity method for several applications.

Classification models and in particular binary classification models are ubiquitous in many branches of science and business. Model performance assessment is traditionally accomplishing by using metrics, derived from the confusion matrix or contingency table. It has been observed recently that *Receiver Operating Characteristic* (ROC) curves visually convey the same information as the confusion matrix in much more intuitive and robust fashion. Hamel illustrates how ROC curves can be deployed for model assessment to provide a much deeper and perhaps more intuitive analysis of classification models.

Molecular classification involves the classification of samples into groups of biological phenotypes based on data obtained from microarray experiments. The high-dimensional and multiclass nature of the classification problem demands work on two specific areas: (1) feature selection (FS) and (2) decomposition paradigms. Ooi introduces a concept called *differential prioritization*, which ensures that the optimal balance between two FS criteria, relevance and redundancy, is achieved based on the number of classes in the classification problem.

Incremental learning is a learning strategy that aims at equipping learning systems with adaptively, which allows them to adjust themselves to new environmental conditions. Usually, it implicitly conveys an indication to future evolution and eventually self correction over time as new events happen, new input becomes available, or new operational conditions occur. Bouchachia brings in incremental learning, discusses the main trends of this subject and outlines some of the contributions of the author.

Sheng and Ling introduce the theory of the cost-sensitive learning. The theory focuses on the most common cost (i.e. misclassification cost), which plays the essential role in cost-sensitive learning. Without loss of generality, the authors assume binary classification in this article. Based on the binary classification, they infer that the original cost matrix in real-world applications can always be converted to a simpler one with only false positive and false negative costs.

Thomopoulos focuses on the cooperation of heterogeneous knowledge for the construction of a domain expertise. A two-stage method is proposed: First, verifying expert knowledge (expressed in the conceptual graph model) by experimental data (in the relational model) and second, discovering unexpected knowledge to refine the expertise. A case study has been carried out to further explain the use of this method.

Recupero discusses the graph matching problem and related filtering techniques. It introduces GrepVS, a new fast graph matching algorithm, which combines filtering ideas from other well-known methods in literature. The chapter presents details on hash tables and the Berkeley DB, used to store efficiently nodes, edges and labels. Also, it compares GrepVS filtering and matching phases with the state of the art graph matching algorithms.

Recent technological advances in 3D digitizing, non-invasive scanning, and interactive authoring have resulted in an explosive growth of 3D models. There is a critical need to develop new mining techniques for facilitating the indexing, retrieval, clustering, comparison, and analysis of large collections of 3D models. Shen and Makedon describe a computational framework for mining 3D objects using shape features, and addresses important shape modeling and pattern discovery issues including spherical harmonic surface representation, shape registration, and surface-based statistical inferences. The mining results localize shape changes between groups of 3D objects.

In Zhao and Yao's opinion, while many DM models concentrate on automation and efficiency, interactive DM models focus on adaptive and effective communications between human users and computer systems. The crucial point is not how intelligent users are, or how efficient systems are, but how well these two parts can be connected, adapted, understood and trusted. Some fundamental issues including processes and forms of interactive DM, as well as complexity of interactive DM systems are discussed in this article.

Rivero, Rabuñal, Dorado, and Pazos describe an application of Evolutionary Computation (EC) tools to develop automatically Artificial Neural Networks (ANNs). It also describes how EC techniques have already

been used for this purpose. The technique described in this article allows both design and training of ANNs, applied to the solution of three well-known problems. Moreover, this tool makes the simplification of ANNs to obtain networks with a small number of neurons. Results show how this technique can produce good results in solving DM problems.

Almost all existing DM algorithms have been manually designed. As a result, in general they incorporate human biases and preconceptions in their designs. Freitas and Pappa propose an alternative approach to the design of DM algorithms, namely the automatic creation of DM algorithms by *Genetic Programming* – a type of Evolutionary Algorithm. This approach opens new avenues for research, providing the means to design novel DM algorithms that are less limited by human biases and preconceptions, as well as the opportunity to create automatically DM algorithms tailored to the data being mined.

Gama and Rodrigues present the new model of data gathering from continuous flows of data. What distinguishes current data sources from earlier ones are the continuous flow of data and the automatic data feeds. The authors do not just have people who are entering information into a computer. Instead, they have computers entering data into one another. Major differences are pointed out between this model and previous ones. Also, the incremental setting of learning from a continuous flow of data is introduced by the authors.

The personal name problem is the situation where the authenticity, ordering, gender, and other information cannot be determined correctly and automatically for every incoming personal name. On this paper topics as the evaluation of, and selection from five very different approaches and the empirical comparisons of multiple phonetics and string similarity techniques for the personal name problem, are remarkably addressed by Phua, Lee, and Smith-Miles.

Lo and Khoo present software specification mining, where novel and existing DM and machine learning techniques are utilized to help recover software specifications which are often poorly documented, incomplete, outdated or even missing. These mined specifications can aid software developers in understanding existing systems, reducing software costs, detecting faults and improving program dependability.

Cooper and Zito investigate the statistical properties of the databases generated by the IBM QUEST program. Motivated by the claim (also supported empirical evidence) that item occurrences in real life market basket databases follow a rather different pattern, we propose an alternative model for generating artificial data.

Software metrics-based quality estimation models include those that provide a quality-based classification of program modules and those that provide a quantitative prediction of a quality factor for the program modules. In this article, two count models, *Poisson regression model* (PRM) and *zero-inflated Poisson* (ZIP) regression model, are developed and evaluated by Gao and Khoshgoftaar from those two aspects for a full-scale industrial software system.

Software based on the *Variable Precision Rough Sets* model (VPRS) and incorporating resampling techniques is presented by Griffiths and Beynon as a modern DM tool. The software allows for data analysis, resulting in a classifier based on a set of 'if ... then ...' decision rules. It provides analysts with clear illustrative graphs depicting 'veins' of information within their dataset, and resampling analysis allows for the identification of the most important descriptive attributes within their data.

Program comprehension is a critical task in the software life cycle. Ioannis addresses an emerging field, namely program comprehension through DM. Many researchers consider the specific task to be one of the "hottest" ones nowadays, with large financial and research interest.

The bioinformatics example already approached in the 1e of the present volume is here addressed by Liberati in a novel way, joining two methodologies developed in different fields, namely *minimum description length principle* and *adaptive Bayesian networks*, to implement a new mining tool. The novel approach is then compared with the previous one, showing pros and cons of the two, thus inducing that a combination of the new technique together with the one proposed in the previous edition is the best approach to face the many aspects of the problem.

Integrative analysis of biological data from multiple heterogeneous sources has been employed for a short while with some success. Different DM techniques for such integrative analyses have been developed (which should not be confused with attempts at data integration). Moturu, Parsons, Zhao, and Liu summarize effectively these techniques in an intuitive framework while discussing the background and future trends for this area.

Bhatnagar and Gupta cover in chronological order, the evolution of the formal "KDD process Model", both at the conceptual and practical level. They analyze the strengths and weaknesses of each model and provide the definitions of some of the related terms.

Cheng and Shih present an improved feature reduction method in the combinational input and feature space for *Support Vector Machines* (SVM). In the input space, they select a subset of input features by ranking their contributions to the decision function. In the feature space, features are ranked according to the weighted support vector in each dimension. By combining both input and feature space, Cheng and Shih develop a fast non-linear SVM without a significant loss in performance.

Im and Ras discuss data security in DM. In particular, they describe the problem of confidential data reconstruction by Chase in distributed knowledge discovery systems, and discuss protection methods.

In problems which possibly involve much feature interactions, attribute evaluation measures that estimate the quality of one feature independently of the context of other features measures are not appropriate. Robnik-Šikonja provides and overviews those measures, which are based on the *Relief algorithm*, taking context into account through distance between the instances.

Kretowski and Grzes present an evolutionary approach to induction of decision trees. The evolutionary inducer generates univariate, oblique and mixed trees, and in contrast to classical top-down methods, the algorithm searches for an optimal tree in a global manner. Development of specialized genetic operators allow the system exchange tree parts, generate new sub-trees, prune existing ones as well as change the node type and the tests. A flexible fitness function enables a user to control the inductive biases, and globally induced decision trees are generally simpler with at least the same accuracy as typical top-down classifiers.

Li, Ye, and Kambhamettu present a very general strategy---without assumption of image alignment---for image representation via interest pixel mining. Under the assumption of image alignment, they have intensive studies on *linear discriminant analysis*. One of their papers, "A two-stage linear discriminant analysis via QR-decomposition", was awarded as a fast-breaking paper by Thomson Scientific in April 2007.

As a part of preprocessing and exploratory data analysis, visualization of the data helps to decide which kind of DM method probably leads to good results or whether outliers need to be treated. Rehm, Klawonn, and Kruse present two efficient methods of visualizing high-dimensional data on a plane using a new approach.

Yuan and Wu discuss the problem of repetitive pattern mining in multimedia data. Initially, they explain the purpose of mining repetitive patterns and give examples of repetitive patterns appearing in image/video/audio data accordingly. Finally, they discuss the challenges of mining such patterns in multimedia data, and the differences from mining traditional transaction and text data. The major components of repetitive pattern discovery are discussed, together with the state-of-the-art techniques.

Tsinaraki and Christodoulakis discuss semantic multimedia retrieval and filtering. Since the MPEG-7 is the dominant standard in multimedia content description, they focus on MPEG-7 based retrieval and filtering. Finally, the authors present the *MPEG-7 Query Language* (MP7QL), a powerful query language that they have developed for expressing queries on MPEG-7 descriptions, as well as an MP7QL compatible *Filtering and Search Preferences* (FASP) model. The data model of the MP7QL is the MPEG-7 and its output format is MPEG-7, thus guaranteeing the closure of the language. The MP7QL allows for querying every aspect of an MPEG-7 multimedia content description.

Richard presents some aspects of audio signals automatic indexing with a focus on music signals. The goal of this field is to develop techniques that permit to extract automatically high-level information from the digital raw audio to provide new means to navigate and search in large audio databases. Following a brief overview of audio indexing background, the major building blocks of a typical audio indexing system are described and illustrated with a number of studies conducted by the authors and his colleagues.

With the progress in computing, multimedia data becomes increasingly important to DW. Audio and speech processing is the key to the efficient management and mining of these data. Tan provides in-depth coverage of audio and speech DM and reviews recent advances.

Li presents how DW techniques can be used for improving the quality of association mining. It introduces two important approaches. The first approach requests users to inputs meta-rules through data cubes to describe

desired associations between data items in certain data dimensions. The second approach requests users to provide condition and decision attributes to find desired associations between data granules. The author has made significant contributions to the second approach recently. He is an Associate Editor of the *International Journal of Pattern Recognition and Artificial Intelligence* and an Associate Editor of the *IEEE Intelligent Informatics Bulletin*.

Data cube compression arises from the problem of gaining access and querying massive multidimensional datasets stored in networked data warehouses. Cuzzocrea focuses on state-of-the-art data cube compression techniques and provides a theoretical review of such proposals, by putting in evidence and criticizing the complexities of the building, storing, maintenance, and query phases.

Conceptual modeling is widely recognized to be the necessary foundation for building a database that is well-documented and fully satisfies the user requirements. Although UML and Entity/Relationship are widespread conceptual models, they do not provide specific support for multidimensional modeling. In order to let the user verify the usefulness of a conceptual modeling step in DW design, Golfarelli discusses the expressivity of the *Dimensional Fact Model*, a graphical conceptual model specifically devised for multidimensional design.

Tu introduces the novel technique of automatically tuning database systems based on feedback control loops via rigorous system modeling and controller design. He has also worked on performance analysis of peer-to-peer systems, QoS-aware query processing, and data placement in multimedia databases.

Currently researches focus on particular aspects of a DW development and none of them proposed a systematic design approach that takes into account the end-user requirements. Nabli, Feki, Ben-Abdallah, and Gargouri present a four-step DM/DW conceptual schema design approach that assists the decision maker in expressing their requirements in an intuitive format; automatically transforms the requirements into DM star schemes; automatically merges the star schemes to construct the DW schema; and maps the DW schema to the data source.

Current data warehouses include a time dimension that allows one to keep track of the evolution of measures under analysis. Nevertheless, this dimension cannot be used for indicating changes to dimension data. Malinowski and Zimányi present a conceptual model for designing temporal data warehouses based on the research in temporal databases. The model supports different temporality types, i.e., lifespan, valid time, transaction time coming from source systems, and loading time, generated in a data warehouse. This support is used for representing time-varying levels, dimensions, hierarchies, and measures.

Verykios investigates a representative cluster of research issues falling under the broader area of privacy preserving DM, which refers to the process of mining the data without impinging on the privacy of the data at hand. The specific problem targeted in here is known as association rule hiding and concerns to the process of applying certain types of modifications to the data in such a way that a certain type of knowledge (the association rules) escapes the mining.

The development of DM has the capacity of compromise privacy in ways not previously possible, an issue not only exacerbated through inaccurate data and ethical abuse but also by a lagging legal framework which struggles, at times, to catch up with technological innovation. Wahlstrom, Roddick, Sarre, Estivill-Castro and Vries explore the legal and technical issues of privacy preservation in DM.

Given large data collections of person-specific information, providers can mine data to learn patterns, models, and trends that can be used to provide personalized services. The potential benefits of DM are substantial, but the analysis of sensitive personal data creates concerns about privacy. Oliveira addresses the concerns about privacy, data security, and intellectual property rights on the collection and analysis of sensitive personal data.

With the advent of the information explosion, it becomes crucial to support intelligent personalized retrieval mechanisms for users to identify the results of a manageable size satisfying user-specific needs. To achieve this goal, it is important to model user preference and mine preferences from implicit user behaviors (e.g., user clicks). Hwang discusses recent efforts to extend mining research to preference and identify goals for the future works.

According to González Císaro & Nigro, due to the complexity of nowadays data and the fact that information stored in current databases is not always present at necessary different levels of detail for decision-making processes, a new data type is needed. It is a *Symbolic Object*, which allows representing physics entities or real

word concepts in dual form, respecting their internal variations and structure. The *Symbolic Object Warehouse* permits the intentional description of most important organization concepts, follow by *Symbolic Methods* that work on these objects to acquire new knowledge.

Castillo, Iglesias, and Serrano present a survey on the most known systems to avoid overloading users' mail inbox with unsolicited and illegitimate e-mails. These filtering systems are mainly relying on the analysis of the origin and links contained in e-mails. Since this information is always changing, the systems effectiveness depends on the continuous updating of verification lists.

The evolution of clearinghouses in many ways reflects the evolution of geospatal technologies themselves. The Internet, which has pushed GIS and related technology to the leading edge, has been in many ways fed by the dramatic increase in available data, tools, and applications hosted or developed through the geospatial data clearinghouse movement. Kelly, Haupt, and Baxter outline those advances and offers the reader historic insight into the future of geospatial information.

Angiulli provides an up-to-date view on distance- and density-based methods for large datasets, on subspace outlier mining approaches, and on outlier detection algorithms for processing data streams. Throughout his document different outlier mining tasks are presented, peculiarities of the various methods are pointed out, and relationships among them are addressed. In another paper, Kaur offers various non-parametric approaches used for outlier detection.

The issue of missing values in DM is discussed by Beynon, including the possible drawbacks from their presence, especially when using traditional DM techniques. The nascent CaRBS technique is exposited since it can undertake DM without the need to manage any missing values present. The benchmarked results, when DM incomplete data and data where missing values have been imputed, offers the reader the clearest demonstration of the effect on results from transforming data due to the presence of missing values.

Dorn and Hou examine the quality of association rules derived based on the well-known support-confidence framework using the Chi-squared test. The experimental results show that around 30% of the rules satisfying the minimum support and minimum confidence are in fact statistically insignificant. Integrate statistical analysis into DM techniques can make knowledge discovery more reliable.

The popular querying and data storage models still work with data that are precise. Even though there has recently been much interest in looking at problems arising in storing and retrieving data that are incompletely specified (hence imprecise), such systems have not gained widespread acceptance yet. Nambiar describes challenges involved in supporting imprecision in database systems, briefly explains solutions developed.

Among the different risks Bonafede's work concentrates on operational risks, which form a banking perspective, is due to processes, people, systems (Endogenous) and external events (Exogenous). Bonafede furnishes a conceptual modeling for measurement operational risk and, statistical models applied in the banking sector but adaptable to other fields.

Friedland describes a hidden social structure that may be detectable within large datasets consisting of individuals and their employments or other affiliations. For the most part, individuals in such datasets appear to behave independently. However, sometimes there is enough information to rule out independence and to highlight coordinated behavior. Such individuals acting together are socially tied, and in one case study aimed at predicting fraud in the securities industry, the coordinated behavior was an indicator of higher-risk individuals.

Akdag and Truck focus on studies in *Qualitative Reasoning*, using degrees on a totally ordered scale in a many-valued logic system. Qualitative degrees are a good way to represent uncertain and imprecise knowledge to model approximate reasoning. The qualitative theory takes place between the probability theory and the possibility theory. After defining formalism by logical and arithmetical operators, they detail several aggregators using possibility theory tools such that our probability-like axiomatic system derives interesting results.

Figini presents a comparison, based on survival analysis modeling, between classical and novel DM techniques to predict rates of customer churn. He shows that the novel DM techniques lead to more robust conclusions. In particular, although the lift of the best models are substantially similar, survival analysis modeling gives more valuable information, such as a whole predicted survival function, rather than a single predicted survival probability.

Recent studies show that the method of modeling score distribution is beneficial to various applications. Doloc-Mihu presents the score distribution modeling approach and briefly surveys theoretical and empirical studies on the distribution models, followed by several of its applications.

Valle discusses, among other topics, the most important statistical techniques built to show the relationship between firm performance and its causes, and illustrates the most recent developments in this field.

Data streams arise in many industrial and scientific applications such as network monitoring and meteorology. Dasu and Weiss discuss the unique analytical challenges posed by data streams such as rate of accumulation, continuously changing distributions, and limited access to data. It describes the important classes of problems in mining data streams including data reduction and summarization; change detection; and anomaly and outlier detection. It also provides a brief overview of existing techniques that draw from numerous disciplines such as database research and statistics.

Vast amounts of data are being generated to extract implicit patterns of ambient air pollutant data. Because air pollution data are generally collected in a wide area of interest over a relatively long period, such analyses should take into account both temporal and spatial characteristics. DM techniques can help investigate the behavior of ambient air pollutants and allow us to extract implicit and potentially useful knowledge from complex air quality data. Kim, Temiyasathit, Park, and Chen present the DM processes to analyze complex behavior of ambient air pollution.

Moon, Simpson, and Kumara introduce a methodology for identifying a platform along with variant and unique modules in a product family using design knowledge extracted with an ontology and DM techniques. *Fuzzy c-means clustering* is used to determine initial clusters based on the similarity among functional features. The clustering result is identified as the platform and the modules by the *fuzzy set theory* and classification. The proposed methodology could provide designers with module-based platform and modules that can be adapted to product design during conceptual design.

Analysis of past performance of production systems is necessary in any manufacturing plan to improve manufacturing quality or throughput. However, data accumulated in manufacturing plants have unique characteristics, such as unbalanced distribution of the target attribute, and a small training set relative to the number of input features. Rokach surveys recent researches and applications in this field.

Seng and Srinivasan discuss the numerous challenges that complicate the mining of data generated by chemical processes, which are characterized for being dynamic systems equipped with hundreds or thousands of sensors that generate readings at regular intervals. The two key areas where DM techniques can facilitate knowledge extraction from plant data, namely (1) process visualization and state-identification, and (2) modeling of chemical processes for process control and supervision, are also reviewed in this article.

The telecommunications industry, because of the availability of large amounts of high quality data, is a heavy user of DM technology. Weiss discusses the DM challenges that face this industry and survey three common types of DM applications: marketing, fraud detection, and network fault isolation and prediction.

Understanding the roles of genes and their interactions is a central challenge in genome research. Ye, Janardan, and Kumar describe an efficient computational approach for automatic retrieval of images with overlapping expression patterns from a large database of expression pattern images for *Drosophila melanogaster*. The approach approximates a set of data matrices, representing expression pattern images, by a collection of matrices of low rank through the iterative, approximate solution of a suitable optimization problem. Experiments show that this approach extracts biologically meaningful features and is competitive with other techniques.

Khoury, Toussaint, Ciampi, Antoniano, Murie, and Nadon present, in the context of clustering applied to DNA microarray probes, a better alternative to classical techniques. It is based on proximity-graphs, which has the advantage of being relatively simple and of providing a clear visualization of the data, from which one can directly determine whether or not the data support the existence of clusters.

There has been no formal research about using a *fuzzy Bayesian* model to develop an autonomous task analysis tool. Lin and Lehto summarize a 4-year study that focuses on a Bayesian based machine learning application to help identify and predict the agents' subtasks from the call center's naturalistic decision making's environment. Preliminary results indicate this approach successfully learned how to predict subtasks from the telephone con-

versations and support the conclusion that Bayesian methods can serve as a practical methodology in research area of task analysis as well as other areas of naturalistic decision making.

Financial time series are a sequence of financial data obtained in a fixed period of time. Bose, Leung, and Lau describe how financial time series data can be analyzed using the knowledge discovery in databases framework that consists of five key steps: goal identification, data preprocessing, data transformation, DM, interpretation and evaluation. The article provides an appraisal of several machine learning based techniques that are used for this purpose and identifies promising new developments in hybrid soft computing models.

Maruster and Faber focus on providing insights about patterns of behavior of a specific user group, namely farmers, during the usage of decision support systems. User's patterns of behavior are analyzed by combining these insights with decision making theories, and previous work concerning the development of farmer groups. It provides a method of automatically analyzing the logs resulted from the usage of the decision support system by process mining. The results of their analysis support the redesigning and personalization of decision support systems in order to address specific farmer's characteristics.

Differential proteomics studies the differences between distinct proteomes like normal versus diseased cells, diseased versus treated cells, and so on. Zhang, Orcun, Ouzzani, and Oh introduce the generic DM steps needed for differential proteomics, which include data transformation, spectrum deconvolution, protein identification, alignment, normalization, statistical significance test, pattern recognition, and molecular correlation.

Protein associated data sources such as sequences, structures and interactions accumulate abundant information for DM researchers. Li, Li, Nanyang, and Zhao glimpse the DM methods for the discovery of the underlying patterns at protein interaction sites, the most dominated regions to mediate protein-protein interactions. The authors proposed the concept of binding motif pairs and emerging patterns in DM field.

The applications of DWM are everywhere: from *Applications in Steel Industry* (Ordieres-Meré, Castejón-Limas, and González-Marcos) to *DM in Protein Identification by Tandem Mass Spectrometry* (Wan); from *Mining Smart Card Data from an Urban Transit Network* (Agard, Morency, and Trépanier) to *Data Warehouse in the Finnish Police* (Juntunen)…The list of DWM applications is endless and the future DWM is promising.

Since the current knowledge explosion pushes DWM, a multidisciplinary subject, to ever-expanding new frontiers, any inclusions, omissions, and even revolutionary concepts are a necessary part of our professional life. In spite of all the efforts of our team, should you find any ambiguities or perceived inaccuracies, please contact me at j.john.wang@gmail.com.

Acknowledgment

The editor would like to thank all of the authors for their insights and excellent contributions to this book. I also want to thank the anonymous reviewers who assisted me in the peer-reviewing process and provided comprehensive, critical, and constructive reviews. Each Editorial Advisory Board member has made a big contribution in terms of guidance and assistance. I owe my thanks to ChunKai Szu and Shaunte Ames, two Editor Assistants, for lending a hand in the whole tedious process.

The editor wishes to acknowledge the help of all involved in the development process of this book, without whose support the project could not have been satisfactorily completed. Fatiha Ouali and Ana Kozyreva, two Graduate Assistants, are hereby graciously acknowledged for their diligent work. A further special note of thanks goes to the staff at IGI Global, whose contributions have been invaluable throughout the entire process, form inception to final publication. Particular thanks go to Kristin M. Roth, Managing Development Editor and Jan Travers, who continuously prodded via e-mail to keep the project on schedule, and to Mehdi Khosrow-Pour, whose enthusiasm motivated me to accept his invitation to join this project.

My appreciation is also due to Montclair State University for awarding me different Faculty Research and Career Development Funds. I would also like to extend my thanks to my brothers Zhengxian Wang, Shubert Wang (an artist, http://www.portraitartist.com/wang/wang.asp), and sister Jixian Wang, who stood solidly behind me and contributed in their own sweet little ways. Thanks go to all Americans, since it would not have been possible for the four of us to come to the U.S. without the support of our scholarships.

Finally, I want to thank my family: my parents, Houde Wang and Junyan Bai for their encouragement; my wife Hongyu Ouyang for her unfailing support, and my sons Leigh Wang and Leon Wang for being without a dad during this project up to two years.

Montclair, New Jersey, USA

About the Editor

John Wang is a professor in the Department of Management and Information Systems at Montclair State University, USA. Having received a scholarship award, he came to the USA and completed his PhD in operations research from Temple University. Due to his extraordinary contributions beyond a tenured full professor, Dr. Wang has been honored with a special range adjustment in 2006. He has published over 100 refereed papers and six books. He has also developed several computer software programs based on his research findings.

He is the Editor-in-Chief of *International Journal of Applied Management Science, International Journal of Data Analysis Techniques and Strategies, International Journal of Information Systems and Supply Chain Management, International Journal of Information and Decision Sciences*. He is the EiC for the *Advances in Information Systems and Supply Chain Management Book Series*. He has served as a guest editor and referee for many other highly prestigious journals. He has served as track chair and/or session chairman numerous times on the most prestigious international and national conferences.

Also, he is an Editorial Advisory Board member of the following publications: *Intelligent Information Technologies: Concepts, Methodologies, Tools, and Applications, End-User Computing: Concepts, Methodologies, Tools, and Applications, Global Information Technologies: Concepts, Methodologies, Tools, and Applications, Information Communication Technologies: Concepts, Methodologies, Tools, and Applications, Multimedia Technologies: Concepts, Methodologies, Tools, and Applications, Information Security and Ethics: Concepts, Methodologies, Tools, and Applications, Electronic Commerce: Concepts, Methodologies, Tools, and Applications, Electronic Government: Concepts, Methodologies, Tools, and Applications*, etc.

Furthermore, he is the Editor of *Data Warehousing and Mining: Concepts, Methodologies, Tools, and Applications* (six-volume) - http://www.igi-global.com/reference/details.asp?id=6946, and the Editor of the *Encyclopedia of Data Warehousing and Mining*, 1st and 2nd Edition - http://www.igi-pub.com/reference/details.asp?id=7956. His long-term research goal is on the synergy of operations research, data mining and cybernetics. His personal interests include gymnastics, swimming, Wushu (Chinese martial arts), jogging, table-tennis, poetry writing, etc.

Action Rules Mining

Zbigniew W. Ras

INTRODUCTION

There are two aspects of interestingness of rules that have been studied in data mining literature, objective and subjective measures (Liu et al., 1997), (Adomavicius & Tuzhilin, 1997), (Silberschatz & Tuzhilin, 1995, 1996). Objective measures are data-driven and domain-independent. Generally, they evaluate the rules based on their quality and similarity between them. Subjective measures, including unexpectedness, novelty and actionability, are user-driven and domain-dependent.

A rule is actionable if user can do an action to his/her advantage based on this rule (Liu et al., 1997). This definition, in spite of its importance, is too vague and it leaves open door to a number of different interpretations of actionability. In order to narrow it down, a new class of rules (called action rules) constructed from certain pairs of association rules, has been proposed in (Ras & Wieczorkowska, 2000). Interventions introduced in (Greco et al., 2006) and the concept of information changes proposed in (Skowron & Synak, 2006) are conceptually very similar to action rules. Action rules have been investigated further in (Wang at al., 2002), (Tsay & Ras, 2005, 2006), (Tzacheva & Ras, 2005), (He at al., 2005), (Ras & Dardzinska, 2006), (Dardzinska & Ras, 2006), (Ras & Wyrzykowska, 2007). To give an example justifying the need of action rules, let us assume that a number of customers have closed their accounts at one of the banks. We construct, possibly the simplest, description of that group of people and next search for a new description, similar to the one we have, with a goal to identify a new group of customers from which no-one left that bank. If these descriptions have a form of rules, then they can be seen as actionable rules. Now, by comparing these two descriptions, we may find the cause why these accounts have been closed and formulate an action which if undertaken by the bank, may prevent other customers from closing their accounts. Such actions are stimulated by action rules and they are seen as precise hints for actionability of rules. For example, an action rule may say that by inviting people from a certain group of customers for a glass of wine by a bank, it is guaranteed that these customers will not close their accounts and they do not move to another bank. Sending invitations by regular mail to all these customers or inviting them personally by giving them a call are examples of an action associated with that action rule.

In (Tzacheva & Ras, 2005) the notion of a cost and feasibility of an action rule was introduced. The cost is a subjective measure and feasibility is an objective measure. Usually, a number of action rules or chains of action rules can be applied to re-classify a certain set of objects. The cost associated with changes of values within one attribute is usually different than the cost associated with changes of values within another attribute. The strategy for replacing the initially extracted action rule by a composition of new action rules, dynamically built and leading to the same reclassification goal, was proposed in (Tzacheva & Ras, 2005). This composition of rules uniquely defines a new action rule. Objects supporting the new action rule also support the initial action rule but the cost of reclassifying them is lower or even much lower for the new rule. In (Ras & Dardzinska, 2006) authors present a new algebraic-type top-down strategy for constructing action rules from single classification rules. Algorithm ARAS, proposed in (Ras & Wyrzykowska, 2007), is a bottom-up strategy generating action rules. In (He at al., 2005) authors give a strategy for discovering action rules directly from a database.

BACKGROUND

In the paper by (Ras & Wieczorkowska, 2000), the notion of an action rule was introduced. The main idea was to generate, from a database, special type of rules which basically form a hint to users showing a way to reclassify objects with respect to some distinguished attribute (called a decision attribute). Clearly, each relational schema gives a list of attributes used to represent objects stored in a database. Values of some of these attributes, for a given object, can be changed and this change can be influenced and controlled by user. However, some of these changes (for instance "profit") can not be done directly to a decision attribute. In such a case, definitions of this decision attribute in terms of other attributes (called classification attributes) have to be learned. These new definitions are used to construct action rules showing what changes in values of some attributes, for a given class of objects, are needed to reclassify objects the way users want. But, users may still be either unable or unwilling to proceed with actions leading to such changes. In all such cases, we may search for definitions of values of any classification attribute listed in an action rule. By replacing a value of such attribute by its definition, we construct new action rules which might be of more interest to business users than the initial rule. Action rules can be constructed from pairs of classification rules, from a single classification rule, and directly from a database.

MAIN THRUST OF THE CHAPTER

The technology dimension will be explored to clarify the meaning of actionable rules including action rules and action rules schema.

Action Rules Discovery in Information Systems

An information system is used for representing knowledge. Its definition, given here, is due to (Pawlak, 1991).

By an information system we mean a pair S = (U, A), where:

1. U is a nonempty, finite set of objects (object identifiers),
2. A is a nonempty, finite set of attributes i.e. $a:U \rightarrow V_a$ for $a \in A$, where V_a is called the domain of a.

Information systems can be seen as decision tables. In any decision table together with the set of attributes a partition of that set into conditions and decisions is given. Additionally, we assume that the set of conditions is partitioned into stable and flexible conditions (Ras & Wieczorkowska, 2000).

Attribute $a \in A$ is called stable for the set U if its values assigned to objects from U can not be changed in time. Otherwise, it is called flexible. "Date of Birth" is an example of a stable attribute. "Interest rate" on any customer account is an example of a flexible attribute. For simplicity reason, we will consider decision tables with only one decision. We adopt the following definition of a decision table:

By a decision table we mean an information system $S = (U, A_{St} \cup A_{Fl} \cup \{d\})$, where $d \notin A_{St} \cup A_{Fl}$ is a distinguished attribute called decision. The elements of A_{St} are called stable conditions, whereas the elements of $A_{Fl} \cup \{d\}$ are called flexible conditions. Our goal is to change values of attributes in A_{Fl} for some objects from U so values of the attribute d for these objects may change as well. A formal expression describing such a property is called an action rule (Ras & Wieczorkowska, 2000), (Tsay & Ras, 2005).

To construct an action rule (Tsay & Ras, 2005), let us assume that two classification rules, each one referring to a different decision class, are considered. We assume here that these two rules have to be equal on their stable attributes, if they are both defined on them. We use Table 1 to clarify the process of action rule construction. Here, "St" means stable attribute and "Fl" means flexible one.

In a standard representation, these two classification rules have a form:

$$r1 = [\, a1 \wedge b1 \wedge c1 \wedge e1 \rightarrow d1 \,], \; r2 = [\, a1 \wedge b2 \wedge g2 \wedge h2 \rightarrow d2 \,].$$

Assume now that object x supports rule r1 which means that x is classified as d1. In order to reclassify x to class d2, we need to change its value b from b1 to b2 but also we have to require that g(x)=g2 and that the value h for object x has to be changed to h2. This is the meaning of the (r1,r2)-action rule r defined by the expression below:

Table 1. Two classification rules extracted from S

a (St)	b (Fl)	c (St)	e (Fl)	g (St)	h (Fl)	d (Decision)
a1	b1	c1	e1			d1
a1	b2			g2	h2	d2

$r = [[a1 \wedge g2 \wedge (b, b1 \rightarrow b2) \wedge (h, \rightarrow h2)] \Rightarrow (d, d1 \rightarrow d2)]$.

The term $[a1 \wedge g2]$ is called the header of the action rule. Assume now that by Sup(t) we mean the number of tuples having property t. By the support of (r1,r2)-action rule r we mean: $Sup[a1 \wedge b1 \wedge g2 \wedge d1]$. Action rule schema associated with rule r2 is defined as:

$[[a1 \wedge g2 \wedge (b, \rightarrow b2) \wedge (h, \rightarrow h2)] \Rightarrow (d, d1 \rightarrow d2)]$.

By the confidence Conf(r) of (r1,r2)-action rule r we mean:

$[Sup[a1 \wedge b1 \wedge g2 \wedge d1]/ Sup[a1 \wedge b1 \wedge g2]] \bullet [Sup[a1 \wedge b2 \wedge c1 \wedge d2]/ Sup[a1 \wedge b2 \wedge c1]]$.

System DEAR (Tsay & Ras, 2005) discovers action rules from pairs of classification rules.

Actions Rules Discovery, a New Simplified Strategy

A bottom-up strategy, called ARAS, generating action rules from single classification rules was proposed in (Ras & Wyrzykowska, 2007). We give an example describing its main steps.

Let us assume that the decision system S = (U, $A_{St} \cup A_{Fl} \cup \{d\}$), where U = {x1,x2,x3,x4,x5,x6,x7,x8}, is represented by Table 2. A number of different methods can be used to extract rules in which the THEN part consists of the decision attribute d and the IF part consists of attributes belonging to $A_{St} \cup A_{Fl}$. In our example, the set A_{St} ={a,b,c} contains stable attributes and A_{Fl} = {e,f,g} contains flexible attributes. System LERS (Grzymala-Busse, 1997) is used to extract classification rules.

We are interested in reclassifying d2-objects either to class d1 or d3. Four certain classification rules describing either d1 or d3 are discovered by LERS from the decision system S. They are given below:

$r1 = [b1 \wedge c1 \wedge f2 \wedge g1] \rightarrow d1$, $r2 = [a2 \wedge b1 \wedge e2 \wedge f2] \rightarrow d3$, $r3 = e1 \rightarrow d1$, $r4 = [b1 \wedge g2] \rightarrow d3$.

Action rule schemas associated with r1, r2, r3, r4 and the reclassification task either $(d, d2 \rightarrow d1)$ or $(d, d2 \rightarrow d3)$ are:

$r1[d2 \rightarrow d1] = [b1 \wedge c1 \wedge (f, \rightarrow f2) \wedge (g, \rightarrow g1)] \Rightarrow (d, d2 \rightarrow d1)$,
$r2[d2 \rightarrow d3] = [a2 \wedge b1 \wedge (e, \rightarrow e2) \wedge (f, \rightarrow f2)] \Rightarrow (d, d2 \rightarrow d3)$,
$r3[d2 \rightarrow d1] = [(e, \rightarrow e1)] \Rightarrow (d, d2 \rightarrow d1)$,
$r4[d2 \rightarrow d3] = [b1 \wedge (g, \rightarrow g2)] \Rightarrow (d, d2 \rightarrow d3)$.

We can show that $Sup(r1[d2 \rightarrow d1])$= {x3, x6, x8}, $Sup(r2[d2 \rightarrow d3])$= {x6, x8}, $Sup(r3[d2 \rightarrow d1])$= {x3,x4,x5,x6,x7,x8}, $Sup(r4[d2 \rightarrow d3])$ = {x3,x4,x6,x8}.

Assuming that $U[r1,d2] = Sup(r1[d2 \rightarrow d1])$, $U[r2,d2] = Sup(r2[d2 \rightarrow d3])$, $U[r3,d2] = Sup(r3[d2 \rightarrow d1])$, $U[r4,d2] = Sup(r4[d2 \rightarrow d3])$ and by applying ARAS algorithm we get:

$[b1 \wedge c1 \wedge a1]^* = \{x1\} \not\subset U[r1,d2]$, $[b1 \wedge c1 \wedge a2]^* = \{x6, x8\} \subseteq U[r1,d2]$,
$[b1 \wedge c1 \wedge f3]^* = \{x6\} \subseteq U[r1,d2]$, $[b1 \wedge c1 \wedge g2]^* = \{x2, x7\} \not\subset U[r1,d2]$,
$[b1 \wedge c1 \wedge g3]^* = \{x3, x8\} \subseteq U[r1,d2]$.

ARAS will construct two action rules for the first action rule schema:

Table 2. Decision system

U	a	b	c	e	f	g	d
x1	a1	b1	c1	e1	f2	g1	d1
x2	a2	b1	c2	e2	f2	g2	d3
x3	a3	b1	c1	e2	f2	g3	d2
x4	a1	b1	c2	e2	f2	g1	d2
x5	a1	b2	c1	e3	f2	g1	d2
x6	a2	b1	c1	e2	f3	g1	d2
x7	a2	b3	c2	e2	f2	g2	d2
x8	a2	b1	c1	e3	f2	g3	d2

$[b1 \wedge c1 \wedge (f, f3 \rightarrow f2) \wedge (g, \rightarrow g1)] \Rightarrow (d, d2 \rightarrow d1)$,
$[b1 \wedge c1 \wedge (f, \rightarrow f2) \wedge (g, g3 \rightarrow g1)] \Rightarrow (d, d2 \rightarrow d1)$.

In a similar way we construct action rules from the remaining three action rule schemas.

ARAS consists of two main modules. To explain them in a better way, we use another example which has no connection with Table 2. The first module of ARAS extracts all classification rules from S following LERS strategy. Assuming that d is the decision attribute and user is interested in reclassifying objects from its value d1 to d2, we treat the rules defining d1 as seeds and build clusters around them. For instance, if A_{St} ={a, b, g} and A_{Fl} = {c, e, h} are attributes in S = $(U, A_{St} \cup A_{Fl} \cup \{d\})$, and r =$[[a1 \wedge b1 \wedge c1 \wedge e1] \rightarrow d1]$ is a classification rule in S, where Va={a1,a2,a3}, Vb={b1,b2,b3}, Vc={c1,c2,c3}, Ve={e1,e2,e3}, Vg={g1,g2,g3}, Vh={h1,h2,h3}, then we remove from S all tuples containing values a2, a3, b2, b3, c1, e1 and we use again LERS to extract rules from the obtained subsystem.

Each rule defining d2 is used jointly with r to construct an action rule. The validation step of each of the set-inclusion relations, in the second module of ARAS, is replaced by checking if the corresponding term was marked by LERS in the first module of ARAS.

FUTURE TRENDS

Business user may be either unable or unwilling to proceed with actions leading to desired reclassifications of objects. Undertaking the actions may be trivial, feasible to an acceptable degree, or may be practically very difficult. Therefore, the notion of a cost of an action rule is of very great importance. New strategies for discovering action rules of the lowest cost either in an autonomous information system or a distributed one, based on ontologies, should be investigated.

(He et al., 2005) proposed a strategy for discovering action rules directly from a database. More research needs to be done also in that area.

CONCLUSION

Attributes are divided into two groups: stable and flexible. By stable attributes we mean attributes which values can not be changed (for instance, age or maiden name). On the other hand attributes (like percentage rate or loan approval to buy a house) which values can be changed are called flexible. Rules are extracted from a decision table, using standard KD methods, with preference given to flexible attributes - so mainly they are listed in a classification part of rules. Most of these rules can be seen as actionable rules and the same used to construct action-rules.

KEY TERMS

A

Actionable Rule: A rule is actionable if user can do an action to his/her advantage based on this rule.

Autonomous Information System: Information system existing as an independent entity.

Domain of Rule: Attributes listed in the IF part of a rule.

Flexible Attribute: Attribute is called flexible if its value can be changed in time.

Knowledge Base: A collection of rules defined as expressions written in predicate calculus. These rules have a form of associations between conjuncts of values of attributes.

Ontology: An explicit formal specification of how to represent objects, concepts and other entities that are assumed to exist in some area of interest and relationships holding among them. Systems that share the same ontology are able to communicate about domain of discourse without necessarily operating on a globally shared theory. System commits to ontology if its observable actions are consistent with definitions in the ontology.

Stable Attribute: Attribute is called stable for the set U if its values assigned to objects from U can not change in time.

Active Learning with Multiple Views

Ion Muslea
SRI International, USA

INTRODUCTION

Inductive learning algorithms typically use a set of labeled examples to learn class descriptions for a set of user-specified concepts of interest. In practice, labeling the training examples is a tedious, time consuming, error-prone process. Furthermore, in some applications, the labeling of each example also may be extremely expensive (e.g., it may require running costly laboratory tests). In order to reduce the number of labeled examples that are required for learning the concepts of interest, researchers proposed a variety of methods, such as active learning, semi-supervised learning, and meta-learning.

This article presents recent advances in reducing the need for labeled data in multi-view learning tasks; that is, in domains in which there are several disjoint subsets of features (views), each of which is sufficient to learn the target concepts. For instance, as described in Blum and Mitchell (1998), one can classify segments of televised broadcast based either on the video or on the audio information; or one can classify Web pages based on the words that appear either in the pages or in the hyperlinks pointing to them. In summary, this article focuses on using multiple views for active learning and improving multi-view active learners by using semi-supervised- and meta-learning.

BACKGROUND

Active, Semi-Supervised, and Multi-view Learning

Most of the research on multi-view learning focuses on semi-supervised learning techniques (Collins & Singer, 1999, Pierce & Cardie, 2001) (i.e., learning concepts from a few labeled and many unlabeled examples). By themselves, the unlabeled examples do not provide any direct information about the concepts to be learned. However, as shown by Nigam, et al. (2000) and Raskutti, et al. (2002), their distribution can be used to boost the accuracy of a classifier learned from the few labeled examples.

Intuitively, semi-supervised, multi-view algorithms proceed as follows: first, they use the small labeled training set to learn one classifier in each view; then, they bootstrap the views from each other by augmenting the training set with unlabeled examples on which the other views make high-confidence predictions. Such algorithms improve the classifiers learned from labeled data by also exploiting the implicit' information provided by the distribution of the unlabeled examples.

In contrast to semi-supervised learning, active learners (Tong & Koller, 2001) typically detect and ask the user to label only the most informative examples in the domain, thus reducing the user's data-labeling burden. Note that active and semi-supervised learners take different approaches to reducing the need for labeled data; the former explicitly search for a minimal set of labeled examples from which to perfectly learn the target concept, while the latter aim to improve a classifier learned from a (small) set of labeled examples by exploiting some additional unlabeled data.

In keeping with the active learning approach, this article focuses on minimizing the amount of labeled data without sacrificing the accuracy of the learned classifiers. We begin by analyzing co-testing (Muslea, 2002), which is a novel approach to active learning. Co-testing is a multi-view active learner that maximizes the benefits of labeled training data by providing a principled way to detect the most informative examples in a domain, thus allowing the user to label only these.

Then, we discuss two extensions of co-testing that cope with its main limitations—the inability to exploit the unlabeled examples that were not queried and the lack of a criterion for deciding whether a task is appropriate for multi-view learning. To address the former, we present Co-EMT (Muslea et al., 2002a), which interleaves co-testing with a semi-supervised, multi-view learner. This hybrid algorithm combines the benefits of active and semi-supervised learning by

detecting the most informative examples, while also exploiting the remaining unlabeled examples. Second, we discuss Adaptive View Validation (Muslea et al., 2002b), which is a meta-learner that uses the experience acquired while solving past learning tasks to predict whether multi-view learning is appropriate for a new, unseen task.

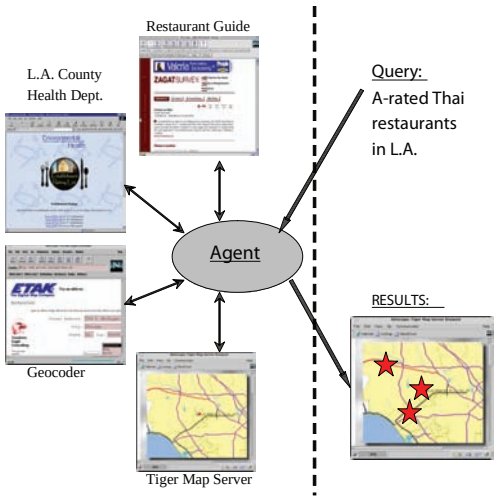
A Motivating Problem: Wrapper Induction

Information agents such as Ariadne (Knoblock et al., 2001) integrate data from pre-specified sets of Web sites so that they can be accessed and combined via database-like queries. For example, consider the agent in Figure 1, which answers queries such as the following:

Show me the locations of all** Thai **restaurants in** L.A. **that are** A-rated **by the L.A. County Health Department.

To answer this query, the agent must combine data from several Web sources:

Figure 1. An information agent that combines data from the Zagat's restaurant guide, the L.A. County Health Department, the ETAK Geocoder, and the Tiger Map service



- From Zagat's, it obtains the name and address of all Thai restaurants in L.A.
- From the L.A. County Web site, it gets the health rating of any restaurant of interest.
- From the Geocoder, it obtains the latitude/longitude of any physical address.
- From Tiger Map, it obtains the plot of any location, given its latitude and longitude.

Information agents typically rely on *wrappers* to extract the useful information from the relevant Web pages. Each wrapper consists of a set of extraction rules and the code required to apply them. As manually writing the extraction rules is a time-consuming task that requires a high level of expertise, researchers designed wrapper induction algorithms that learn the rules from user-provided examples (Muslea et al., 2001).

In practice, information agents use hundreds of extraction rules that have to be updated whenever the format of the Web sites changes. As manually labeling examples for each rule is a tedious, error-prone task, one must learn high accuracy rules from just a few labeled examples. Note that both the small training sets and the high accuracy rules are crucial to the successful deployment of an agent. The former minimizes the amount of work required to create the agent, thus making the task manageable. The latter is required in order to ensure the quality of the agent's answer to each query: when the data from multiple sources is integrated, the errors of the corresponding extraction rules get compounded, thus affecting the quality of the final result; for instance, if only 90% of the Thai restaurants and 90% of their health ratings are extracted correctly, the result contains only 81% (90% x 90% = 81%) of the A-rated Thai restaurants.

We use wrapper induction as the motivating problem for this article because, despite the practical importance of learning accurate wrappers from just a few labeled examples, there has been little work on active learning for this task. Furthermore, as explained in Muslea (2002), existing general-purpose active learners cannot be applied in a straightforward manner to wrapper induction.

MAIN THRUST

In the context of wrapper induction, we intuitively describe three novel algorithms: Co-Testing, Co-EMT,

and Adaptive View Validation. Note that these algorithms are *not* specific to wrapper induction, and they have been applied to a variety of domains, such as text classification, advertisement removal, and discourse tree parsing (Muslea, 2002).

Co-Testing: Multi-View Active Learning

Co-Testing (Muslea, 2002, Muslea et al., 2000), which is the first multi-view approach to active learning, works as follows:

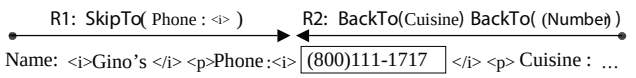
- First, it uses a small set of labeled examples to learn one classifier in each view.
- Then, it applies the learned classifiers to all unlabeled examples and asks the user to label one of the examples on which the views predict different labels.
- It adds the newly labeled example to the training set and repeats the whole process.

Intuitively, Co-Testing relies on the following observation: if the classifiers learned in each view predict a different label for an unlabeled example, at least one of them makes a mistake on that prediction. By asking the user to label such an example, Co-Testing is guaranteed to provide useful information for the view that made the mistake.

To illustrate Co-Testing for wrapper induction, consider the task of extracting restaurant phone numbers from documents similar to the one shown in Figure 2. To extract this information, the wrapper must detect both the beginning and the end of the phone number. For instance, to find where the phone number begins, one can use the following rule:

R1 = *SkipTo*(**Phone:<i>**)

Figure 2. The forward rule R1 and the backward rule R2 detect the beginning of the phone number. Forward and backward rules have the same semantics and differ only in terms of from where they are applied (start/end of the document) and in which direction



This rule is applied *forward*, from the beginning of the page, and it ignores everything until it finds the string **Phone:<i>**. Note that this is not the only way to detect where the phone number begins. An alternative way to perform this task is to use the following rule:

R2 = *BackTo*(**Cuisine**) *BackTo*((***Number***))

which is applied *backward*, from the end of the document. R2 ignores everything until it finds "Cuisine" and then, again, skips to the first number between parentheses.

Note that R1 and R2 represent descriptions of the same concept (i.e., beginning of phone number) that are learned in two different views (see Muslea et al. [2001] for details on learning forward and backward rules). That is, views V1 and V2 consist of the sequences of characters that precede and follow the beginning of the item, respectively. View V1 is called the forward view, while V2 is the backward view. Based on V1 and V2, Co-Testing can be applied in a straightforward manner to wrapper induction. As shown in Muslea (2002), Co-Testing clearly outperforms existing state-of-the-art algorithms, both on wrapper induction and a variety of other real world domains.

Co-EMT: Interleaving Active and Semi-Supervised Learning

To further reduce the need for labeled data, Co-EMT (Muslea et al., 2002a) combines active and semi-supervised learning by interleaving Co-Testing with Co-EM (Nigam & Ghani, 2000). Co-EM, which is a semi-supervised, multi-view learner, can be seen as the following iterative, two-step process: first, it uses the hypotheses learned in each view to probabilistically label all the unlabeled examples; then it learns a new hypothesis in each view by training on the probabilistically labeled examples provided by the other view.

By interleaving active and semi-supervised learning, Co-EMT creates a powerful synergy. On one hand, Co-Testing boosts Co-EM's performance by providing it with highly informative labeled examples (instead of random ones). On the other hand, Co-EM provides Co-Testing with more accurate classifiers (learned from both labeled and unlabeled data), thus allowing Co-Testing to make more informative queries.

Co-EMT was not yet applied to wrapper induction, because the existing algorithms are not probabilistic

learners; however, an algorithm similar to Co-EMT was applied to information extraction from free text (Jones et al., 2003). To illustrate how Co-EMT works, we describe now the generic algorithm Co-EMT^{WI}, which combines Co-Testing with the semi-supervised wrapper induction algorithm described next.

In order to perform semi-supervised wrapper induction, one can exploit a third view, which is used to evaluate the confidence of each extraction. This new content-based view (Muslea et al., 2003) describes the actual item to be extracted. For example, in the phone numbers extraction task, one can use the labeled examples to learn a simple grammar that describes the field content: (*Number*) *Number – Number*. Similarly, when extracting URLs, one can learn that a typical URL starts with the string "http://www.'', ends with the string ".html'', and contains no HTML tags.

Based on the forward, backward, and content-based views, one can implement the following semi-supervised wrapper induction algorithm. First, the small set of labeled examples is used to learn a hypothesis in each view. Then, the forward and backward views feed each other with unlabeled examples on which they make high-confidence extractions (i.e., strings that are extracted by either the forward or the backward rule and are also compliant with the grammar learned in the third, content-based view).

Given the previous Co-Testing and the semi-supervised learner, Co-EMT^{WI} combines them as follows. First, the sets of labeled and unlabeled examples are used for semi-supervised learning. Second, the extraction rules that are learned in the previous step are used for Co-Testing. After making a query, the newly labeled example is added to the training set, and the whole process is repeated for a number of iterations. The empirical study in Muslea, et al., (2002a) shows that, for a large variety of text classification tasks, Co-EMT outperforms both Co-Testing and the three state-of-the-art semi-supervised learners considered in that comparison.

View Validation: Are the Views Adequate for Multi-View Learning?

The problem of *view validation* is defined as follows: given a new unseen multi-view learning task, how does a user choose between solving it with a multi- or a single-view algorithm? In other words, how does one know whether multi-view learning will outperform pooling all features together and applying a single-view learner? Note that this question must be answered while having access to just a few labeled and many unlabeled examples: applying both the single- and multi-view active learners and comparing their relative performances is a self-defeating strategy, because it doubles the amount of required labeled data (one must label the queries made by both algorithms).

The need for view validation is motivated by the following observation: while applying Co-Testing to dozens of extraction tasks, Muslea et al. (2002b) noticed that the forward and backward views are appropriate for most, but not all, of these learning tasks. This view adequacy issue is related tightly to the best extraction accuracy reachable in each view. Consider, for example, an extraction task in which the forward and backward rules lead to a high- and low-accuracy rule, respectively. Note that Co-Testing is not appropriate for solving such tasks; by definition, multi-view learning applies only to tasks in which each view is sufficient for learning the target concept (obviously, the low-accuracy view is insufficient for accurate extraction).

To cope with this problem, one can use Adaptive View Validation (Muslea et al., 2002b), which is a meta-learner that uses the experience acquired while solving past learning tasks to predict whether the views of a new unseen task are adequate for multi-view learning. The view validation algorithm takes as input several solved extraction tasks that are labeled by the user as having views that are adequate or inadequate for multi-view learning. Then, it uses these solved extraction tasks to learn a classifier that, for new unseen tasks, predicts whether the views are adequate for multi-view learning.

The (meta-) features used for view validation are properties of the hypotheses that, for each solved task, are learned in each view (i.e., the percentage of unlabeled examples on which the rules extract the same string, the difference in the complexity of the forward and backward rules, the difference in the errors made on the training set, etc.). For both wrapper induction and text classification, Adaptive View Validation makes accurate predictions based on a modest amount of training data (Muslea et al., 2002b).

FUTURE TRENDS

There are several major areas of future work in the field of multi-view learning. First, there is a need for a

view detection algorithm that automatically partitions a domain's features in views that are adequate for multi-view learning. Such an algorithm would remove the last stumbling block against the wide applicability of multi-view learning (i.e., the requirement that the user provides the views to be used). Second, in order to reduce the computational costs of active learning (re-training after each query is CPU-intensive), one must consider look-ahead' strategies that detect and propose (near) optimal sets of queries. Finally, Adaptive View Validation has the limitation that it must be trained separately for each application domain (e.g., once for wrapper induction, once for text classification, etc.). A major improvement would be a *domain-independent* view validation algorithm that, once trained on a mixture of tasks from various domains, can be applied to any new learning task, independently of its application domain.

CONCLUSION

In this article, we focus on three recent developments that, in the context of multi-view learning, reduce the need for labeled training data.

- **Co-Testing:** A general-purpose, multi-view active learner that outperforms existing approaches on a variety of real-world domains.
- **Co-EMT:** A multi-view learner that obtains a robust behavior over a wide spectrum of learning tasks by interleaving active and semi-supervised multi-view learning.
- **Adaptive View Validation:** A meta-learner that uses past experiences to predict whether multi-view learning is appropriate for a new unseen learning task.

KEY TERMS

Active Learning: Detecting and asking the user to label only the most informative examples in the domain (rather than randomly-chosen examples).

Inductive Learning: Acquiring concept descriptions from labeled examples.

Meta-Learning: Learning to predict the most appropriate algorithm for a particular task.

Multi-View Learning: Explicitly exploiting several disjoint sets of features, each of which is sufficient to learn the target concept.

Semi-Supervised Learning: Learning from both labeled and unlabeled data.

View Validation: Deciding whether a set of views is appropriate for multi-view learning.

Wrapper Induction: Learning (highly accurate) rules that extract data from a collection of documents that share a similar underlying structure.

Adaptive Web Presence and Evolution through Web Log Analysis

Xueping Li
University of Tennessee, Knoxville, USA

INTRODUCTION

The Internet has become a popular medium to disseminate information and a new platform to conduct electronic business (e-business) and electronic commerce (e-commerce). With the rapid growth of the WWW and the intensified competition among the businesses, effective web presence is critical to attract potential customers and retain current customer thus the success of the business. This poses a significant challenge because the web is inherently dynamic and web data is more sophisticated, diverse, and dynamic than traditional well-structured data. Web mining is one method to gain insights into how to evolve the web presence and to ultimately produce a predictive model such that the evolution of a given web site can be categorized under its particular context for strategic planning. In particular, web logs contain potentially useful information and the analysis of web log data have opened new avenues to assist the web administrators and designers to establish adaptive web presence and evolution to fit user requirements.

BACKGROUND

People have realized that web access logs are a valuable resource for discovering various characteristics of customer behaviors. Various data mining or machine learning techniques are applied to model and understand the web user activities (Borges and Levene, 1999; Cooley et al., 1999; Kosala et al., 2000; Srivastava et al., 2000; Nasraoui and Krishnapuram, 2002). The authors in (Kohavi, 2001; Mobasher et al., 2000) discuss the pros and cons of mining the e-commerce log data. Lee and Shiu (Lee and Shiu, 2004) propose an adaptive website system to automatically change the website architecture according to user browsing activities and to improve website usability from the viewpoint of efficiency. Recommendation systems are used by an ever-increasing number of e-commerce sites to help consumers find products to purchase (Schafer et al, 2001). Specifically, recommendation systems analyze the users' and communities' opinions and transaction history in order to help individuals identify products that are most likely to be relevant to their preferences (e.g. Amazon.com, eBay.com). Besides web mining technology, some researches investigate on Markov chain to model the web user access behavior (Xing et al., 2002; Dhyani et al., 2003; Wu et al., 2005). Web log analysis is used to extract terms to build web page index, which is further combined with text-based and anchor-based indices to improve the performance of the web site search (Ding and Zhou, 2007). A genetic algorithm is introduced in a model-driven decision-support system for web site optimization (Asllani and Lari, 2007). A web forensic framework as an alternative structure for clickstream data analysis is introduced for customer segmentation development and loyal customer identification; and some trends in web data analysis are discussed (Sen et al., 2006).

MAIN FOCUS

Broadly speaking, web log analysis falls into the range of web usage mining, one of the three categories of web mining (Kosala and Blockeel, 2000; Srivastava et al., 2002). There are several steps involved in web log analysis: web log acquisition, cleansing and preprocessing, and pattern discovery and analysis.

Web Log Data Acquisition

Web logs contain potentially useful information for the study of the effectiveness of web presence. Most websites enable logs to be created to collect the server and client activities such as access log, agent log, error log, and referrer log. Access logs contain the bulk of data including the date and time, users' IP addresses,

requested URL, and so on. Agent logs provide the information of the users' browser type, browser version, and operating system. Error logs provide problematic and erroneous links on the server such as "file not found", "forbidden to access", et al. Referrer logs provide information about web pages that contain the links to documents on the server.

Because of the stateless characteristic of the Hyper Text Transfer Protocol (HTTP), the underlying protocol used by the WWW, each request in the web log seems independent of each other. The identification of user sessions, in which all pages that a user requests during a single visit, becomes very difficulty (Cooley et al., 1999). Pitkow (1995, 1997, 1998) pointed out that local caching and proxy servers are two main obstacles to get reliable web usage data. Most browsers will cache the recently pages to improve the response time. When a user clicks the "back" button in a browser, the cached document is displayed instead of retrieving the page from the web server. This process can not be recorded by the web log. The existence of proxy servers makes it even harder to identify the user session. In the web server log, requests from a proxy server will have the same identifier although the requests may come from several different users. Because of the cache ability of proxy servers, one requested page in web server logs may actually be viewed by several users. Besides the above two obstacles, the dynamic content pages such as Active Server Pages (ASP) and Java Server Pages (JSP) will also create problems for web logging. For example, although the same Uniform Resource Locator (URL) appears in a web server log, the content that is requested by users might be totally different.

To overcome the above obstacles of inaccuracy web log resulting from caching, proxy server and dynamic web pages, specialized logging techniques are needed. One way is to configure the web server to customize the web logging. Another is to integrate the web logging function into the design of the web pages. For example, it is beneficial to an e-commerce web site to log the customer shopping cart information which can be implemented using ASP or JSP. This specialized log can record the details that the users add items to or remove items from their shopping carts thus to gain insights into the user behavior patterns with regard to shopping carts.

Besides web server logging, package sniffers and cookies can be used to further collection web log data. Packet sniffers can collect more detailed information than web server log by looking into the data packets transferred on the wire or air (wireless connections). However, it suffers from several drawbacks. First, packet sniffers can not read the information of encrypted data. Second, it is expensive because each server needs a separate packet sniffer. It would be difficult to manage all the sniffers if the servers are located in different geographic locations. Finally, because the packets need to be processed by the sniffers first, the usage of packet sniffers may reduce the performance of the web servers. For these reasons, packet sniffing is not widely used as web log analysis and other data collecting techniques.

A cookie is a small piece of information generated by the web server and stored at the client side. The client first sends a request to a web server. After the web server processes the request, the web server will send back a response containing the requested page. The cookie information is sent with the response at the same time. The cookie typically contains the session id, expiration date, user name and password and so on. This information will be stored at the client machine. The cookie information will be sent to the web server every time the client sends a request. By assigning each visitor a unique session id, it becomes easy to identify the sessions. However, some users prefer to disable the usage of cookies on their computers which limits the wide application of cookies.

Web Log Data Cleansing and Preprocessing

Web log data cleansing and preprocessing is critical to the success of the web log analysis. Even though most of the web logs are collected electronically, serious data quality issues may arise from a variety of sources such as system configuration, software bugs, implementation, data collection process, and so on. For example, one common mistake is that the web logs collected from different sites use different time zone. One may use Greenwich Mean Time (GMT) while the other uses Eastern Standard Time (EST). It is necessary to cleanse the data before analysis.

There are some significant challenges related to web log data cleansing. One of them is to differentiate the web traffic data generated by web bots from that generated by "real" web visitors. Web bots, including web robots and

spiders/crawlers, are automated programs that browse websites. Examples of web bots include Google Crawler (Brin and Page, 1998), Ubicrawler (Boldi et al. 2004), and Keynote (www.keynote.com). The traffic from the web bots may tamper the visiting statistics, especially in the e-commerce domain. Madsen (Madsen, 2002) proposes a page tagging method of clickstream collection through the execution of JavaScript at the client's browsers. Other challenges include the identification of sessions and unique customers.

Importing the web log into traditional database is another way to preprocess the web log and to allow further structural queries. For example, web access log data can be exported to a database. Each line in the access log represents a single request for a document on the web server. The typical form of an access log of a request is as follows:

hostname - - [dd/Mon/yyyy:hh24:mm:ss tz] request status bytes

An example is:

uplherc.upl.com - - [01/Aug/1995:00:00:07 -0400] "GET / HTTP/1.0" 304 0

which is from the classical data collected from the web server at the NASA's Kennedy Space Center. Each entry of the access log consists of several fields. The meaning of each field is as following:

- **Host name**: A hostname when possible; otherwise, the IP address if the host name could not be looked up.
- **Timestamp**: In the format " *dd/Mon/yyyy:hh24:mm:ss tz* ", where *dd* is the day of the month, *Mon* is the abbreviation name of the month, *yyyy* is the year, *hh24:mm:ss* is the time of day using a 24-hour clock, and *tz* stands for time zone as shown in the example "*[01/Aug/1995:00:00:07 -0400]*". For consistency, hereinafter we use "day/month/year" date format.
- **Request:** Requests are given in quotes, for example "*GET / HTTP/1.0*". Inside the quotes, "*GET*" is the HTTP service name, "*/*" is the request object, and "*HTTP/1.0*" is the HTTP protocol version.
- **HTTP reply code:** The status code replied by the web server. For example, a reply code "200" means the request is successfully processed. The detailed description about HTTP reply codes refers to RFC (http://www.ietf.org/rfc).
- **Reply Bytes:** This field shows the number of bytes replied.

In the above example, the request came from the host "*uplherc.upl.com*" at *01/Aug/1995:00:00:07*. The requested document was the root homepage "/". The status code was "*304*" which meant that the client copy of document was up to date and thus "*0*" bytes were responded to the client. Then, each entry in the access log can be mapped into a field of a table in a database for query and pattern discovery.

Pattern Discovery and Analysis

A variety of methods and algorithms have been developed in the fields of statistics, pattern recognition, machine learning and data mining (Fayyad et al., 1994; Duda et al., 2000). This section describes the techniques that can be applied in the web log analysis domain.

(1) **Statistical Analysis –** It is the most common and simple yet effective method to explore the web log data and extract knowledge of user access patterns which can be used to improve the design of the web site. Different descriptive statistical analyses, such as mean, standard deviation, median, frequency, and so on, can be performed on variables including number of requests from hosts, size of the documents, server reply code, requested size from a domain, and so forth.

There are a few interesting discoveries about web log data through statistical analysis. Recently, the power law distribution has been shown to apply to the web traffic data in which the probability $P(x)$ that a performance measure x decays as a power law, following $P(x) \sim x^{-\alpha}$. A few power law distributions have been discovered: the number of visits to a site (Adamic et al., 1999), the number of page within a site (Huberman et al., 1999), and the number of links to a page (Albert et al., 1999; Barabási et al., 1999).

Given the highly uneven distribution of the documents request, the e-commerce websites should adjust the caching policy to improve the visitor's experience. C. Cunha (1997) point out that small images account for the majority of the

traffic. It would be beneficial if the website can cache these small size documents in memory. For e-commerce websites, the highly populated items should be arranged to allow fast access because these items will compose over 50% of the total requests. These insights are helpful for the better design and adaptive evolution of the web sites.

2. **Clustering and Classification –** Techniques to group a set of items with similar characteristics and/or to map them into predefined classes. In the web log analysis domain, there are two major clusters of interest to discover: web usage clustering and web pages clustering. Clustering of web usage can establish the groups of users that exhibit similar browsing behaviors and infer user demographic information. Such knowledge is especially useful for marketing campaign in e-commerce applications and personalized web presence. On the other hand, clustering analysis of the web pages can discover the web pages with related content. This is useful for the development of Internet search engine. Classification can be accomplished through well developed data mining algorithms including Bayesian classifier, k-nearest neighbor classifier, support vector machines, and so on (Duda et al., 2000).
3. **Associative Rules** – Associative rules mining is to find interesting associations or correlations among large data sets. In the web log mining domain, one is interested in discovering the implications or correlations of user access patterns. For example, users who access page *A* also visit page *B*; customers who purchase product *C* also purchase product *D*. A typical associative rule application is market basket analysis. This knowledge is useful for effective web presence and evolution by laying out user friendly hyper links for easier access. It can help for e-commerce web site to promote products as well.
4. **Sequential Patterns** – The sequential patterns mining attempts to find inter-transaction patterns such that the presence of one event is followed by another (Mannila et al., 1995, Srikant and Agrawal, 1996). In the context of web log analysis, the discovery of sequential patterns helps to predict user visit patterns and to target certain groups based on these patterns.

FUTURE TRENDS

With the explosive growth of the Internet and ever increasing popularity of e-commerce, privacy is becoming a sensitive topic that attracts many research efforts. How to make sure the identity of an individual is not compromised while effective web log analysis can be conducted is a big challenge. An initiative called Platform for Privacy Preference (P3P) is ongoing at the World Wide Web Consortium (W3C). How to analyze the web log online and make timely decision to update and evolve the web sites is another promising topic.

CONCLUSION

An effective web presence is crucial to enhance the image of a company, increase the brand and product awareness, provide customer services, and gather information. The better understanding of the web's topology and user access patterns, along with modeling and designing efforts, can help to develop search engines and strategies to evolve the web sites. Web logs contain potentially useful information for the study of the effectiveness of web presence. The components of web log analysis are described in this chapter. The approaches and challenges of acquisition and preprocessing of web logs are presented. Pattern discovery techniques including statistical analysis, clustering and classification, associative rules and sequential pattern are discussed in the context of web log analysis towards adaptive web presence and evolution.

KEY TERMS

Web Access Log: Access logs contain the bulk of data including the date and time, users' IP addresses, requested URL, and so on. The format of the web log varies depending on the configuration of the web server.

Web Agent Log: Agent logs provide the information of the users' browser type, browser version, and operating system.

Web Error Log: Error logs provide problematic and erroneous links on the server such as "file not found", "forbidden to access", et al. and can be used to diagnose the errors that the web serve encounters in processing the requests.

Web Log Acquisition: The process of obtaining the web log information. The web logs can be recorded through the configuration of the web server.

Web Log Analysis: The process of parsing the log files from a web server to derive information about the user access patterns and how the server processes the requests. It helps to assist the web administrators to establish effective web presence, assess marketing promotional campaigns, and attract customers.

Web Log Pattern Discovery: The process of application of data mining techniques to discover the interesting patterns from the web log data.

Web Log Preprocessing and Cleansing: The process of detecting and removing inaccurate web log records that arise from a variety of sources such as system configuration, software bugs, implementation, data collection process, and so on.

Web Presence: A collection of web files focusing on a particular subject that is presented on a web server on the World Wide Web.

Web Referrer Log: Referrer logs provide information about web pages that contain the links to documents on the server.

Web Usage Mining: The subfield of web mining that aims at analyzing and discovering interesting patterns of web server log data.

Aligning the Warehouse and the Web

INTRODUCTION

Data warehouses have established themselves as necessary components of an effective IT strategy for large businesses. To augment the streams of data being siphoned from transactional/operational databases warehouses must also integrate increasing amounts of external data to assist in decision support. Modern warehouses can be expected to handle up to 100 Terabytes or more of data. (Berson and Smith, 1997; Devlin, 1998; Inmon 2002; Imhoff et al, 2003; Schwartz, 2003; Day 2004; Peter and Greenidge, 2005; Winter and Burns 2006; Ladley, 2007).

The arrival of newer generations of tools and database vendor support has smoothed the way for current warehouses to meet the needs of the challenging global business environment (Kimball and Ross, 2002; Imhoff et al, 2003; Ross, 2006).

We cannot ignore the role of the Internet in modern business and the impact on data warehouse strategies. The web represents the richest source of external data known to man (Zhenyu et al, 2002; Chakrabarti, 2002; Laender et al, 2002) but we must be able to couple raw text or poorly structured data on the web with descriptions, annotations and other forms of summary meta-data (Crescenzi et al, 2001).

In recent years the Semantic Web initiative has focussed on the production of "smarter data". The basic idea is that instead of making programs with near human intelligence, we rather carefully add meta-data to existing stores so that the data becomes "marked up" with all the information necessary to allow not-so-intelligent software to perform analysis with minimal human intervention. (Kalfoglou et al, 2004)

The Semantic Web builds on established building block technologies such as Unicode, URIs(Uniform Resource Indicators) and XML (Extensible Markup Language) (Dumbill, 2000; Daconta et al, 2003; Decker et al, 2000). The modern data warehouse must embrace these emerging web initiatives. In this paper we propose a model which provides mechanisms for sourcing external data resources for analysts in the warehouse.

BACKGROUND

Data Warehousing

Data warehousing is an evolving IT strategy in which data is periodically siphoned off from multiple heterogeneous operational databases and composed in a specialized database environment for business analysts posing queries. Traditional data warehouses tended to focus on historical/archival data but modern warehouses are required to be more nimble, utilizing data which becomes available within days of creation in the operational environments (Schwartz , 2003; Imhoff et al, 2003; Strand and Wangler, 2004; Ladley, 2007). Data warehouses must provide different views of the data, allowing users the options to "drill down" to highly granular data or to produce highly summarized data for business reporting. This flexibility is supported by the use of robust tools in the warehouse environment (Berson and Smith, 1997; Kimball and Ross, 2002).

Data Warehousing accomplishes the following:

- Facilitates ad hoc end-user querying
- Facilitates the collection and merging of large volumes of data
- Seeks to reconcile the inconsistencies and fix the errors that may be discovered among data records
- Utilizes meta-data in an intensive way.
- Relies on an implicit acceptance that external data is readily available

Some major issues in data warehousing design are:

- Ability to handle vast quantities of data
- Ability to view data at differing levels of granularity
- Query Performance versus ease of query construction by business analysts
- Ensuring Purity, Consistency and Integrity of data entering warehouse
- Impact of changes in the business IT environments supplying the warehouse
- Costs and Return-on-Investment (ROI)

External Data and Search Engines

External data is an often ignored but essential ingredient in the decision support analysis performed in the data warehouse environment. Relevant sources such as trade journals, news reports and stock quotes are required by warehouse decision support personnel when reaching valid conclusions based on internal data (Inmon, 2002; Imhoff et al, 2003).

External data, if added to the warehouse, may be used to put into context data originating from operational systems. The web has long provided a rich source of external data, but robust Search Engine (SE) technologies must be used to retrieve this data (Chakrabarti, 2002; Sullivan, 2000). In our model we envisage a cooperative nexus between the data warehouse and search engines. We introduce a special intermediate and independent data staging layer called the meta-data engine (M-DE).

Search Engines are widely recognized as imperfect yet practical tools to access global data via the Internet. Search Engines continue to mature with new regions, such as the Deep Web, once inaccessible, now becoming accessible (Bergman, 2001; Wang and Lochovsky, 2003; Zillman, 2005). The potential of current and future generations of SEs for harvesting huge tracts of external data cannot be underestimated.

Our model allows a naïve (business) user to pose a query which can be modified to target the domain(s) of interest associated with the user. The SE acts on the modified query to produce results. Once results are retrieved from the SE there is a further processing stage to format the results data for the requirements of the data warehouse.

MAIN THRUST

A

Detailed Model

We now examine the contribution of our model. In particular we highlight the Query Modifying Filter (QMF), Search Engines submission and retrieval phases, and meta-data engine components. The approaches taken in our model aims to enhance the user experience while maximizing the efficiency in the search process.

A query modification process is desirable due to the intractable nature of composing queries. We also wish to target several different search engines with our queries. We note that search engines may independently provide special operators and/or programming tools (e.g. Google API) to allow for tweaking of the default operations of the engine. Thus the Query Modifying Filter (labeled filter in the diagram) may be used to fine tune a generic query to meet the unique search features of a particular search engine. We may need to enhance terms supplied by a user to better target the domain(s) of a user. Feedback from the meta-data engine can be used to guide the development of the Query Modifying Filter.

The use of popular search engines in our suite guarantees the widest possible coverage by our engine. The basic steps in the querying process is:

1. Get user's (naïve) query
2. Apply QMF to produce several modified, search engine specific queries
3. Submit modified queries to their respective search engines
4. Retrieve results and form seed links
5. Use seed links and perform depth/breadth first traversals using seed links
6. Store results from step. 5 to disk

Architecture

For effective functioning, our proposed system must address a number of areas pertaining to both the data warehouse and SE environments, namely:

1. Relevance of retrieved data to a chosen domain
2. Unstructured/semi-structured nature of data on the web
3. Analysis & Generation of meta-data

4. Granularity
5. Temporal Constraints (time stamps, warehouse cycles etc.)
6. Data Purity

Our model bridges the disparate worlds of the warehouse and the web by applying maturing technologies while making key observations about the data warehouse and search engine domains. Directly introducing an integrated search engine into the data warehouse environment, albeit a quick fix solution, would have serious limitations. We would be confronted with a problematic and incongruous situation in which highly structured data in the warehouse would be brought in contact with web data which is often unstructured or semi-structured. We can make far fewer assumptions about unstructured data when compared with structured data.

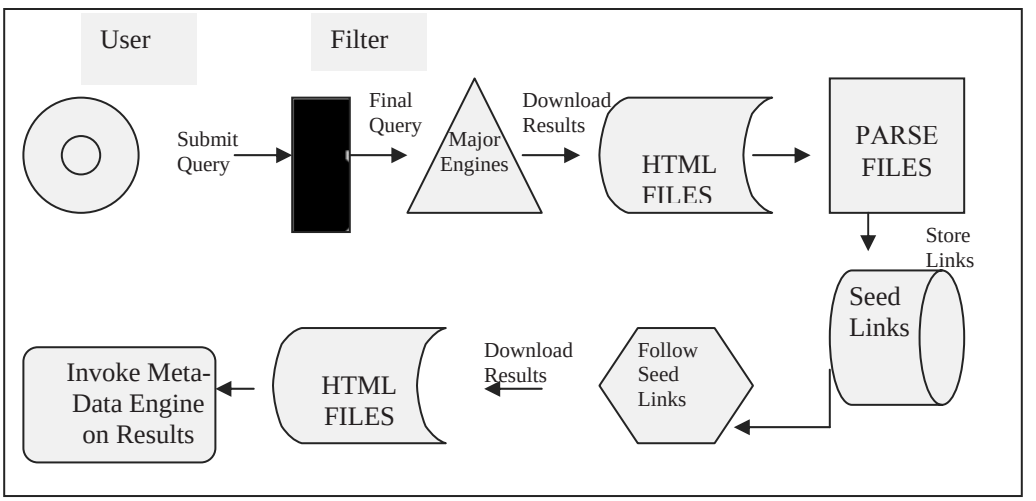
A standard SE ordinarily consists of two parts; a crawler program, and an indexing program. Meta-search engines function by querying other search engines and then ranking combined results in order of relevance. In our model we take the meta-search approach instead of initiating a separate crawler and then utilize the meta-data engine components to assume the role of an indexing program. The meta-data engine forms a bridge between the warehouse and search engine environments.

The M-DE in our model provides an interface in which initially poorly structured or semi-structured data becomes progressively more structured, through the generation of meta-data, to conform to the processing requirements of the data warehouse.

Research is currently very active in the use of XML and related technologies, which can encode web data with the necessary labeling from the time the data is generated. Older, pre-existing web data may also be retrofitted with necessary meta-data. The Semantic Web initiative holds promise that some day most web data will be transparent and readable by intelligent agent software. Closely associated with the Semantic Web is the concept of web services in which business software interoperates using special online directories and protocols. In the worse case we may have to resort to traditional Information Retrieval (IR), Natural Language Processing (NLP), Machine Learning (ML) and other Artificial Intelligence (AI) techniques to grapple with latent semantic issues in the free text (Shah et al, 2002; Laender et al, 2002; Hassell et al, 2006; Holzinger et al, 2006).

The architecture of the M-DE allows for a variety of technologies to be applied. Data on the Web covers a wide continuum including free text in natural language, poorly structured data, semi-structured data, and also highly structured data. Perversely, highly structured data may yet be impenetrable if the structure is unknown, as in the case with some data existing in Deep Web databases (Wang and Lochovsky, 2003; Zillman, 2005).

Figure 1. Query and retrieval in hybrid search engine



We now examine the M-DE component operation in detail. Logically we divide the model into four components. In the diagram these are labeled Filter, Modify, Analyze and Format respectively.

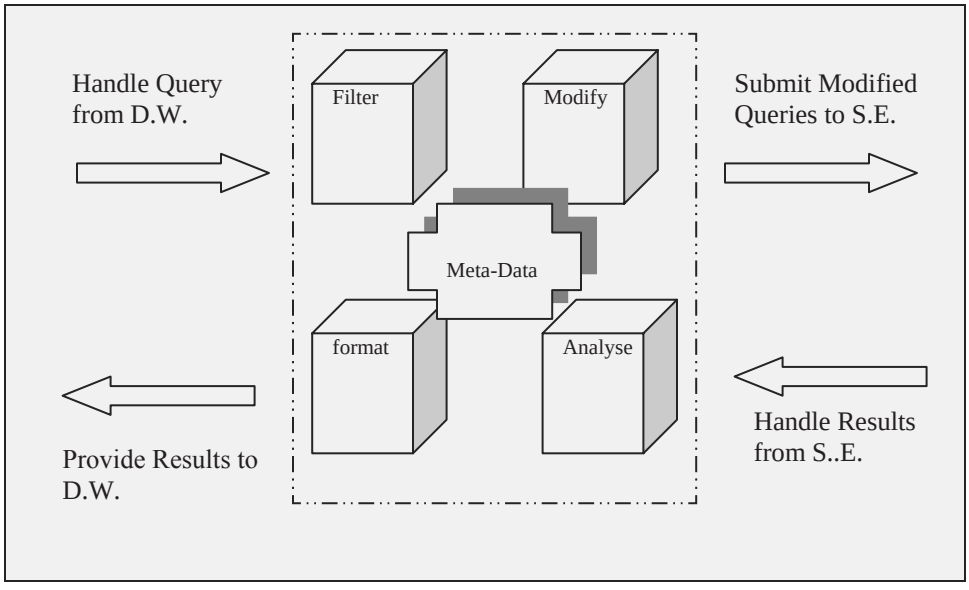
Firstly, the Filter component takes a query from a user and checks that it is valid and suitable for further action. In some cases the user is directed immediately to existing results, or may request a manual override. The filter may be customized to the needs of the user(s). Next the Modify component handles the task of query modification. This is done to address the uniqueness of search criteria present across individual search engines. The effect of the modifications is to maximize the success rates of searches across the suite of search engines interrogated.

The modified queries are sent to the search engines and the returned results are analyzed, by the Analyze component, to determine structure, content type and viability. At this stage redundant documents are eliminated and common web file types are handled including .HTML, .doc, .pdf, .xml and .ps. Current search engines sometimes produce large volumes of irrelevant results. To tackle this problem we must consider semantic issues, as well as structural and syntactic ones. Standard IR techniques are applied to focus on the issue of relevance in the retrieved documents collection. Many tools exist to aid us in applying both IR and data retrieval techniques to the results obtained from the web (Manning et al, 2007; Zhenyu et al, 2002; Daconta et al, 2003).

Semantic Issues

In the Data Warehouse much attention is paid to retaining the purity, consistency and integrity of data originating from operational databases. These databases take several steps to codify meaning through the use of careful design, data entry procedures, database triggers, etc. The use of explicit meta-data safeguards the meaning of data in these databases. Unfortunately on the web the situation is often chaotic. One promising avenue in addressing the issue of relevance in a heterogeneous environment is the use of formal, knowledge representation constructs known as Ontologies. These constructs have again recently been the subject of revived interest in view of Semantic Web initiatives. In our model we plan to use a domain-specific ontology or taxonomy in the format module to match the results' terms and hence distinguish relevant from non-relevant results (Ding et al, 2007; Decker et al, 2000; Chakrabarti, 2002; Kalfoglou et al, 2004; Hassell et al, 2006; Holzinger et al, 2006).

Figure 2. Meta-data engine operation



Data Synchronization

Data entering the warehouse must be synchronized due to the fact that several sources are utilized. Without synchronization the integrity of the data may be threatened. Data coming from the web should also be synchronized where possible. There is also the issue of the time basis of information including page postings, retrieval times, and page expiration dates, etc. Calculating the time basis of information on the web is an inexact science and can sometimes rely on tangential evidence. Some auxiliary time basis indicators include Internet Archives, Online Libraries, web server logs, content analysis and third party reporting. For instance, content analysis on a date field, in a prominent position relative to a heading, may reveal the publication date.

Analysis of the Model

The model seeks to relieve information overload as users may compose naïve queries which will be augmented and tailored to individual search engines. When results are retrieved they are analyzed to produce the necessary meta-data which allows for the integration of relevant external data into the warehouse.

The strengths of this model include:

- Value-added data
- Flexibility
- Generation of meta-data
- Extensibility
- Security
- Independence (both Logical & Physical)
- Relies on proven technologies

This model, when implemented fully, will extend the usefulness of data in the warehouse by allowing its ageing internal data stores to have much needed context in the form of external web based data. Flexibility is demonstrated since the M-DE is considered a specialized activity under a separate administration and queries are tailored to specific search engines. An important side effect is the generation of meta-data. Relevant descriptors of stored data are as important as the data itself. This meta-data is used to inform the system in relation to future searches.

The logical and physical independence seen in the tri-partite nature of the model allows for optimizations, decreases in development times and enhanced maintainability of the system. Security is of vital concern especially in relation to the Internet. The model bolsters security by providing a buffer between an unpredictable online environment and the data warehouse. We envisage development in at least 3 languages, especially SQL for the warehouse proper, Java for the search engine components and Perl to handle the parsing intensive components of the M-DE.

Some obvious weaknesses of the model include:

- Inexact matching and hence skewed estimations of relevance
- Handling of granularity
- Need to store large volumes of irrelevant information
- Manual fine-tuning required by system administrators
- Handling of Multimedia content
- Does not directly address inaccessible “Deep Web” databases

FUTURE TRENDS

We are already considering the rise of newer modes of external data sources on the web such as blogs and RSS feeds. These may well become more important than the e-zines, online newspapers and electronic forums of today. Search Engine technology is continuing to mature. Heavy investments by commercial engines like Yahoo!, Google and MSN are starting to yield results. We expect that future searches will handle relevance, multimedia and data on the Deep Web with far greater ease. Developments on the Semantic Web, particularly in areas such as Ontological Engineering and Health Care (Eysenbach, 2003; Qazi, 2006; Sheth, 2006), will allow web-based data to be far more transparent to software agents. The data warehouse environment will continue to evolve, having to become more nimble and more accepting of data in diverse formats, including multimedia. The issue of dirty data in the warehouse must be tackled, especially as the volume of data in the warehouse continues to mushroom (Kim, 2003).

CONCLUSION

The model presented seeks to promote the availability and quality of external data for the warehouse through

the introduction of an intermediate data-staging layer. Instead of clumsily seeking to combine the highly structured warehouse data with the lax and unpredictable web data, the meta-data engine we propose mediates between the disparate environments. Key features are the composition of domain specific queries which are further tailor made for individual entries in the suite of search engines being utilized. The ability to disregard irrelevant data through the use of Information Retrieval (IR), Natural Language Processing (NLP) and/or Ontologies is also a plus. Furthermore the exceptional independence and flexibility afforded by our model will allow for rapid advances as niche-specific search engines and more advanced tools for the warehouse become available.

KEY TERMS

Decision Support System (DSS): An interactive arrangement of computerized tools tailored to retrieve and display data regarding business problems and queries.

Deep Web: Denotes those significant but often neglected portions of the web where data is stored in inaccessible formats that cannot be readily indexed by the major search engines. In the literature the term "*Invisible Web*" is sometimes used.

External data: Data originating from other than the operational systems of a corporation.

Metadata: Data about data; in the data warehouse it describes the contents of the data warehouse.

Operational Data: Data used to support the daily processing a company does.

Refresh Cycle: The frequency with which the data warehouse is updated : for example, once a week.

Semantic Web: Area of active research in which XML based technologies are being used to make web data "smarter" so that it can be readily handled by software agents.

Transformation: The conversion of incoming data into the desired form.

Analytical Competition for Managing Customer Relations

Dan Zhu
Iowa State University, USA

INTRODUCTION

With the advent of technology, information is available in abundance on the World Wide Web. In order to have appropriate and useful information users must increasingly use techniques and automated tools to search, extract, filter, analyze and evaluate desired information and resources. Data mining can be defined as the extraction of implicit, previously unknown, and potentially useful information from large databases.

On the other hand, text mining is the process of extracting the information from an unstructured text. A standard text mining approach will involve categorization of text, text clustering, and extraction of concepts, granular taxonomies production, sentiment analysis, document summarization, and modeling (Fan et al, 2006). Furthermore, Web mining is the discovery and analysis of useful information using the World Wide Web (Berry, 2002; Mobasher, 2007). This broad definition encompasses "web content mining," the automated search for resources and retrieval of information from millions of websites and online databases, as well as "web usage mining," the discovery and analysis of users' website navigation and online service access patterns.

Companies are investing significant amounts of time and money on creating, developing, and enhancing individualized customer relationship, a process called customer relationship management or CRM. Based on a report by the Aberdeen Group, worldwide CRM spending reached close to $20 billion by 2006. Today, to improve the customer relationship, most companies collect and refine massive amounts of data available through the customers. To increase the value of current information resources, data mining techniques can be rapidly implemented on existing software and hardware platforms, and integrated with new products and systems (Wang et al., 2008). If implemented on high-performance client/server or parallel processing computers, data mining tools can analyze enormous databases to answer customer-centric questions such as, "Which clients have the highest likelihood of responding to my next promotional mailing, and why." This paper provides a basic introduction to data mining and other related technologies and their applications in CRM.

BACKGROUND

Customer Relationship Management

Customer relationship management (CRM) is an enterprise approach to customer service that uses meaningful communication to understand and influence consumer behavior. The purpose of the process is two-fold: 1) to impact all aspects to the consumer relationship (e.g., improve customer satisfaction, enhance customer loyalty, and increase profitability) and 2) to ensure that employees within an organization are using CRM tools. The need for greater profitability requires an organization to proactively pursue its relationships with customers (Gao et al., 2007). In the corporate world, acquiring, building, and retaining customers are becoming top priorities. For many firms, the quality of its customer relationships provides its competitive edge over other businesses. In addition, the definition of "customer" has been expanded to include immediate consumers, partners and resellers—in other words, virtually everyone who participates, provides information, or requires services from the firm.

Companies worldwide are beginning to realize that surviving an intensively competitive and global marketplace requires closer relationships with customers. In turn, enhanced customer relationships can boost profitability three ways: 1) reducing cots by attracting more suitable customers; 2) generating profits through cross-selling and up-selling activities; and 3) extending profits through customer retention. Slightly expanded explanations of these activities follow.

- **Attracting more suitable customers:** Data mining can help firms understand which customers are most likely to purchase specific products and services, thus enabling businesses to develop targeted marketing programs for higher response rates and better returns on investment.
- **Better cross-selling and up-selling:** Businesses can increase their value proposition by offering additional products and services that are actually desired by customers, thereby raising satisfaction levels and reinforcing purchasing habits.
- **Better retention:** Data mining techniques can identify which customers are more likely to defect and why. This information can be used by a company to generate ideas that allow them maintain these customers.

In general, CRM promises higher returns on investments for businesses by enhancing customer-oriented processes such as sales, marketing, and customer service. Data mining helps companies build personal and profitable customer relationships by identifying and anticipating customer's needs throughout the customer lifecycle.

Data Mining: An Overview

Data mining can help reduce information overload and improve decision making. This is achieved by extracting and refining useful knowledge through a process of searching for relationships and patterns from the extensive data collected by organizations. The extracted information is used to predict, classify, model, and summarize the data being mined. Data mining technologies, such as rule induction, neural networks, genetic algorithms, fuzzy logic and rough sets, are used for classification and pattern recognition in many industries.

Data mining builds models of customer behavior using established statistical and machine learning techniques. The basic objective is to construct a model for one situation in which the answer or output is known, and then apply that model to another situation in which the answer or output is sought. The best applications of the above techniques are integrated with data warehouses and other interactive, flexible business analysis tools. The analytic data warehouse can thus improve business processes across the organization, in areas such as campaign management, new product rollout, and fraud detection. Data mining integrates different technologies to populate, organize, and manage the data store. Since quality data is crucial to accurate results, data mining tools must be able to "clean" the data, making it consistent, uniform, and compatible with the data store. Data mining employs several techniques to extract important information. Operations are the actions that can be performed on accumulated data, including predictive modeling, database segmentation, link analysis, and deviation detection.

Statistical procedures can be used to apply advanced data mining techniques to modeling (Yang & Zhu, 2002; Huang et al., 2006). Improvements in user interfaces and automation techniques make advanced analysis more feasible. There are two groups of modeling and associated tools: theory-driven and data driven. The purpose of theory-driven modeling, also called hypothesis testing, is to substantiate or disprove a priori notions. Thus, theory-driven modeling tools ask the user to specify the model and then test its validity. On the other hand, data-driven modeling tools generate the model automatically based on discovered patterns in the data. The resulting model must be tested and validated prior to acceptance. Since modeling is an evolving and complex process, the final model might require a combination of prior knowledge and new information, yielding a competitive advantage (Davenport & Harris, 2007).

MAIN THRUST

Modern data mining can take advantage of increasing computing power and high-powered analytical techniques to reveal useful relationships in large databases (Han & Kamber, 2006; Wang et al., 2007). For example, in a database containing hundreds of thousands of customers, a data mining process can process separate pieces of information and uncover that 73% of all people who purchased sport utility vehicles also bought outdoor recreation equipment such as boats and snowmobiles within three years of purchasing their SUVs. This kind of information is invaluable to recreation equipment manufacturers. Furthermore, data mining can identify potential customers and facilitate targeted marketing.

CRM software applications can help database marketers automate the process of interacting with their customers (Kracklauer et al., 2004). First, data-

base marketers identify market segments containing customers or prospects with high profit potential. This activity requires processing of massive amounts of data about people and their purchasing behaviors. Data mining applications can help marketers streamline the process by searching for patterns among the different variables that serve as effective predictors of purchasing behaviors. Marketers can then design and implement campaigns that will enhance the buying decisions of a targeted segment, in this case, customers with high income potential. To facilitate this activity, marketers feed the data mining outputs into campaign management software that focuses on the defined market segments. Here are three additional ways in which data mining supports CRM initiatives.

- **Database marketing:** Data mining helps database marketers develop campaigns that are closer to the targeted needs, desires, and attitudes of their customers. If the necessary information resides in a database, data mining can model a wide range of customer activities. The key objective is to identify patterns that are relevant to current business problems. For example, data mining can help answer questions such as "Which customers are most likely to cancel their cable TV service?" and "What is the probability that a customer will spent over $120 from a given store?" Answering these types of questions can boost customer retention and campaign response rates, which ultimately increases sales and returns on investment.
- **Customer acquisition:** The growth strategy of businesses depends heavily on acquiring new customers, which may require finding people who have been unaware of various products and services, who have just entered specific product categories (for example, new parents and the diaper category), or who have purchased from competitors. Although experienced marketers often can select the right set of demographic criteria, the process increases in difficulty with the volume, pattern complexity, and granularity of customer data. Highlighting the challenges of customer segmentation has resulted in an explosive growth in consumer databases. Data mining offers multiple segmentation solutions that could increase the response rate for a customer acquisition campaign. Marketers need to use creativity and experience to tailor new and interesting offers for customers identified through data mining initiatives.
- **Campaign optimization:** Many marketing organizations have a variety of methods to interact with current and prospective customers. The process of optimizing a marketing campaign establishes a mapping between the organization's set of offers and a given set of customers that satisfies the campaign's characteristics and constraints, defines the marketing channels to be used, and specifies the relevant time parameters. Data mining can elevate the effectiveness of campaign optimization processes by modeling customers' channel-specific responses to marketing offers.

Database marketing software enables companies to send customers and prospective customers timely and relevant messages and value propositions. Modern campaign management software also monitors and manages customer communications on multiple channels including direct mail, telemarketing, email, Web, point-of-sale, and customer service. Furthermore, this software can be used to automate and unify diverse marketing campaigns at their various stages of planning, execution, assessment, and refinement. The software can also launch campaigns in response to specific customer behaviors, such as the opening of a new account.

Generally, better business results are obtained when data mining and campaign management work closely together. For example, campaign management software can apply the data mining model's scores to sharpen the definition of targeted customers, thereby raising response rates and campaign effectiveness. Furthermore, data mining may help to resolve the problems that traditional campaign management processes and software typically do not adequately address, such as scheduling, resource assignment, etc. While finding patterns in data is useful, data mining's main contribution is providing relevant information that enables better decision making. In other words, it is a tool that can be used along with other tools (e.g., knowledge, experience, creativity, judgment, etc.) to obtain better results. A data mining system manages the technical details, thus enabling decision-makers to focus on critical business questions such as "Which current customers are likely to be interested in our new product?" and "Which market segment is the best for the launch of our new product?"

FUTURE TRENDS

Data mining is a modern technology that offers competitive firms a method to manage customer information, to retain customers, and to pursue new and hopefully profitable customer relationships. With the emergence new technologies, data mining has been further enhanced and segregated into text mining and web mining.

Text Mining

With the advancement and expansion of data mining there is a large scope and need of an area which can serve the purpose various domains. Fusion of techniques from data mining, language, information process retrieval and visual understanding, created an interdisciplinary field called text mining. Text data mining, referred as, text mining is the process of extracting the information from an unstructured text. In order to obtain high text information, a process of pattern division and trends is done. For an efficient text mining system, the unstructured text is parsed and attached or removed some level of linguistic feature, thus making it structured text. A standard text mining approach will involve categorization of text, text clustering, and extraction of concepts, granular taxonomies production, sentiment analysis, document summarization, and modeling.

Text mining involves a two stage processing of text. In the first step a description of document and its content is done. This process is called categorization process. In the second step, called as classification, the document is divided into descriptive categories and an inter document relationship is established. Of the late, text mining has been useful in many areas, i.e. security applications, software applications, academic applications etc. In the competitive world of business, there is a rush to grab the pie of text mining benefits. With every company focusing on customer relationship management the need for a technique to analyze the customer response in an efficient and effective ways is in demand. This is where text mining fills in the void.

Companies generally concentrate in a smaller quantitative picture of customer response and thus neglecting a broader perspective of CRM. Furthermore, people managing CRM do not put a heed to the day to day communications, suggestions, complaints and praises. This leads to further weaken the CR analysis. With the use of text mining a link to the behavioral data can be obtained which will be an additional asset to the standard numerical analysis. With the involvement of text mining which in itself involves artificial intelligence, machine learning and statistics can be very useful in predicting the future course of customer relationship management.

Web Mining

With the explosion of information we are entering into a flood of information. This information explosion is strongly supported by the internet which by all means has become a universal infrastructure of information (Abbasi & Chen, 2007; Turekten & Sharda, 2007). With the fact that web content is exponentially increasing it is getting difficult day by day to get the appropriate information which is as close as possible to what a user is looking for. Web mining can be used in customizing the web sites based on the contents as well as the user interaction. Types of web mining generally include usage mining, content mining and structure mining.

Data mining, text mining and web mining employ many techniques to extract relevant information from massive data sources so that companies can make better business decisions with regard to their customer relationships. Hence, data, text mining and web mining promote the goals of customer relationship management, which are to initiate, develop, and personalize customer relationships by profiling customers and highlighting segments.

However, data mining presents a number of issues that must be addressed. Data privacy is a trigger-button issue (Atahan & Sarkar, 2007; Zhu et al., 2007). Recently, privacy violations, complaints, and concerns have grown in significance as merchants, companies, and governments continue to accumulate and store large amounts of personal data. There are concerns not only about the collection of personal data, but also the analyses and uses of the data. For example, transactional information is collected from the customer for the processing of a credit card payment, then, without prior notification, the information is used for other purposes (e.g., data mining). This action would violate principles of data privacy. Fueled by the public's concerns about the rising volume of collected data and potent technologies, clashes between data privacy and data mining likely will cause higher levels of scrutiny in the coming years. Legal challenges are quite possible in this regard.

There are other issues facing data mining as well (Olson, 2008). Data inaccuracies can cause analyses, results, and recommendations to veer off-track. Customers' submission of erroneous or false information and data type incompatibilities during the data importation process pose real hazards to data mining's effectiveness. Another risk is that data mining might be easily confused with data warehousing. Companies that build data warehouses without implementing data mining software likely will not reach top productivity nor receive the full benefits. Likewise, cross-selling can be a problem if it violates customers' privacy, breaches their trust, or annoys them with unwanted solicitations. Data mining can help to alleviate the latter issue by aligning marketing programs with targeted customers' interests and needs.

CONCLUSION

Despite the potential issues and impediments, the market for data mining is projected to grow by several billion dollars. Database marketers should understand that some customers are significantly more profitable than others. Data mining can help to identify and target these customers, whose data is "buried" in massive databases, thereby helping to redefine and to reinforce customer relationships.

Data mining tools can predict future trends and behaviors that enable businesses to make proactive, knowledge-based decisions. This is one of the reasons why data mining is also known as knowledge discovery. It is the process of analyzing data from different perspectives, grouping the relationships identified and finally concluding to a set of useful information. This set of information can be further analyzed and utilized by companies to increase revenue, cut costs or a combination of both. With the use of data mining business are finding it easy to answer questions pertaining to business intelligence which were difficult to analyze and conclude before.

KEY TERMS

Application Service Providers: Offer outsourcing solutions that supply, develop, and manage application-specific software and hardware so that customers' internal information technology resources can be freed-up.

Business Intelligence: The type of detailed information that business managers need for analyzing sales trends, customers' purchasing habits, and other key performance metrics in the company.

Classification: Distribute things into classes or categories of the same type, or predict the category of categorical data by building a model based on some predictor variables.

Clustering: Identify groups of items that are similar. The goal is to divide a data set into groups such that records within a group are as homogeneous as possible, and groups are as heterogeneous as possible. When the categories are unspecified, this may be called "unsupervised learning".

Genetic Algorithm: Optimization techniques based on evolutionary concepts that employ processes such as genetic combination, mutation and natural selection in a design.

Online Profiling: The process of collecting and analyzing data from website visits, which can be used to personalize a customer's subsequent experiences on the website.

Rough Sets: A mathematical approach to extract knowledge from imprecise and uncertain data.

Rule Induction: The extraction of valid and useful "if-then-else" type of rules from data based on their statistical significance levels, which are integrated with commercial data warehouse and OLAP platforms.

Web Usage Mining: The analysis of data related to a specific user browser along with the forms submitted by the user during a web transaction.

Analytical Knowledge Warehousing for Business Intelligence

Chun-Che Huang
National Chi Nan University, Taiwan

Tzu-Liang (Bill) Tseng
The University of Texas at El Paso, USA

INTRODUCTION

The Information Technology and Internet techniques are rapidly developing. Interaction between enterprises and customers has dramatically changed. It becomes critical that enterprises are able to perform rapid diagnosis and quickly respond to market change. How to apply business intelligence (BI), manage, and diffuse discovered knowledge efficiently and effectively has attracted much attention (Turban *et al.*, 2007). In this chapter, an "analytical knowledge warehousing" approach is proposed to apply business intelligence, and solve the knowledge management and diffusion issues for decision-making. Analytical knowledge is referred to a set of discovered knowledge, i.e., core of BI, which is extricated from databases, knowledge bases, and other data storage systems through aggregating data analysis techniques and domain experts from business perspective. The solution approach includes conceptual framework of analytical knowledge, analytical knowledge externalization, design and implementation of analytical knowledge warehouse. The methodology has integrated with multi-dimensional analytical techniques to efficiently search analytical knowledge documents. The techniques include static and dynamic domains and solve problems from the technical and management standpoints. The use of analytical knowledge warehouse and multidimensional analysis techniques shows the promising future to apply BI and support decision-making in business.

BACKGROUND

As businesses continue to use computer systems for a growing number of functions, they face the challenge of processing and analyzing huge amounts of data and turning it into profits. In response to this, enterprises are trying to build their business intelligence (BI), which is a set of tools and technologies designed to efficiently extract useful information from oceans of data. Business intelligence which introduces advanced technology into enterprise management (such as data warehouses, OLAP, data mining), not only provides enterprises with the ability to obtain necessary information, but also to turn them into useful knowledge that will improve an enterprises' competitive advantage (Xie *et al.*, 2001). The functions of business intelligence include management of data, analysis of data, support of decision, and excellence of business (Liang *et al.*, 2002). Business intelligence system queries a data source, uses techniques such as online analytical processing and data mining to analyze information in the source, and reports the results of its work (Ortiz, 2002). Business intelligence tools enable organizations to understand their internal and external environment through the systematic acquisition, collation, analysis, interpretation and exploitation of information (Chung *et al.*, 2003). However, the primary challenge of BI is how to represent the sets of knowledge discovered by using advanced technologies, manage, and diffuse them. In most cases, enterprises build knowledge management systems. However, these systems do not consider the dynamic characteristics of knowledge activities (Maier, 2007).

In an enterprise, the structure of knowledge activity, which depicts activities in the knowledge life cycle (Alavi and Leidner, 2001) and potential issues in the process, is dynamic (Figure 1). Two systems are observed in Figure 1. The lower part of Figure 1 shows the "knowledge activity" main system, which projects internal and external changes. The upper part of Figure 1 depicts the system, which starts from requirement of solution approach, and is followed by knowledge sharing, knowledge innovation, knowledge similarity, knowledge externalization and break through knowledge. Furthermore, there are two "feedback" mechanisms

in each system. In Figure 1, the solid line represents the flow and relationship between each knowledge activity. In contrast to the solid line, the dashed line represents the model of barrier of knowledge activity, which often occurs in the real world. Note that the dash line also shows "adjusted" feedback, which brings in an adjusted (opposite) function into the system.

Some business approaches focus on the "enhanced" feedback (solid lines) in order to increase effectiveness of Knowledge Management (KM) and decision-making (Alavi and Leidner, 2001). However, those approaches are merely temporary solutions and in ad hoc manners. Those approaches become dysfunctional eventually. Therefore, a leverage approach (i.e., focusing on improving the adjusted feedbacks, which is represented by the dash lines in Figure 1) is practical and desirable to achieve effectiveness of BI in decision-making.

To model analytical knowledge in an explicit and sharable manner and avoid the ineffectiveness of applying BI in decision-making, it is required to makes clarification of the following issues:

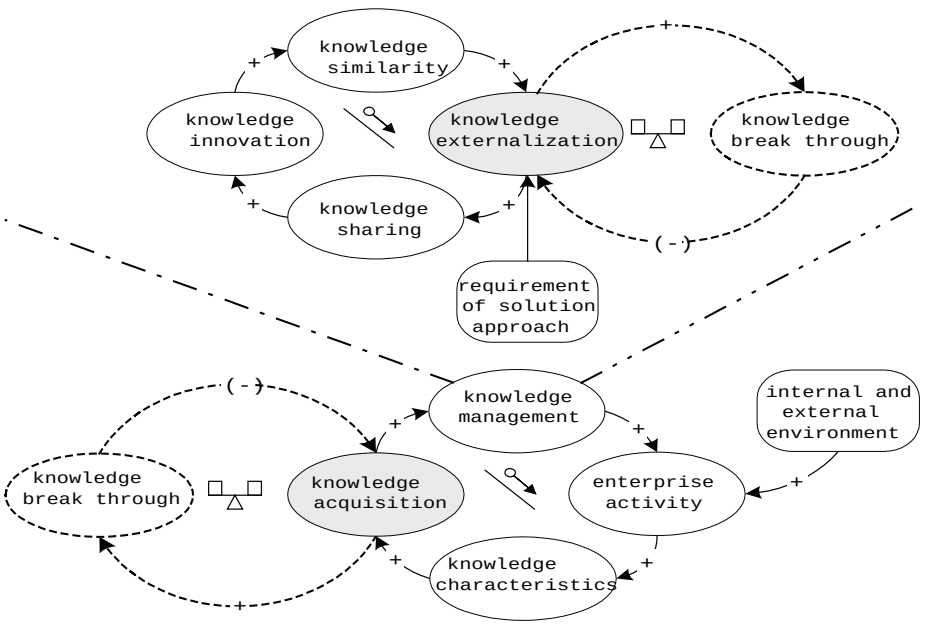
1. Businesses are required to efficiently induce the core knowledge domain (Dieng *et al.*, 1999) and make efforts on high-value and applicable knowledge.
2. From standpoint of technology, knowledge is required to accumulate itself and then be shared with other sources.
3. The lack of well-structured knowledge storage has made the integration of knowledge spiral activities impossible (Nonaka and Takeuchi, 1995).
4. Based on the AK warehousing, the paper uses the multidimensional technique to illustrate the analytical knowledge. The proposed analytical knowledge warehousing eventually stores the paths of analytical knowledge documents, which is classified as non-numerical data.
5. Analytical techniques are used to project potential facts and knowledge in a particular scenario or with some assumptions. The representation is static, rather than dynamic.

MAIN FOCUS

This chapter is based on the data warehousing and knowledge discovery techniques: (1) identify and represent analytical knowledge, which is a result of data analytical techniques, (2) store and manage the analytical knowledge efficiently, (3) accumulate, share, distribute, and integrate the analytical knowledge for BI. This chapter is conceptualized in Figure 2 and illustrated in five levels:

1. In the bottom area, there are two research domains: the left side corresponds to the data storage system

Figure 1. The dynamic structure of knowledge activity in enterprise

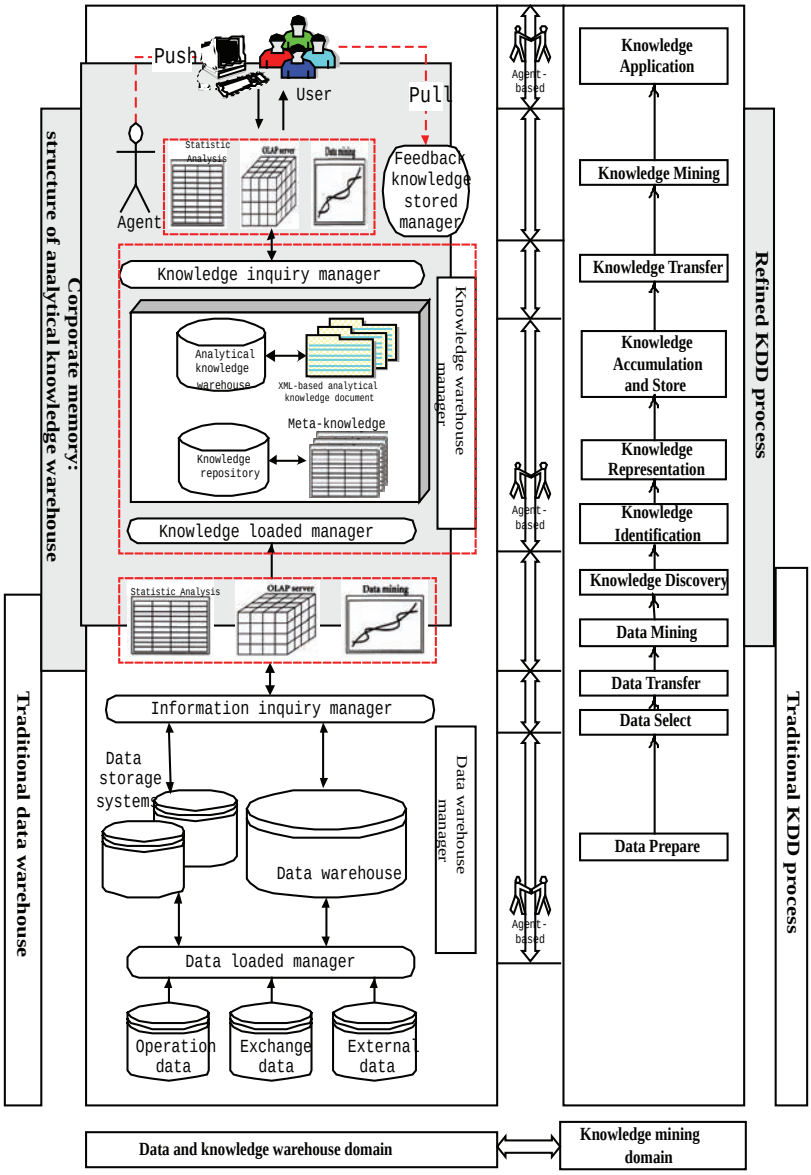


techniques, e.g., data warehousing and knowledge warehousing techniques – a systematic view to aim at the store and management of data and knowledge; and the right side corresponds to the knowledge discovery – an abstract view to aim at the understanding of knowledge discovery processes.

2. The core research of this chapter, the "warehouse for analytical knowledge" is on the left-lower side which corresponds to the traditional data warehouse architecture. Knowledge warehouse of analytical knowledge refers to the management and storage of analytical knowledge documents, which result from the analytical techniques. The structure of AK is defined with the Zachman Framework (Inmon, 2005) and stored in the knowledge depository. The AK warehousing is based on and modified from traditional data warehousing techniques.
3. The white right-bottom side corresponds to the traditional knowledge discovery processes. The right-upper side corresponds to the refined processes of knowledge discovery, which aims at structurally depicting detailed development processes of knowledge discovery.

A

Figure 2. Research structure diagram



4. The two-direction arrow in the middle area refers to the agent-based concept, which aims at the integration of data/knowledge warehousing and knowledge discovery processes and clarification of the mapping between system development and conceptual projection processes. The agent-based systematic approach is proposed to overcome the difficulties of integration, which often occurs in individual and independent development.
5. In the upper area, user knowledge application level, there are two important concepts in the analysis of knowledge warehousing: The "push" concept (the left-upper corner) uses intelligent agents to detect, reason, and respond to the knowledge changes in knowledge warehouse. The agents actively deliver the important messages to knowledge workers to support decision-making on time, rather than in a traditional way, doing jobs by manager's commands. The "pull" concept (the right-upper corner) feedbacks the messages to knowledge warehouse after the users browse and analyze particular analytical knowledge, in such a way to accumulate and share knowledge passively.

Analytical Knowledge (AK)

Analytical knowledge, a core part of BI, is defined as a set of knowledge, which is extricated from databases, knowledge bases, and other data storage systems through aggregating data analysis techniques and domain experts. Data analysis techniques are related to different domains. Each domain comprises several components for example, including statistics, artificial intelligence and database domains. Each domain is not mutually exclusive but correlated to each other. The components under each domain may be reflected at different levels. Those levels are technical application, software platform and fundamental theory. Clearly, all of technical application and software platform are supported by fundamental theory.

Analytical knowledge is different from general knowledge and is constituted only by experts' knowledge, data analysis techniques and data storage systems. Another key feature of analytical knowledge is that domain experts' knowledge should be based on data analysis techniques as well as data storage systems (Davenport and Prusak, 1998).

Numerous classification approaches have been used to distinguish different types of knowledge. For example, knowledge can be further divided into tacit or explicit knowledge (Nonaka, 1991). Analytical knowledge is classified through the following criteria: tacit or explicit, removable or un-removable, expert or un-professional, and strategic resources (Alavi and Leidner, 2001). Note that the definition of expertise includes three categories: know-what, know-how and know-why.

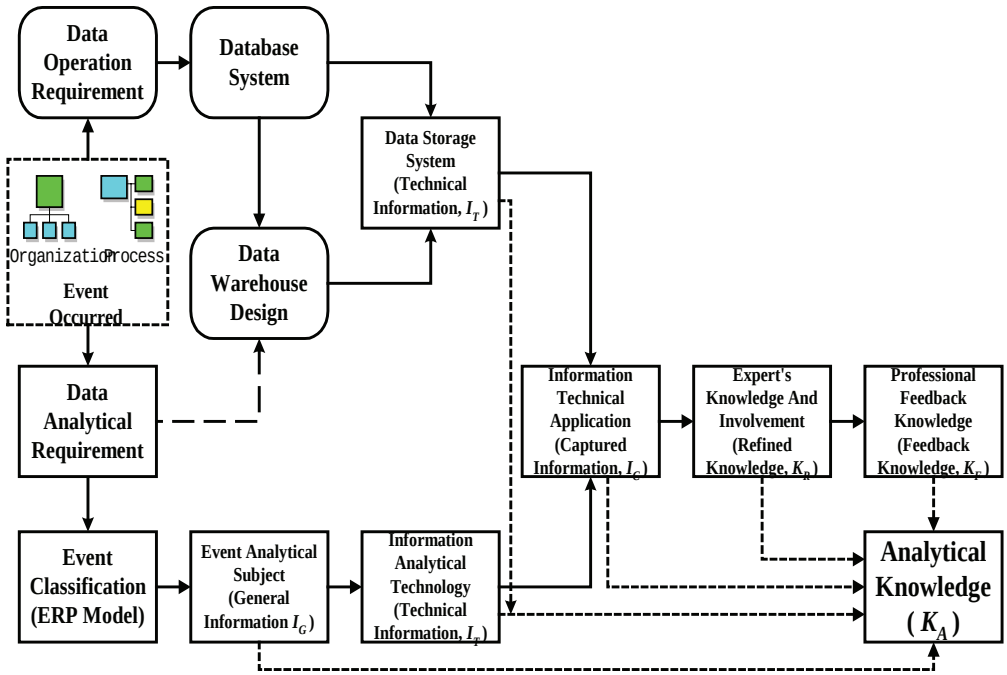
Executive personnel of analytical knowledge are summarized through the Zachman Framework (Inmon *et al.*, 1997). Seven dimensions (entity, location, people, time, motivation, activity, and information) are listed for this summary. Basically, the first six categories correspond to the 5W1H (What, Where, Who, When, Why, and How) technique. Furthermore, five categories are used to represent executive personnel. Data analyzer, knowledge analyzer, knowledge editor, knowledge manager and knowledge user are formed for these categories. Note that the same person might be involved in more than one category since an individual could play multi roles in the organization.

As mentioned before, analytical knowledge is transformed from different stages. Sophisticated process is involved from the first step (e.g., event occurred) to the last step (e.g., knowledge generated). Figure 3 exemplifies the process of generating analytical knowledge. More details are introduced as follows:

(1) A dashed line represents the source of data, which means "event." Here, the needs of data or information analysis from enterprise are triggered by the events from a working process or organization; (2) The blocks represent the entities in the process. There are requirements assessment, events classification, topics identification, techniques identification, techniques application, experts' involvement and group discussions; (3) The oval blocks represent data storage systems; (4) Three different types of arrows are used in the diagram. The solid line arrow illustrates the direction of the process, while the long dash line arrow points out the needs of the data warehouse. The dot dash line shows paths to construct analytical knowledge.

In general, technical information and captured information are highly correlated to the data analysis techniques. Different types of knowledge are produced through different data analysis approaches. For example, an association rule approach in data mining can be implemented to generate technical information

Figure 3. A flow diagram of generating analytical knowledge



while a classification approach can be used to form captured information. However, the nature of these two different kinds of knowledge is significant. Therefore, it is essential to design the structure of knowledge to achieve knowledge externalization and allow the analytical knowledge to reside, e.g., an eXtensible Markup Language (XML) application.

The XML-based externalization process is proposed in Figure 4, which shows the flow chart of the externalization process of analytical knowledge. The results of externalization are stored into a knowledge warehouse by using XML.

To be able to support analytical knowledge warehousing, XML is implemented to define standard documents for externalization, which includes five different categories as above. The XML-based externalization provides a structured and standard way for analytical knowledge representation and development of knowledge warehousing.

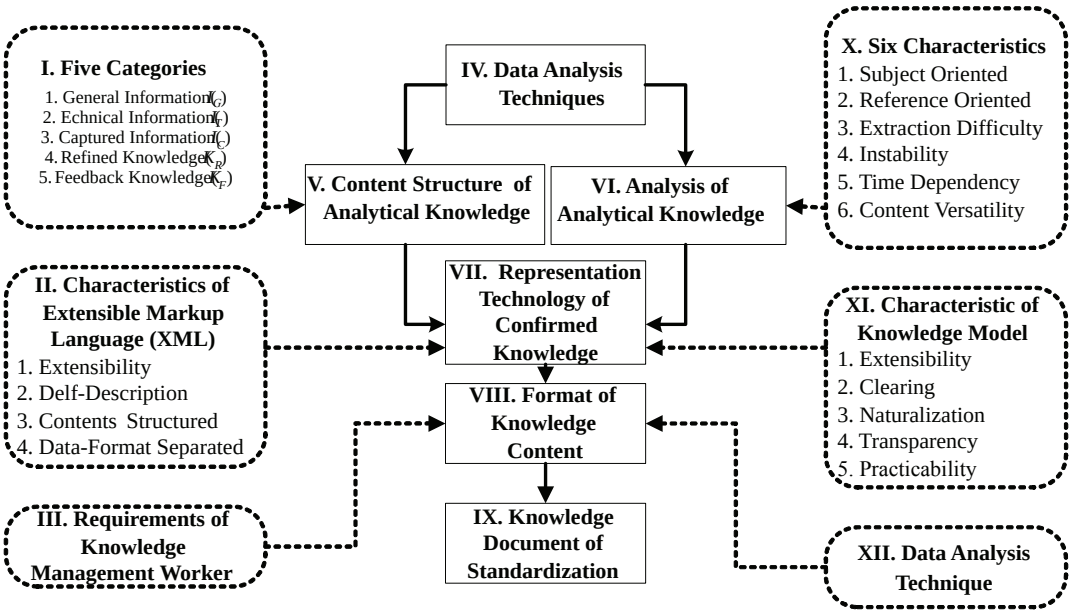
Qualitative Multi-Dimensional Analysis

The multi-dimensional analysis requires numerical data as input entries. This type of quantitative data is critical because it helps the aggregation function to represent the characteristics of data cube and provide rapid access to the entire data warehouse. However, non-numerical data cannot be operated through the multi-dimensional analysis technique. Therefore, this section develops a dynamic solution approach of "qualitative" multidimensional technique for decision-making based on traditional multidimensional techniques and OLAP techniques.

The nature of data classifies two different types of the multi-dimensional analysis. For numerical data, quantitative multi-dimensional analysis (Q-n MA) is used to operate on this type of data. For example, the OLAP fits in this class. For non- numerical data, qualitative multi-dimensional analysis (Q-l MA) is implemented to operate on it. There is not much literature published in the qualitative multi-dimensional analysis area. Contemporary software cannot perform qualitative multi-dimensional analysis effectively due to the lack of commonality of data sharing.

In general, there are two different types of multi-dimensional analysis based on single fact or multiple facts: static and dynamic. The key difference between static and dynamic is that "static" represents merely a fact without taking any variability into consideration while "dynamic" reflects any changes. For example, in the time dimension analysis, emphasizing sales of only one specific month is a "static" status. Modeling the

Figure 4. The flow chart of externalization process of analytical knowledge



sales changes among different months is a "dynamic" analysis. Based on the "static" and "dynamic" status, the operation characteristics of quantitative and qualitative multi-dimensional analysis are as follows:

1. Quantitative static multi-dimensional analysis
   For Q-n MA, the aggregation function embedded in the data cube can be generated. The results of the aggregation function only show the facts under a particular situation. Therefore, it is called "static."
2. Qualitative static multi-dimensional analysis
   The Q-l MA approach operates on non-numerical data. The application of "static" techniques, which shows detailed facts in the data cube, can be observed.
3. Quantitative dynamic multi-dimensional analysis
   In Q-n MA, the dynamic approach should be capable of modeling any input entry changes for the aggregation function from data cubes through a selection of different dimensions and levels. Based on structures of the dimension and level, there are two types of analysis: parallel and vertical analysis. Parallel analysis concentrates on the relationship between elements in the data cube at the same level. Relationship between brothers is an example of this kind of relationship. Vertical analysis emphasizes the relationship in the data cube at different but consecutive levels. In Q-l MA, the dynamic approach includes orthogonal, parallel and vertical analysis.

The orthogonal analysis concentrates on different facts in the same data cube. Because the facts depend on the selection of different dimensions and levels in the cube, the important information could be identified through orthogonal analysis. However the elicited information requires additional analysis through domain experts. Based on dimension and level structures, there are also two different types of analysis: parallel and vertical analysis. Again, "parallel analysis" focuses on the specific level in data cubes and extracts some identical events. Then the events are compared. The "vertical analysis" concentrates on the different but contiguous levels in data cubes. For analytical knowledge, "similarity" or "difference" depends on usage of the data analysis techniques.

Development of Analytical Knowledge Warehouse (AKW)

In this section, analytical knowledge is modeled and stored as a similar way of data warehousing using the

dimensional modeling approach that is one of the best ways to model/store decision support knowledge for data warehouse (Kimball *et al.*, 1998).

The analytical knowledge warehouse stores XML-based analytical knowledge (AK) documents (Li, 2001). Analytical knowledge warehouse emphasizes that "based on data warehouse techniques, the XML-based AK documents can be efficiently and effectively stored and managed." The warehouse helps enterprises carry out the activities in knowledge life cycle and support decision-making in enterprise (Turban and Aronson, 2001).

The purpose of this design is that the knowledge documents can be viewed multi-dimensionally. Dimensional modeling is a logical design technique that seeks to present the data in a standard framework that is intuitive and allows for high-performance access. It is inherently dimensional and adheres to a discipline that uses the relational model with some important restrictions. Every dimensional model is composed of one table with a multipart key, called the fact tables, and a set of smaller tables called dimensional tables. Note that a dimension is a collection of text-like attributes that are highly correlated with each other.

In summary, the goals of analytical knowledge warehouse are to apply the quantitative multi-dimension analysis technique, to explore static and dynamic knowledge, and to support enterprise for decision-making.

FUTURE TRENDS

1. A systematic mechanism to analyze and study the evolution of analytical knowledge over time. For example, mining operations of different types of analytical knowledge evolved could be executed after a particular event (e.g., 911 Event) in order to discover more potential knowledge.
2. Enhancement of maintainability for the well-structured analytical knowledge warehouse. Moreover, revelation of different types of analytical knowledge (e.g., outcomes extracted through the OLAP or AI techniques) is critical and possible solution approaches need to be proposed in further investigation.
3. Application of intelligent agents. Currently, the process of knowledge acquisition is to passively deliver knowledge documents to the user, who requests. If the useful knowledge could be transmitted into the relevant staff members actively, the value of that knowledge can be intensified. It is very difficult to intelligently detect the useful knowledge because the conventional knowledge is not structural. In this research, knowledge has been manipulated through the multi-dimensional analysis technique into analytical knowledge (documents), which is the result of knowledge externalization process. Consequently, if the functionality of intelligent agent can be modeled, then the extracted knowledge can be pushed to desired users automatically. Application of intelligent agent will be a cutting edge approach and the future of application of intelligent agent should be promising.

CONCLUSION

In the chapter, representation of analytical knowledge and system of analytical knowledge warehousing through XML were proposed. Components and structures of the multi-dimensional analysis were introduced. Models of the qualitative multi-dimensional analysis were developed. The proposed approach enhanced the multi-dimensional analysis in terms of apprehending dynamic characteristics and qualitative nature. The qualitative models of the multi-dimensional analysis showed great promise for application in analytical knowledge warehouse. The main contribution of this chapter is that analytical knowledge has been well and structurally defined that could be represented by XML and stored in the AK warehouse. Practically, analytical knowledge not only efficiently facilitates the exploration of useful knowledge but also shows the ability to conduct meaningful knowledge mining on the web for business intelligence.

KEY TERMS

Business Intelligence: Sets of tools and technologies designed to efficiently extract useful information from oceans of data.

Data Analysis Techniques: The technique to analyze data such as data warehouses, OLAP, data mining.

Data Mining: The nontrivial extraction of implicit, previously unknown, and potentially useful information from data and the science of extracting useful information from large data sets or databases.

Data Warehouses: The main repository of an organization's historical data, its corporate memory. It contains the raw material for management's decision support system. The critical factor leading to the use of a data warehouse is that a data analyst can perform complex queries and analysis, such as data mining, on the information without slowing down the operational systems.

Knowledge Management: Manage knowledge in an efficient way through knowledge externalization, sharing, innovation, and socialization.

On-Line Analytical Processing: An approach to quickly providing answers to analytical queries that are multidimensional in nature.

Qualitative Data: The data extremely varied in nature includes virtually any information that can be captured that is not numerical in nature.

Anomaly Detection for Inferring Social Structure

Lisa Friedland
University of Massachusetts Amherst, USA

INTRODUCTION

In traditional data analysis, data points lie in a Cartesian space, and an analyst asks certain questions: (1) What distribution can I fit to the data? (2) Which points are outliers? (3) Are there distinct clusters or substructure? Today, data mining treats richer and richer types of data. Social networks encode information about people and their communities; relational data sets incorporate multiple types of entities and links; and temporal information describes the dynamics of these systems. With such semantically complex data sets, a greater variety of patterns can be described and views constructed of the data.

This article describes a specific social structure that may be present in such data sources and presents a framework for detecting it. The goal is to identify *tribes*, or small groups of individuals that intentionally coordinate their behavior—individuals with enough in common that they are unlikely to be acting independently.

While this task can only be conceived of in a domain of interacting entities, the solution techniques return to the traditional data analysis questions. In order to find hidden structure (3), we use an anomaly detection approach: develop a model to describe the data (1), then identify outliers (2).

BACKGROUND

This article refers throughout to the case study by Friedland and Jensen (2007) that introduced the tribes task. The National Association of Securities Dealers (NASD) regulates the securities industry in the United States. (Since the time of the study, NASD has been renamed the Financial Industry Regulatory Authority.) NASD monitors over 5000 securities firms, overseeing their approximately 170,000 branch offices and 600,000 employees that sell securities to the public. One of NASD's primary activities is to predict and prevent fraud among these employees, called registered representatives, or *reps*. Equipped with data about the reps' past employments, education, and "disclosable events," it must focus its investigatory resources on those reps most likely to engage in risky behavior. Publications by Neville et al. (2005) and Fast et al. (2007) describe the broader fraud detection problem within this data set.

NASD investigators suspect that fraud risk depends on the social structure among reps and their employers. In particular, some cases of fraud appear to be committed by what we have termed *tribes*—groups of reps that move from job to job together over time. They hypothesized such coordinated movement among jobs could be predictive of future risk. To test this theory, we developed an algorithm to detect tribe behavior. The algorithm takes as input the employment dates of each rep at each branch office, and outputs small groups of reps who have been co-workers to a striking, or anomalous, extent.

This task draws upon several themes from data mining and machine learning:

Inferring latent structure in data. The data we observe may be a poor view of a system's underlying processes. It is often useful to reason about objects or categories we believe exist in real life, but that are not explicitly represented in the data. The hidden structures can be inferred (to the best of our ability) as a means to further analyses, or as an end in themselves. To do this, typically one assumes an underlying model of the full system. Then, a method such as the expectation-maximization algorithm recovers the best match between the observed data and the hypothesized unobserved structures. This type of approach is ubiquitous, appearing for instance in mixture models and clustering (MacKay, 2003), and applied to document and topic models (Hofmann, 1999; Steyvers, et al. 2004).

In relational domains, the latent structure most commonly searched for is clusters. Clusters (in graphs) can be described as groups of nodes densely connected by edges. Relational clustering algorithms hypothesize the existence of this underlying structure, then partition the data so as best to reflect the such groups (Newman, 2004; Kubica et al., 2002; Neville & Jensen, 2005). Such methods have analyzed community structures within, for instance, a dolphin social network (Lusseau & Newman, 2004) and within a company using its network of emails (Tyler et al., 2003). Other variations assume some alternative underlying structure. Gibson et al. (1998) use notions of hubs and authorities to reveal communities on the web, while a recent algorithm by Xu et al. (2007) segments data into three types—clusters, outliers, and hub nodes.

For datasets with links that change over time, a variety of algorithms have been developed to infer structure. Two projects are similar to tribe detection in that they search for specific scenarios of malicious activity, albeit in communication logs: Gerdes et al. (2006) look for evidence of chains of command, while Magdon-Ismail et al. (2003) look for hidden groups sending messages via a public forum.

For the tribes task, the underlying assumption is that most individuals act independently in choosing employments and transferring among jobs, but that certain small groups make their decisions jointly. These tribes consist of members who have worked together unusually much in some way. Identifying these unusual groups is an instance of anomaly detection.

Anomaly detection. Anomalies, or outliers, are examples that do not fit a model. In the literature, the term anomaly detection often refers to intrusion detection systems. Commonly, any deviations from normal computer usage patterns, patterns which are perhaps learned from the data as by Teng and Chen (1990), are viewed as signs of potential attacks or security breaches. More generally for anomaly detection, Eskin (2000) presents a mixture model framework in which, given a model (with unknown parameters) describing normal elements, a data set can be partitioned into normal versus anomalous elements. When the goal is fraud detection, anomaly detection approaches are often effective because, unlike supervised learning, they can highlight both rare patterns plus scenarios not seen in training data. Bolton and Hand (2002) review a number of applications and issues in this area.

MAIN FOCUS

As introduced above, the tribe-detection task begins with the assumption that most individuals make choices individually, but that certain small groups display anomalously coordinated behavior. Such groups leave traces that should allow us to recover them within large data sets, even though the data were not collected with them in mind.

In the problem's most general formulation, the input is a bipartite graph, understood as linking individuals to their affiliations. In place of reps working at branches, the data could take the form of students enrolled in classes, animals and the locations where they are sighted, or customers and the music albums they have rated. A tribe of individuals choosing their affiliations in coordination, in these cases, becomes a group enrolling in the same classes, a mother-child pair that travels together, or friends sharing each other's music. Not every tribe will leave a clear signature, but some groups will have sets of affiliations that are striking, either in that a large number of affiliations are shared, or in that the particular combination of affiliations is unusual.

Framework

We describe the algorithm using the concrete example of the NASD study. Each rep is employed at a series of branch offices of the industry's firms. The basic framework consists of three procedures:

1. For every pair of reps, identify which branches the reps share.
2. Assign a similarity score to each pair of reps, based on the branches they have in common.
3. Group the most similar pairs into tribes.

Step 1 is computationally expensive, but straightforward: For each branch, enumerate the pairs of reps who worked there simultaneously. Then for each pair of reps, compile the list of all branches they shared.

The similarity score of Step 2 depends on the choice of model, discussed in the following section. This is the key component determining what kind of groups the algorithm returns.

After each rep pair is assigned a similarity score, the modeler chooses a threshold, keeps only the most highly similar pairs, and creates a graph by placing an

edge between the nodes of each remaining pair. The graph's connected components become the tribes. That is, a tribe begins with a similar pair of reps, and it expands by including all reps highly similar to those already in the tribe.

Models of "Normal"

The similarity score defines how close two reps are, given the set of branches they share. A pair of reps should be considered close if their set of shared jobs is unusual, i.e., shows signs of coordination. In deciding what makes a set of branches unusual, the scoring function implicitly or explicitly defines a model of normal movement.

Some options for similarity functions include:

Count the jobs. The simplest way to score the likelihood of a given set of branches is to count them: A pair of reps with three branches in common receives the score 3. This score can be seen as stemming from a naïve model of how reps choose employments: At each decision point, a rep either picks a new job, choosing among all branches with equal probability, or else stops working. Under this model, any given sequence of *n* jobs is equally likely and is more likely than a sequence of *n+1* jobs.

Measure duration. Another potential scoring function is to measure how long the pair worked together. This score could arise from the following model: Each day, reps independently choose new jobs (which could be the same as their current jobs). Then, the more days a pair spends as co-workers, the larger the deviation from the model.

Evaluate likelihood according to a Markov process. Each branch can be seen as a state in a Markov process, and a rep's job trajectory can be seen as a sequence generated by this process. At each decision point, a rep either picks a new job, choosing among branches according to the transition probabilities, or else stops working.

This Markov model captures the idea that some job transitions are more common than others. For instance, employees of one firm may regularly transfer to another firm in the same city or the same market. Similarly, when a firm is acquired, the employment data records its workforce as "changing jobs" en masse to the new firm, which makes that job change appear popular. A model that accounts for common versus rare job transitions can judge, for instance, that a pair of independent colleagues in Topeka, Kansas (where the number of firms is limited) is more likely to share three jobs by chance, than a pair in New York City is (where there are more firms to choose from); and that both of these are more likely than for an independent pair to share a job in New York City, then a job in Wisconsin, then a job in Arizona.

The Markov model's parameters can be learned using the whole data set. The likelihood of a particular (ordered) sequence of jobs,

$$P(\text{Branch A} \rightarrow \text{Branch B} \rightarrow \text{Branch C} \rightarrow \text{Branch D})$$

is

$$P(\text{start at Branch A}) \cdot P(A \rightarrow B) \cdot P(B \rightarrow C) \cdot P(C \rightarrow D)$$

The branch-branch transition probabilities and starting probabilities are estimated using the number of reps who worked at each branch and the number that left each branch for the next one. Details of this model, including needed modifications to allow for gaps between shared employments, can be found in the original paper (Friedland & Jensen, 2007).

Use any model that estimates a multivariate binary distribution. In the Markov model above, it is crucial that the jobs be temporally ordered: A rep works at one branch, then another. When the data comes from a domain without temporal information, such as customers owning music albums, an alternative model of "normal" is needed. If each rep's set of branch memberships is represented as a vector of 1's (memberships) and 0's (non-memberships), in a high-dimensional binary space, then the problem becomes estimation of the probability density in this space. Then, to score a particular set of branches shared by a pair of reps, the estimator computes the marginal probability of that set. A number of models, such as Markov random fields, may be suitable; determining which perform well, and which dependencies to model, remains ongoing research.

Evaluation

In the NASD data, the input consisted of the complete table of reps and their branch affiliations, both historical and current. Tribes were inferred using three of the models described above: counting jobs (JOBS),

measuring duration (YEARS), and the Markov process (PROB). Because it was impossible to directly verify the tribe relationships, a number of indirect measures were used to validate the resulting groups, as summarized in Table 1.

The first properties evaluate tribes with respect to their rarity and geographic movement (see table lines 1-2). The remaining properties confirm two joint hypotheses: that the algorithm succeeds at detecting the coordinated behavior of interest, and that this behavior is helpful in predicting fraud. Fraud was measured via a risk score, which described the severity of all reported events and infractions in a rep's work history. If tribes contain many reps known to have committed fraud, then they will be useful in predicting future fraud (line 3). And ideally, groups identified as tribes should fall into two categories. First is high-risk tribes, in which all or most of the members have known infractions. (In fact, an individual with a seemingly clean history in a tribe with several high-risk reps would be a prime candidate for future investigation.) But much more common will be the innocuous tribes, the result of harmless sets of friends recruiting each other from job to job. Within ideal tribes, reps are not necessarily high-risk, but they should match each other's risk scores (line 4).

Throughout the evaluations, the JOBS and PROB models performed well, whereas the YEARS model did not. JOBS and PROB selected different sets of tribes, but the tribes were fairly comparable under most evaluation measures: compared to random groups of reps, tribes had rare combinations of jobs, traveled geographically (particularly for PROB), had higher risk scores, and were homogenous. The tribes identified by YEARS poorly matched the desired properties: not only did these reps not commit fraud, but the tribes often consisted of large crowds of people who shared very typical job trajectories.

Informally, JOBS and PROB chose tribes that differed in ways one would expect. JOBS selected some tribes that shared six or more jobs but whose reps appeared to be caught up in a series of firm acquisitions: many other reps also had those same jobs. PROB selected some tribes that shared only three jobs, yet clearly stood out: Of thousands of colleagues at each branch, only this pair had made any of the job transitions in the series. One explanation why PROB did not perform conclusively better is its weakness at small branches. If a pair of reps works together at a two-person branch, then transfers elsewhere together, the model judges this transfer to be utterly unremarkable, because it is what 100% of their colleagues at that branch (i.e., just the two of them) did. For reasons like this, the model seems to miss potential tribes that work at multiple small branches together. Correcting for this situation, and understanding other such effects, remain as future work.

FUTURE TRENDS

One future direction is to explore the utility of the tribe structure to other domains. For instance, an online bookstore could use the tribes algorithm to infer book clubs—individuals that order the same books at the same times. More generally, customers with unusually similar tastes might want to be introduced; the similarity scores could become a basis for matchmaking on

Table 1. Desirable properties of tribes

Property	Why this is desirable
Tribes share rare combinations of jobs.	An ideal tribe should be fairly unique in its job-hopping behavior.
Tribes are more likely to traverse multiple zip codes.	Groups that travel long distances together are unlikely to be doing so by chance.
Tribes have much higher risk scores than average.	If fraud does tend to occur in tribe-like structures, then on average, reps in tribes should have worse histories.
Tribes are homogenous: reps in a tribe have similar risk scores.	Each tribe should either be innocuous or high-risk.

dating websites, or for connecting researchers who read or publish similar papers. In animal biology, there is a closely related problem of determining family ties, based on which animals repeatedly appear together in herds (Cairns & Schwager, 1987). These "association patterns" might benefit from being formulated as tribes, or even vice versa.

Work to evaluate other choices of scoring models, particularly those that can describe affiliation patterns in non-temporal domains, is ongoing. Additional research will expand our understanding of tribe detection by examining performance across different domains and by comparing properties of the different models, such as tractability and simplicity.

CONCLUSION

The domains discussed here (stock brokers, online customers, etc.) are rich in that they report the interactions of multiple entity types over time. They embed signatures of countless not-yet-formulated behaviors in addition to those demonstrated by tribes.

The tribes framework may serve as a guide to detecting any new behavior that a modeler describes. Key aspects of this approach include searching for occurrences of the pattern, developing a model to describe "normal" or chance occurrences, and marking outliers as entities of interest.

The compelling motivation behind identifying tribes or similar patterns is in detecting hidden, but very real, relationships. For the most part, individuals in large data sets appear to behave independently, subject to forces that affect everyone in their community. However, in certain cases, there is enough information to rule out independence and to highlight coordinated behavior.

KEY TERMS

Anomaly Detection: Discovering anomalies, or outliers, in data.

Branch: In the NASD schema, a branch is the smallest organizational unit recorded: every firm has one or more branch offices.

Branch Transition: The NASD study examined patterns of job changes. If employees who work at Branch A often work at Branch B next, we say the (branch) transition between Branches A and B is common.

Latent Structure: In data, a structure or pattern that is not explicit. Recovering such structures can make data more understandable, and can be a first step in further analyses.

Markov Process: Model that stochastically chooses a sequence of states. The probability of selecting any state depends only on the previous state.

Registered Representative (rep): Term for individual in the NASD data.

Tribe: Small group of individuals acting in a coordinated manner, e.g., moving from job to job together.

The Application of Data-Mining to Recommender Systems

J. Ben Schafer
University of Northern Iowa, USA

INTRODUCTION

In a world where the number of choices can be overwhelming, recommender systems help users find and evaluate items of interest. They connect users with items to "consume" (purchase, view, listen to, etc.) by associating the content of recommended items or the opinions of other individuals with the consuming user's actions or opinions. Such systems have become powerful tools in domains from electronic commerce to digital libraries and knowledge management. For example, a consumer of just about any major online retailer who expresses an interest in an item – either through viewing a product description or by placing the item in his "shopping cart" – will likely receive recommendations for additional products. These products can be recommended based on the top overall sellers on a site, on the demographics of the consumer, or on an analysis of the past buying behavior of the consumer as a prediction for future buying behavior. This paper will address the technology used to generate recommendations, focusing on the application of data mining techniques.

BACKGROUND

Many different algorithmic approaches have been applied to the basic problem of making accurate and efficient recommender systems. The earliest "recommender systems" were content filtering systems designed to fight information overload in textual domains. These were often based on traditional information filtering and information retrieval systems. Recommender systems that incorporate information retrieval methods are frequently used to satisfy ephemeral needs (short-lived, often one-time needs) from relatively static databases. For example, requesting a recommendation for a book preparing a sibling for a new child in the family. Conversely, recommender systems that incorporate information-filtering methods are frequently used to satisfy persistent information (long-lived, often frequent, and specific) needs from relatively stable databases in domains with a rapid turnover or frequent additions. For example, recommending AP stories to a user concerning the latest news regarding a senator's re-election campaign.

Without computers, a person often receives recommendations by listening to what people around him have to say. If many people in the office state that they enjoyed a particular movie, or if someone he tends to agree with suggests a given book, then he may treat these as recommendations. Collaborative filtering (CF) is an attempt to facilitate this process of "word of mouth." The simplest of CF systems provide generalized recommendations by aggregating the evaluations of the community at large. More personalized systems (Resnick & Varian, 1997) employ techniques such as user-to-user correlations or a nearest-neighbor algorithm.

The application of user-to-user correlations derives from statistics, where correlations between variables are used to measure the usefulness of a model. In recommender systems correlations are used to measure the extent of agreement between two users (Breese, Heckerman, & Kadie, 1998) and used to identify users whose ratings will contain high predictive value for a given user. Care must be taken, however, to identify correlations that are actually helpful. Users who have only one or two rated items in common should not be treated as strongly correlated. Herlocker et al. (1999) improved system accuracy by applying a significance weight to the correlation based on the number of co-rated items.

Nearest-neighbor algorithms compute the distance between users based on their preference history. Distances vary greatly based on domain, number of users, number of recommended items, and degree of co-rating between users. Predictions of how much a user will like an item are computed by taking the weighted average

of the opinions of a set of neighbors for that item. As applied in recommender systems, neighbors are often generated online on a query-by-query basis rather than through the off-line construction of a more thorough model. As such, they have the advantage of being able to rapidly incorporate the most up-to-date information, but the search for neighbors is slow in large databases. Practical algorithms use heuristics to search for good neighbors and may use opportunistic sampling when faced with large populations.

Both nearest-neighbor and correlation-based recommenders provide a high level of personalization in their recommendations, and most early systems using these techniques showed promising accuracy rates. As such, CF-based systems have continued to be popular in recommender applications and have provided the benchmarks upon which more recent applications have been compared.

DATA MINING IN RECOMMENDER APPLICATIONS

The term data mining refers to a broad spectrum of mathematical modeling techniques and software tools that are used to find patterns in data and user these to build models. In this context of recommender applications, the term data mining is used to describe the collection of analysis techniques used to infer recommendation rules or build recommendation models from large data sets. Recommender systems that incorporate data mining techniques make their recommendations using knowledge learned from the actions and attributes of users. These systems are often based on the development of user profiles that can be persistent (based on demographic or item "consumption" history data), ephemeral (based on the actions during the current session), or both. These algorithms include clustering, classification techniques, the generation of association rules, and the production of similarity graphs through techniques such as Horting.

Clustering techniques work by identifying groups of consumers who appear to have similar preferences. Once the clusters are created, averaging the opinions of the other consumers in her cluster can be used to make predictions for an individual. Some clustering techniques represent each user with partial participation in several clusters. The prediction is then an average across the clusters, weighted by degree of participation. Clustering techniques usually produce less-personal recommendations than other methods, and in some cases, the clusters have worse accuracy than CF-based algorithms (Breese, Heckerman, & Kadie, 1998). Once the clustering is complete, however, performance can be very good, since the size of the group that must be analyzed is much smaller. Clustering techniques can also be applied as a "first step" for shrinking the candidate set in a CF-based algorithm or for distributing neighbor computations across several recommender engines. While dividing the population into clusters may hurt the accuracy of recommendations to users near the fringes of their assigned cluster, pre-clustering may be a worthwhile trade-off between accuracy and throughput.

Classifiers are general computational models for assigning a category to an input. The inputs may be vectors of features for the items being classified or data about relationships among the items. The category is a domain-specific classification such as malignant/benign for tumor classification, approve/reject for credit requests, or intruder/authorized for security checks. One way to build a recommender system using a classifier is to use information about a product and a customer as the input, and to have the output category represent how strongly to recommend the product to the customer. Classifiers may be implemented using many different machine-learning strategies including rule induction, neural networks, and Bayesian networks. In each case, the classifier is trained using a training set in which ground truth classifications are available. It can then be applied to classify new items for which the ground truths are not available. If subsequent ground truths become available, the classifier may be retrained over time.

For example, Bayesian networks create a model based on a training set with a decision tree at each node and edges representing user information. The model can be built off-line over a matter of hours or days. The resulting model is very small, very fast, and essentially as accurate as CF methods (Breese, Heckerman, & Kadie, 1998). Bayesian networks may prove practical for environments in which knowledge of consumer preferences changes slowly with respect to the time needed to build the model but are not suitable for environments in which consumer preference models must be updated rapidly or frequently.

Classifiers have been quite successful in a variety of domains ranging from the identification of fraud

and credit risks in financial transactions to medical diagnosis to intrusion detection. Good et al. (1999) implemented induction-learned feature-vector classification of movies and compared the classification with CF recommendations; this study found that the classifiers did not perform as well as CF, but that combining the two added value over CF alone.

One of the best-known examples of data mining in recommender systems is the discovery of association rules, or item-to-item correlations (Sarwar et. al., 2001). These techniques identify items frequently found in "association" with items in which a user has expressed interest. Association may be based on co-purchase data, preference by common users, or other measures. In its simplest implementation, item-to-item correlation can be used to identify "matching items" for a single item, such as other clothing items that are commonly purchased with a pair of pants. More powerful systems match an entire set of items, such as those in a customer's shopping cart, to identify appropriate items to recommend. These rules can also help a merchandiser arrange products so that, for example, a consumer purchasing a child's handheld video game sees batteries nearby. More sophisticated temporal data mining may suggest that a consumer who buys the video game today is likely to buy a pair of earplugs in the next month.

Item-to-item correlation recommender applications usually use current interest rather than long-term customer history, which makes them particularly well suited for ephemeral needs such as recommending gifts or locating documents on a topic of short lived interest. A user merely needs to identify one or more "starter" items to elicit recommendations tailored to the present rather than the past.

Association rules have been used for many years in merchandising, both to analyze patterns of preference across products, and to recommend products to consumers based on other products they have selected. An association rule expresses the relationship that one product is often purchased along with other products. The number of possible association rules grows exponentially with the number of products in a rule, but constraints on confidence and support, combined with algorithms that build association rules with itemsets of n items from rules with n-1 item itemsets, reduce the effective search space. Association rules can form a very compact representation of preference data that may improve efficiency of storage as well as performance. They are more commonly used for larger populations rather than for individual consumers, and they, like other learning methods that first build and then apply models, are less suitable for applications where knowledge of preferences changes rapidly. Association rules have been particularly successfully in broad applications such as shelf layout in retail stores. By contrast, recommender systems based on CF techniques are easier to implement for personal recommendation in a domain where consumer opinions are frequently added, such as online retail.

In addition to use in commerce, association rules have become powerful tools in recommendation applications in the domain of knowledge management. Such systems attempt to predict which Web page or document can be most useful to a user. As Géry (2003) writes, "The problem of finding Web pages visited together is similar to finding associations among itemsets in transaction databases. Once transactions have been identified, each of them could represent a basket, and each web resource an item." Systems built on this approach have been demonstrated to produce both high accuracy and precision in the coverage of documents recommended (Geyer-Schultz et al., 2002).

Horting is a graph-based technique in which nodes are users, and edges between nodes indicate degree of similarity between two users (Wolf et al., 1999). Predictions are produced by walking the graph to nearby nodes and combining the opinions of the nearby users. Horting differs from collaborative filtering as the graph may be walked through other consumers who have not rated the product in question, thus exploring transitive relationships that traditional CF algorithms do not consider. In one study using synthetic data, Horting produced better predictions than a CF-based algorithm (Wolf et al., 1999).

FUTURE TRENDS

As data mining algorithms have been tested and validated in their application to recommender systems, a variety of promising applications have evolved. In this section we will consider three of these applications – meta-recommenders, social data mining systems, and temporal systems that recommend when rather than what.

Meta-recommenders are systems that allow users to personalize the merging of recommendations from

a variety of recommendation sources employing any number of recommendation techniques. In doing so, these systems let users take advantage of the strengths of each different recommendation method. The SmartPad supermarket product recommender system (Lawrence et al., 2001) suggests new or previously unpurchased products to shoppers creating shopping lists on a personal digital assistant (PDA). The SmartPad system considers a consumer's purchases across a store's product taxonomy. Recommendations of product subclasses are based upon a combination of class and subclass associations drawn from information filtering and co-purchase rules drawn from data mining. Product rankings within a product subclass are based upon the products' sales rankings within the user's consumer cluster, a less personalized variation of collaborative filtering. MetaLens (Schafer et al., 2002) allows users to blend content requirements with personality profiles to allow users to determine which movie they should see. It does so by merging more persistent and personalized recommendations, with ephemeral content needs such as the lack of offensive content or the need to be home by a certain time. More importantly, it allows the user to customize the process by weighting the importance of each individual recommendation.

While a traditional CF-based recommender typically requires users to provide explicit feedback, a social data mining system attempts to mine the social activity records of a community of users to implicitly extract the importance of individuals and documents. Such activity may include Usenet messages, system usage history, citations, or hyperlinks. TopicShop (Amento et al., 2003) is an information workspace which allows groups of common Web sites to be explored, organized into user defined collections, manipulated to extract and order common features, and annotated by one or more users. These actions on their own may not be of large interest, but the collection of these actions can be mined by TopicShop and redistributed to other users to suggest sites of general and personal interest. Agrawal et al. (2003) explored the threads of newsgroups to identify the relationships between community members. Interestingly, they concluded that due to the nature of newsgroup postings – users are more likely to respond to those with whom they disagree – "links" between users are more likely to suggest that users should be placed in differing partitions rather than the same partition. Although this technique has not been directly applied to the construction of recommendations, such an application seems a logical field of future study.

Although traditional recommenders suggest what item a user should consume they have tended to ignore changes over time. Temporal recommenders apply data mining techniques to suggest when a recommendation should be made or when a user should consume an item. Adomavicius and Tuzhilin (2001) suggest the construction of a recommendation warehouse, which stores ratings in a hypercube. This multidimensional structure can store data on not only the traditional user and item axes, but also for additional profile dimensions such as time. Through this approach, queries can be expanded from the traditional "what items should we suggest to user X" to "at what times would user X be most receptive to recommendations for product Y." Hamlet (Etzioni et al., 2003) is designed to minimize the purchase price of airplane tickets. Hamlet combines the results from time series analysis, Q-learning, and the Ripper algorithm to create a multi-strategy data-mining algorithm. By watching for trends in airline pricing and suggesting when a ticket should be purchased, Hamlet was able to save the average user 23.8% when savings was possible.

CONCLUSION

Recommender systems have emerged as powerful tools for helping users find and evaluate items of interest. These systems use a variety of techniques to help users identify the items that best fit their tastes or needs. While popular CF-based algorithms continue to produce meaningful, personalized results in a variety of domains, data mining techniques are increasingly being used in both hybrid systems, to improve recommendations in previously successful applications, and in stand-alone recommenders, to produce accurate recommendations in previously challenging domains. The use of data mining algorithms has also changed the types of recommendations as applications move from recommending what to consume to also recommending when to consume. While recommender systems may have started as largely a passing novelty, they clearly appear to have moved into a real and powerful tool in a variety of applications, and that data mining algorithms can be and will continue to be an important part of the recommendation process.

KEY TERMS

Association Rules: Used to associate items in a database sharing some relationship (e.g., co-purchase information). Often takes the for "if this, then that," such as, "If the customer buys a handheld videogame then the customer is likely to purchase batteries."

Collaborative Filtering: Selecting content based on the preferences of people with similar interests.

Meta-Recommenders: Provide users with personalized control over the generation of a single recommendation list formed from the combination of rich recommendation data from multiple information sources and recommendation techniques.

Nearest-Neighbor Algorithm: A recommendation algorithm that calculates the distance between users based on the degree of correlations between scores in the users' preference histories. Predictions of how much a user will like an item are computed by taking the weighted average of the opinions of a set of nearest neighbors for that item.

Recommender Systems: Any system that provides a recommendation, prediction, opinion, or user-configured list of items that assists the user in evaluating items.

Social Data-Mining: Analysis and redistribution of information from records of social activity such as newsgroup postings, hyperlinks, or system usage history.

Temporal Recommenders: Recommenders that incorporate time into the recommendation process. Time can be either an input to the recommendation function, or the output of the function.

José Luis Rojo-Álvarez
Universidad Rey Juan Carlos, Spain

INTRODUCTION

In this chapter, we give a survey of applications of the kernel methods introduced in the previous chapter. We focus on different application domains that are particularly active in both direct application of well-known kernel methods, and in new algorithmic developments suited to a particular problem. In particular, we consider the following application fields: biomedical engineering (comprising both biological signal processing and bioinformatics), communications, signal, speech and image processing.

KERNEL METHODS IN BIOMEDICINE AND BIOINFORMATICS

Kernel methods have been extensively used to solve biomedical problems. For instance, a study of prediction of cyclosporine dosage in patients after kidney transplantation using neural networks and kernel-based methods was carried out in (Camps-Valls et al., 2002). Recently, (Osowski, Hoai, & Markiewicz, 2004) proposed a committee of experts formed by several support vector machines (SVM) for the recognition of 13 heart rhythm types.

The most impressive results of kernels have been obtained in genomics and computational biology, due to both the special characteristics of data and the great interest in solving biological problems since the Human genome sequencing. Their ability to work with high dimensional data, to process and efficiently integrate non-vectorial string data, make them very suitable to solve various problems arising in computational biology. Since the early papers using SVM in bioinformatics (Mukherjee et al., 1998), the applications of these methods have grown exponentially, and many novel and powerful methods have been developed (only in 2004, more than 1000 papers have been devoted to this topic). The use of kernel methods in computational biology has been accompanied by new developments to match the specificities and the needs of the field, such as methods for *feature selection* in combination with the classification of high-dimensional data, the introduction of *string kernels* to process biological sequences, or the development of methods to *learn from several kernels simultaneously* ('composite kernels'). The interested reader can find a comprehensive introduction in (Vert, 2006).

KERNEL METHODS IN COMMUNICATIONS

There are four situations that make kernel methods good candidates for use in electromagnetics (Martínez-Ramon, 2006): 1) No close solutions exist, and the only approaches are trial and error methods. In these cases, kernel algorithms can be employed to solve the problem. 2) The application requires operating in real time, and the computation time is limited. In these cases, a kernel algorithm can be trained off-line, and used in test mode in real time. The algorithms can be embedded in any hardware device. 3) Faster convergence rates and smaller errors are required. Kernel algorithms have shown superior performance in generalization ability in many problems. Also, the block optimization and the uniqueness of solutions make kernelized versions of linear algorithms (as SVM) faster than many other methods. 4) Enough measured data exist to train a

regression algorithm for prediction and no analytical tools exist. In this case, one can actually use an SVM to solve the part of the problem where no analytical solution exist and combine the solution with other existing analytical and closed form solutions.

The use of kernelized SVMs has been already proposed to solve a variety of digital communications problems. The decision feedback equalizer (Sebald & Buclew, 2000) and the adaptive multi-user detector for Code Division Multiple Access (CDMA) signals in multipath channels (Chen et al., 2001) are addressed by means of binary SVM nonlinear classifiers. In (Rahman et al., 2004) signal equalization and detection for a MultiCarrier (MC)-CDMA system is based on an SVM linear classification algorithm. Koutsogiannis et al. (2002) introduced the use of KPCA for classification and de-noising of communication signals.

KERNEL METHODS IN SIGNAL PROCESSING

Many signal processing supervised and unsupervised schemes such as discriminant analysis, clustering, principal/independent component analysis, or mutual information extraction have been addressed using kernels (see previous chapters). Also, an interesting perspective for signal processing using SVM can be found in (Mattera, 2005), which relies on a different point of view to signal processing.

The use of time series with supervised SVM algorithms has mainly focused on two DSP problems: (1) non-linear system identification of the underlying relationship between two simultaneously recorded discrete-time processes, and (2) time series prediction (Drezet and Harrison 1998; Gretton et al., 2001; Suykens, 2001). In both of them, the conventional SVR considers lagged and buffered samples of the available signals as its input vectors.

These approaches pose several problems and opportunities. First, the statement of linear signal models in the primal problem, which will be called *SVM primal signal models*, will allow us to obtain robust estimators of the model coefficients (Rojo-Álvarez et al., 2005a) in classical DSP problems, such as ARMA modeling, the γ-filter, and spectral analysis (Rojo-Álvarez et al., 2003, Camps-Valls et al., 2004, Rojo-Álvarez et al., 2004). Second, the consideration of nonlinear SVM-DSP algorithms can be addressed from two different approaches: (1) *RKHS signal models*, which state the signal model equation in the feature space (Martínez-Ramón et al., 2005), and (2) *dual signal models*, which are based on the nonlinear regression of each single time instant with appropriate Mercer's kernels (Rojo-Álvarez et al., 2005b).

KERNEL METHODS IN SPEECH PROCESSING

An interesting and active research field is that of speech recognition and speaker verification. First, there have been many attempts to apply SVMs to improve existing speech recognition systems. Ganapathiraju (2002) uses SVMs to estimate Hidden Markov Models state likelihoods, Venkataramani et al. (2003) applied SVMs to refine the decoding search space, and in (Gales and Layton, 2004) statistical models for large vocabulary continuous speech recognition were trained using SVMs. Second, early SVM approaches by Schmidt and Gish (1996), and then by Wan and Campbell (2000), used polynomial and RBF kernels to model the distribution of cepstral input vectors. Further improvements considered mapping to *feature space* using sequence kernels (Fine et al. 2001). In the case of speaker verification, the recent works of Shriberg et al. (2005) for processing high-level stylistic or lexical features are worth mentioning.

Voice processing has been performed by using KPCA. Lima et al. (2005) used sparse KPCA for voice feature extraction and then used them for speech recognition. Mak et al. (2005) used KPCA to introduce speaker adaptation in voice recognition schemes.

KERNEL METHODS IN IMAGE PROCESSING

One of the first works proposing kernel methods in the context of image processing was (Osuna *et al.*, 1997), where a face detection system was proposed. Also, in (Papagiorgiou & Poggio, 2000) a face, pedestrian, and car detection method based on SVMs and Haar wavelets to represent images was presented.

The previous global approaches demonstrated good results for detecting objects under fixed viewing conditions. However, problems occur when the viewpoint and pose vary. Different methods have been built to

tackle these problems. For instance, the *component-based* approach (Heisele *et al.*, 2001) alleviates this face detection problem. Nevertheless, the main issues in this context are related to: the inclusion of geometric relationships between components, which were partially addressed in (Mohan *et al.*, 2001) using a two-level strategy; and automatically choose components, which was improved in (Heisele *et al.*, 2002) based on the incorporation of 3D synthetic face models database. Alternative approaches, completely automatic, have been later proposed in the literature (Ullman *et al.* 2002), and kernel direct discriminate analysis (KDDA) was used by Lu et al (2006) for face recognition.

Liu et al. (2004) used KICA to model face appearance, showing that the method is robust with respect to illumination, expression and pose variations. Zheng et al. (2006) used KKCA for facial expression recognition. Another application is *object recognition*. In the special case where the objects are human faces, it opens to *face recognition*, an extremely lively research field, with applications to video surveillance and security (see http://www.face-rec.org/). For instance, (Pontil & Verri, 1998) identified objects in the COIL database (http://www1.cs.columbia.edu/CAVE/). Vaswani et al. (2006) use KPCA for image and video classification. Texture classification using kernel independent component analysis has been, for example, used by Cheng et al. (2004), and KPCA, KCCA and SVM are compared in Horikawa (2005). Finally, it is worth mentioning the *matching kernel* (Wallraven *et al.*, 2003), which uses local image descriptors; a *modified local kernel* (Boughorbel, 2005), or the *pyramid local descriptions* (Grauman & Darrell, 2005).

Kernel methods have been used in multi-dimensional images, i.e. those acquired in (relatively high) number N of spectral bands acquired from airborne or satellite sensors. Support Vector Machines (SVMs) were first applied to hyperspectral image classification in (Gualtieri & Cromp, 1998) and their capabilities were further analyzed in (Camps-Valls et al., 2004) in terms of stability, robustness to noise, and accuracy. Some other kernel methods have been recently presented to improve classification, such as the kernel Fisher discriminant (KFD) analysis (Dundar & Langrebe, 2004), or Support Vector Clustering (SVC) (Song, Cherian, & Fan, 2005). In (Camps-Valls & Bruzzone, 2005), an extensive comparison of kernel-based classifiers was conducted in terms of the accuracy of methods when working in noisy environments, high input dimension, and limited training sets. Finally, a full family of *composite kernels* for efficient combination of spatial and spectral information in the scene has been presented in (Camps-Valls, 2006).

Classification of functional magnetic resonance images (fMRI) is a novel technique that may lead to a quantity of discovery tools in neuroscience. Classification in this domain is intended to automatically identify differences in distributed neural substrates resulting from cognitive tasks. The application of kernel methods has given reasonable results in accuracy and generalization ability. Recent work by Cox and Savoy (Cox and Savoy, 2003) demonstrated that linear discriminant analysis (LDA) and support vector machines (SVM) allow discrimination of 10 class visual activation patterns evoked by the visual presentation of various categories of objects on a trial-by-trial basis within individual subjects. LaConte et al., (2005) used a linear SVM for online pattern recognition of left and right motor activation in single subjects. Wang et al (Wang et al., 2004) applied an SVM classifier to detect brain cognitive states across multiple subjects. In (Martínez-Ramón et al., 2005a), a work has been presented that splits the activation maps into areas, applying a local (or base) classifier to each one. In (Koltchinskii et al, 2005), theoretical bounds on the performance of the method for the binary case have been presented, and in (Martínez-Ramón et al, 2006), a distributed boosting takes advantage of the fact that the distribution of the information in the brain is sparse.

FUTURE TRENDS

Kernel methods have been applied in bioinformatics, signal and speech processing, and communications, but there are many areas of science and engineering in which these techniques have not been applied, namely the emerging techniques of chemical sensing (such as olfaction), forecasting, remote sensing, and many others. Our prediction is that, provided that kernel methods are systematically showing improved results over other techniques, these methods will be applied in a growing amount of engineering areas, as long as to an increasing amount of activity in the areas surveyed in this chapter.

CONCLUSION

This chapter has revised the main applications encountered in the active field of machine learning known as kernel methods. This well-established field has emerged very useful in many application domains, mainly due to the versatility of the provided solutions, the possibility to adapt the method to the application field, the mathematical elegance and many practical properties. The interested reader can find more information on these application domains in (Camps-Valls, 2006), where a suite of applications and novel kernel developments are provided. The application and development of kernel methods to new fields and also the challenging questions answered so far ensure exciting results in the near future.

KEY TERMS

Bioinformatics: This is the application of informatics to analysis of experimental data and simulation of biological systems.

Biomedicine: This refers to the application of engineering to the medicine. It involves the design of medical equipment, prosthesis, and systems and algorithms for diagnose and therapy.

Communications: Communication is the act of sending a message to one or more receivers. In this context, we use the word communication to refer to the technologies and theory of telecommunications engineering.

Composite Kernels: A composite kernel (see chapter 1 for a definition of kernel) is a linear combination of several Mercer kernels $K_i(\mathbf{x}_i,\mathbf{x}_j)$ of the form

$$K\left(\mathbf{x}_i,\mathbf{x}_j\right)=\sum_{i=1}^{L} a_i K_i\left(\mathbf{x}_i,\mathbf{x}_j\right)$$

For the composite kernel to be a Mercer kernel, it needs to be semi definite positive. A sufficient condition for a linear combination of Mercer kernels to be a valid Mercer kernel is simply $a_i \geq 0$.

Image Processing: This term refers to any manipulation of digital images in order to compress/decompress, transfer it through a communications channel or alter its properties, such as color, textures, definition, etc. More interestingly, image processing includes all techniques used in order to obtain information embedded in a digital image or a sequence of digital images, for example, detection and classification of objects or events into a sequence of images.

Kernel Methods: A shortened name for Kernel-based learning methods (see previous chapter for an introduction to kernel methods). Kernel methods include all machine learning algorithms that are intrinsically linear but, through a nonlinear transformation of the input data into a highly dimensional Hilbert space, present nonlinear properties from the point of view of the input data. The Hilbert space must be provided with an inner product that can be expressed as a function of the input data itself, thus avoiding the explicit use of vectors in these spaces. Such an inner product satisfies the so called Mercer conditions and is called a Mercer Kernel.

Signal Processing: It is the analysis, interpretation and manipulation of signals. Usually, one calls signal to a set of data that has been collected sequentially and thus it has temporal properties. Signal processing includes, among others, storage, reconstruction, detection of information in presence of noise, interferences or distortion, compression, encoding, decoding and many other processing techniques that may involve machine learning.

Speech Processing: Signal processing of speech signals. An important group of speech processing techniques are those devoted to speech communications. Here, the processing includes analog to digital and digital to analog conversions, and compression/decompression algorithms that usually use speech modeling through autoregressive models of small voice frames, exploiting their local stationarity properties. Another important block of techniques is the speech recognition, which involves machine learning techniques. Traditionally, Hidden Markov Models have been used for speech recognition, but recently kernel methods have been used with promising results. Also, there is an intense research in text-to-speech conversion.

Support Vector Machines (SVM): A SVM is a linear learning machine constructed through an algorithm that uses an optimization criterion which is based on the compromise between the training error and the complexity of the resulting learning machine. The optimization criterion for classification is

$$L=\frac{1}{2}\|\mathbf{w}\|^2+C\sum_{i=1}^{N}\xi_i$$

subject to

$$y_i\left(\mathbf{w}^T\mathbf{x}_i+b\right)>1-\xi_i$$
$$\xi_i \geq 0$$

where $\mathbf{w}$ are the parameters of the learning machine, $\mathbf{x}_i$ are the training data and y_i are their corresponding labels, and ξ_i are the so called slack variables. The criterion minimizes the training data classification error plus the complexity of the machine through the minimization of the norm of the machine parameters. This is equivalent to maximize the generalization properties of the machine. The resulting parameters are expressed as a linear combination of a subset of the training data (the support vectors). This algorithm is easily extensible to a nonlinear algorithm using the kernel trick, reason for what it is usually considered a kernel method. A similar algorithm is used for regression.

Architecture for Symbolic Object Warehouse

Sandra Elizabeth González Císaro
Universidad Nacional del Centro de la Provincia de Buenos Aires, Argentina

Héctor Oscar Nigro
Universidad Nacional del Centro de la Provincia de Buenos Aires, Argentina

INTRODUCTION

Much information stored in current databases is not always present at necessary different levels of detail or granularity for Decision-Making Processes (DMP). Some organizations have implemented the use of central database - Data Warehouse (DW) - where information performs analysis tasks. This fact depends on the Information Systems (IS) maturity, the type of informational requirements or necessities the organizational structure and business own characteristic.

A further important point is the *intrinsic structure of complex data*; nowadays it is very common to work with complex data, due to syntactic or semantic aspects and the processing type (Darmont et al., 2006). Therefore, we must design systems, which can to maintain data complexity to improve the DMP.

OLAP systems solve the problem of present different aggregation levels and visualization for multidimensional data through cube's paradigm. The classical data analysis techniques (factorial analysis, regression, dispersion, etc.) are applied to individuals (tuples or individuals in transactional databases). The classic analysis objects are not expressive enough to represent tuples, which contain distributions, logic rules, multivaluate attributes, and intervals. Also, they must be able to respect their internal variation and taxonomy maintaining the dualism between individual and class.

Consequently, we need a new data type holding these characteristics. This is just the mathematical concept model introduced by Diday called Symbolic Object (SO). SO allows modeling physic entities or real world concepts. The former are the tuples stored in transactional databases and the latter are high entities obtained from expert's analysis, automatic classification or some particular aggregation taken from analysis units (Bock & Diday, 2000).

The SO concept helps construct the DW and it is an important development for Data Mining (DM): for the manipulation and analysis of aggregated information (Nigro & González Císaro, 2005). According to Calvanese, data integration is a central problem in the design of DWs and Decision Support Systems (Calvanese, 2003; Cali, et al., 2003); we make the architecture for Symbolic Object Warehouse construction with integrative goal. Also, it combines with Data Analysis tasks or DM.

This paper is presented as follows: First, Background: DW concepts are introduced. Second, Main Focus divided into: SOs Basic Concepts, Construing SOs and Architecture. Third, Future Trends, Conclusions, References and Key Terms.

Background

The classical definition given by the theme's pioneer is "a Data Warehouse is a subject-oriented, integrated, time-variant, and non-volatile collection of data in support of management's Decision-Making Process" (Inmon, 1996). The fundamental purpose of a DW is to empower the business staff with information that allows making decisions based on consolidated information. In essence, a DW is in a continuous process of transformation as regards information and business rules; both of them must be considered at design time to assure increase robustness and flexibility of the system.

Extraction, Transformation and Load (ETL) constitute the fundamental process in the DW. It is liable for the extraction of data from several sources, their cleansing, customization and insertion into a DW (Simitsis, et al., 2005). When complex data is involved, this process becomes difficult, because of the integration of different semantics (especially with text data, sound, images, etc) or complex structures. So, it is necessary to include integration functions able to join and to merge them.

Metadata management, in DW construction, helps the user understand the stored contents. Information about the meaning of data elements and the availability of reports are indispensable to successfully use the DW.

The generation and management of metadata serve two purposes (Staudt et al., 1999):

1. To minimize the efforts for development and administration of a DW
2. To improve the extraction from it.

Web Warehouse (WW) is a major topic widely researched and developed (Han & Kamber, 2001), as a result of the increasing and intensive use in e-commerce and e-business applications. WW tools and applications are morphing into enterprise portals and analytical applications are being extended to transactional systems. With the same direction, the audiences for WW have expanded as analytical applications have rapidly moved (indirectly) into the transactional world ERP, SCM and CRM (King, 2000).

Spatial data warehousing (SDW) responds to the need of providing users with a set of operations for easily exploring large amounts of spatial data, as well as for aggregating spatial data into synthetic information most suitable for decision-making (Damiani & Spaccapietra, 2006). Gorawski & Malczok (2004) present a distributed SDW system designed for storing and analyzing a wide range of spatial data. The SDW works with the new data model called cascaded star model that allows efficient storing and analyzes of huge amounts of spatial data.

MAIN FOCUS

SOs Basic Concepts

Formally, a SO is a triple s = (a, R, d) where R is a relation between descriptions, d is a description and "a" is a mapping defined from Ω(discourse universe) in L depending on R and d (Diday, 2003).

According to Gowda's definition: "SOs are extensions of classical data types and they are defined by a logical conjunction of events linking values and variables in which the variables can take one or more values, and all the SOs need not be defined on the same variables" (Gowda, 2004). We consider SOs as a new data type for complex data define algebra at Symbolic Data Analysis.

An SO models an individual or a class maintaining its taxonomy and internal variation. In fact, we can represent a concept by its intentional description, i.e. the necessary attributes to characterize to the studied phenomenon and the description allows distinguishing ones from others.

The key characteristics enumerated by Gowda (2004) that do SO a complex data are:

- All objects of a symbolic data set may not be defined on the same variables.
- Each variable may take more than one value or even an interval of values.
- In complex SOs, the values, which the variables take, may include one or more elementary objects.
- The description of an SO may depend on the existing relations between other objects.
- The descriptor values may have typicality values, which indicate frequency of occurrence, relative likelihood, level of importance of the values, …

There are two main kinds of SOs (Diday & Billard, 2002):

- *Boolean SOs*: The instance of one binary relation between the descriptor of the object and the definition domain, which is defined to have values true or false. If [y (w) R d] = {true, false} is a Boolean SO. Example: s=(pay-mode ∈ {good; regular}), here we are describing an individual/class of customer whose payment mode is good or regular.
- *Modal SOs*: In some situations, we cannot say true or false, we have a degree of belonging, or some linguistic imprecision as always true, often true, fifty-fifty, often false, always false; here we say that the relation is fuzzy. If [y (w) R d] ∈ L = [0,1] is a Modal SO. Example: s=(pay-mode ∈ [(0.25) good; (0.75) regular]), at this point we are describing an individual/class of customer that has payment mode: 0.25 good; 0.75 regular.

The *SO extension* is a function that helps recognize when an individual belongs to the class description or a class fits into a more generic one. In the Boolean case,

the extent of an SO is denoted Ext(s) and defined by the extent of "a", which is: Extent (a) = {w ∈ Ω / a (w) = true}. In the Modal instance, given a threshold α, it is defined by Ext_{α} (s)= $Extent_{\alpha}$ (a)= {w ∈ Ω / a (w) ≥ α}.

It is possible to work with SOs in two ways:

- Induction: We know values of their attributes then we know what class they belong.
- Generalization: We want to form a class from the generalization/specialization process of the values of the attributes of a set of individuals.

There is an important number of methods (Bock et al, 2000) developed to analyze SO, which were implemented in Sodas 1.2 and Sodas 2.5 software through Sodas and Asso projects respectively; whose aim is to analyze official data from Official Statistical Institutions (see ASSO or SODAS Home Page).

The principal advantages in SO use are (Bock & Diday, 2000; Diday, 2003):

- It preserves the confidentiality of the information.
- It supports the initial language in the one that SOs were created.
- It allows the spread of concepts between Databases.
- Being independent from the initial table, they are capable of identifying some individual coincidence described in another table.

As a result of working with higher units called *concepts* necessarily described by more complex data, DM is extended to Knowledge Mining (Diday 2004).

Construing SOs

Now we are going to create SOs, Let's suppose we want to know client's profile grouped by work's activity. How do we model this kind of situations with SOs?

The SOs descriptor must have the following attributes:

1. Continent
2. Age
3. Study Level

Suppose that in our operational databases we have stored the relational Tables 1 and 2.

Notice we take an SO as every value of the variable work activity. The SOs descriptors are written in the same notation used in Bock and Diday's book:

SO-Agriculture(4)=[Study Level={"low"(0.50), "medium"(0.50)}] ∧ [Continent = {"America"(0.5), "Europe"(0.25), "Oceania"(0.25)}] ∧ [Age= [30:42]]].
SO-Manufactures (3) = [Study Level ={"low"(0.33), "medium"(0.33), "high"(0.33)}] ∧ [Continent = {"Asia"(0.33), "Europe"(0.66)}] ∧ [Age= [28:50]]].

Table 1. Customer

#Customer	…	Initial Transaction	Age	Country	Study Level	Work's Activity
041	…	23-May-03	50	Spain	Medium	Manufactures
033	…	25-Jul-03	45	China	High	Manufactures
168	…	30-Jul-03	30	Australia	Low	Agriculture
457	…	2-Jan-04	39	Sudan	High	Services
542	…	12-Feb-04	35	Argentina	Medium	Agriculture
698	…	13-April-04	48	India	High	Services
721	…	22-Aug-04	60	France	High	Services
844	…	15-Sep-04	53	Canada	Medium	Services
987	…	25-Oct-04	42	Italy	Low	Agriculture
1002	…	10-Nov-04	28	Germany	Low	Manufactures
1299	…	28-Dec-04	34	EEUU	Medium	Agriculture

Table 2. Taxonomy

Country	Continent
Spain	Europe
China	Asia
Australia	Oceania
Sudan	Africa
Argentina	America
India	Asia
France	Europe
Canada	America
Italy	Europe
Germany	Europe
EEUU	America

SO-Services (4) [Study Level = {"medium"(0.25), "high"(0.75)}] ∧ [Continent = {"Africa" (0.25), "America"(0.25), "Asia"(0.25), "Europe"(0.25)}] ∧ [Age= [39:60]]].

Now we have second order units representing the concept activity of our clients. The number in brackets is the quantity of individuals belonging to the SO, the variables show the values for the class, for example SO-Manufactures: the variable Study Level shows equal probability. The clients are distributed 33 % in Asia and 66 % in Europe. The age is between 39 and 60 years.

To plan the analysis units or SOs we need:

- Knowledge domain,
- Rules of the business,
- Type of information stored in the operational systems, -organizational structures.

We call the former elements *Background Knowledge*.

Architecture

Figure 1 shows the information flows, information knowledge and the most important tasks covered by this architecture (González Císaro, Nigro & Xodo, 2006). Generally, almost all current DW and DM solutions are based on decoupled architectures. DM tools suppose the data to be already selected, cleaned and transformed. Solutions integrating steps must be addressed.

Figure 2 shows a conceptual architecture to identify the most important modules of the system. A manager is associated to each of them, so that they achieve flexibility (it is simple to add new functions); and the functionality encapsulation in every component helps the design organization and modularization. Thus, we can distinguish:

- System functionalities.
- What component carries out each task
- Information/knowledge workflows.

In the next paragraphs, a briefly explanation of each component functionality is completed.

Intelligent Interface: It is responsible for the connection between the system and the user. We design this component with two *Intelligent Discovery Assistants* (Bernstein et al., 2005); one assists in DW tasks and the other with analysis or DM.

ETL Manager: The user defines the SO descriptor and the system must obtain the data from operational databases and external sources. Two different types loads are assumed:

- Initial a predefined SO descriptor, which models the principal business concepts.
- *Ad hoc* with new SOs, which respond to new informational requirements.

The major sub components of ETL Manager module are:

- **ETL Scheduler**
- **Extraction Engine &Load Engine**
- **Transformation & Clean Engine**

Mining & Layout Manager: It is the core analysis. It shows SOs descriptors and makes all type of graphics. Particularly, graphic subcomponent has to implement Zoom Star graphic (Noirhomme, 2000, 2004), which is the best way to visualize SOs. The main subcomponents are:

- **Mining Scheduler**
- **Method Engine**
- **Method DB**
- **Graphic Manager**
- **Exploration Manager**

Figure 1. Information & knowledge flow

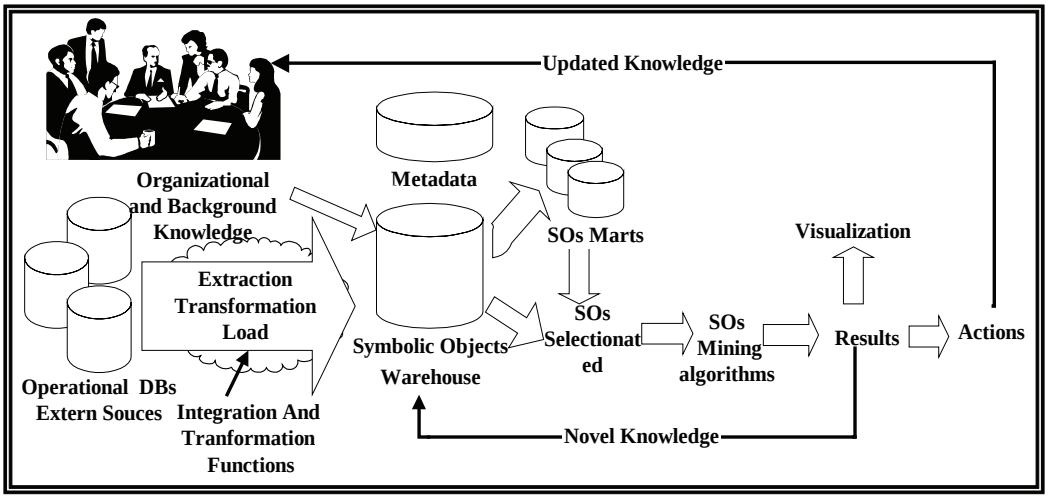

Figure 2. Conceptual architecture

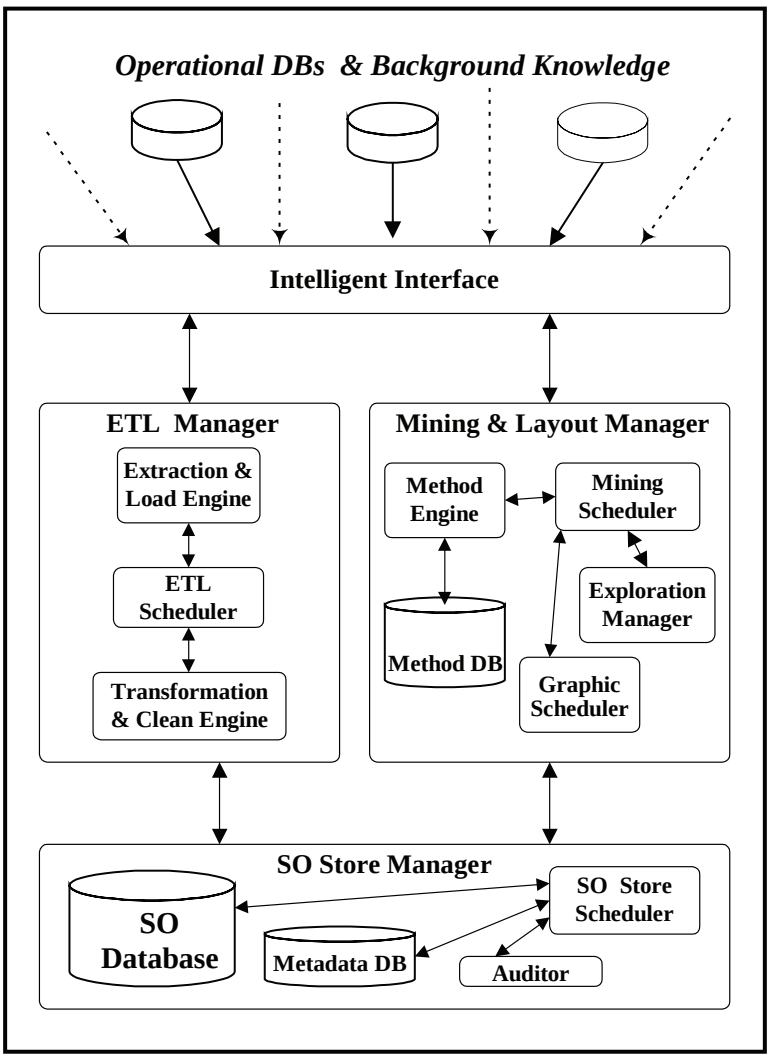

SO Store Manager: It stores the SOs, SOs metadata, does concurrence control, audits and it is safe. Also, the component logs, controls, assigns and changes roles with the users.

Metadata for SOs, as Vardaki (2004) affirms, should describe the symbolic variables, their nature, components and domain. All metadata necessary for Symbolic data creation and processing can be presented as a metadata template or modeled in a separate metadata schema. The advance of the modeling process is that it will indicate not only the metadata items considered and in a structured format, specify their relation and the operators/transformations that can be applied for further manipulations. In this architecture, an independently adopted schema to store metadata about SOs- Metadata DB was adopted.

The SO Store Management has four key subcomponents:

- ***SO & Metadata Scheduler***
- ***SO Database***
- ***Metadata DB***
- ***Auditor***

Future Trends

The next step is the formal specification of the architecture in terms of design. The problems to be resolved are:

- The construction of a language to manipulate SOs.
- How to store SOs since temporary and spatial efficiency is necessary.

Given the functional modularity, an object-oriented implementation would be the most suitable. Another implementation that would be very attractive is through a multi-agents system.

Potential progress in the algorithms that work on SOs will be guided by the techniques to be explored and developed. The most important and useful in DM are: Association Rules, Regressions, Cluster Interpretability and other types of Neuronal Networks.

CONCLUSION

An SO allows representing physics entities or real word concepts in dual form, respecting their internal variations and structure. The SO Warehouse permits the intentional description of most important concepts by means of the initial language users make use of.

The quality control, security and accuracy of information are obtained in SO creation processes, since the null values means are established in this process and the metadata are included (the latter are especially important in DW and the DMP).

One of the most valued advantages in the use of SO is the capacity to carry out various levels of analysis, with which the output of one method is the input of the other. This can be observed in clustering or classification methods, as in most cases the output is a SOs set.

The principal disadvantages arisen by the use of SOs are:

- The complexity in the determination of whom will be the best SOs that will represent the analysis tasks in the organization.
- When to update or to change SOs.

As a result of the flexibility and modularity of its design, our architecture allows an integrated environment of work, with possibilities of improvement and growth. As regards Symbolic Data Analysis, DW & DM integration is very important since it can be very practical to add the discovered knowledge into DW. We discover new potential clients characteristics or relations thus SO descriptors in DW can be updated, creating new SOs. Therefore, the work with higher units like SOs could improve Knowledge Management and Decision-Making Processes.

KEY TERMS

Cascaded Star Model: A main fact table. The main dimensions form smaller star schemas in which some dimension tables may become a fact table for other, nested star schemas.

Customer Relationship Management (CRM): A methodology used to learn more about customers' wishes and behaviors in order to develop stronger relationships with them.

Enterprise Recourse Planning (ERP): A software application that integrates planning, manufacturing, distribution, shipping, and accounting functions into a single system, designed to serve the needs of each different department within the enterprise.

Intelligent Discovery Assistant: Helps data miners with the exploration of the space of valid DM processes. It takes advantage of an explicit ontology of data-mining techniques, which defines the various techniques and their properties. (Bernstein et al, 2005, pp 503-504).

Knowledge Management: An integrated, systematic approach to identifying, codifying, transferring, managing, and sharing all knowledge of an organization.

Supply Chain Management (SCM): The practice of coordinating the flow of goods, services, information and finances as they move from raw materials to parts supplier to manufacturer to wholesaler to retailer to consumer.

Symbolic Data Analysis: A relatively new field that provides a range of methods for analyzing complex datasets. It generalizes classical methods of exploratory, statistical and graphical data analysis to the case of complex data. Symbolic data methods allow the user to build models of the data and make predictions about future events (Diday 2002).

Zoom Star: A graphical representation for SO where each axis correspond to a variable in a radial graph. Thus it allows variables with intervals, multivaluate values, weighted values, logical dependences and taxonomies to be represented. A 2D and 3D representation have been designed allowing different types of analysis.

INTRODUCTION

An association pattern describes how a group of items (for example, retail products) are statistically associated together, and a meaningful association pattern identifies 'interesting' knowledge from data. A well-established association pattern is the *association rule* (Agrawal, Imielinski & Swami, 1993), which describes how *two sets of items* are associated with each other. For example, an association rule *A-->B* tells that 'if customers buy the set of product *A*, they would also buy the set of product *B* with probability greater than or equal to *c*'.

Association rules have been widely accepted for their simplicity and comprehensibility in problem statement, and subsequent modifications have also been made in order to produce more interesting knowledge, see (Brin, Motani, Ullman and Tsur, 1997; Aggarwal and Yu, 1998; Liu, Hsu and Ma, 1999; Bruzzese and Davino, 2001; Barber and Hamilton, 2003; Scheffer, 2005; Li, 2006). A relevant concept is the *rule interest* and excellent discussion can be found in (Shapiro 1991; Tan, Kumar and Srivastava, 2004). Huang et al. recently developed *association bundles* as a new pattern for association analysis (Huang, Krneta, Lin and Wu, 2006). Rather than replacing the association rule, the association bundle provides a distinctive pattern that can present meaningful knowledge not explored by association rules or any of its modifications.

BACKGROUND

Association bundles are important to the field of Association Discovery. The following comparison between association bundles and association rules support this argument. This comparison is made with focus on the association structure.

An *association structure* describes the structural features of an association pattern. It tells how many association relationships are presented by the pattern, and whether these relationships are asymmetric or symmetric, between-set or between-item. For example, an association rule contains one association relationship, and this relationship exists between two sets of item, and it is asymmetric from the rule antecedent to the rule consequent. However, the asymmetric between-set association structure limits the application of association rules in two ways. Firstly, when reasoning based on an association rule, the items in the rule antecedent (or consequent) must be treated as whole -a combined item, not as individual items. One can not reason based on an association rule that a certain individual antecedent item, as one of the many items in rule antecedent, is associated with any or all of the consequent items. Secondly, one must be careful that this association between the rule antecedent and the rule consequent is asymmetric. If the occurrence of the entire set of antecedent items is not deterministically given, for example, the only given information is that a customer has chosen the consequent items, not the antecedent items, it is highly probably that she/he does not chose any of the antecedent items. Therefore, for applications where between-item

symmetric associations are required, for example, cross selling a group of items by discounting on one of them, association rules cannot be applied.

The association bundle is developed to resolve the above problems by considering the symmetric pair-wise between-item association structure. There are multiple association relationships existing in an association bundle - every two bundle-elements are associated with each other, and this between-element association is symmetric – there is no difference between the two associated items in terms of antecedence or consequence. With the symmetric between-element association structure, association bundles can be applied to applications where the asymmetric between-set association rules fail. Association bundles support marketing efforts where the sales improvement is expected on *every element* in a product group. One such example is the shelf management. An association bundle suggests that whenever and whichever an item *i* in the bundle is chosen by customers, every other item *j* in the bundle should possibly be chosen as well, thus items from the same bundle should be put together in the same shelf. Another example is the cross-selling by discounting. Every weekend retailers print on their flyers the discount list, and if two items have strong positive correlation, they should perhaps not be discounted simultaneously. With this reasoning, an association bundle can be used to do list checking, such that only one item in an association bundle will be discounted.

PRINCIPAL IDEAS

Let S be a transaction data set of N records, and I the set of items defining S. The *probability of an item k* is defined as $Pr(k) = |S(k)| / N$, where $|S(k)|$ is the number of records containing the item k. The *joint probability of two items j and k* is defined as $Pr(j,k) = |S(j,k)| / N$, where $|S(j,k)|$ is the number of records containing both j and k. The *conditional probability of the item j with respect to the item k* is defined as $Pr(j|k) = Pr(j) / Pr(j,k)$, and the *lift the item j and k* is defined as $Lift(j,k) = Pr(j,k) / (Pr(j)*Pr(k))$.

Definition. An association bundle is a group of items $b=\{i_1,\ldots,i_m\}$, a subset of I, that any two elements i_j and i_k of b are associated by satisfying that

(i). the lift for i_j and i_k is greater than or equal to a given threshold L, that is,

$Pr(i_j, i_k) / (Pr(i_j) * Pr(i_k)) >= L$;

(ii). both conditional probabilities between i_j and i_k are greater than or equal to a given threshold T, that is,

$$Pr(i_j | i_k) >= T \quad \text{and} \quad Pr(i_k | i_j) >= T.$$

An example is shown in the Figure 1 on association bundles. Figure 1 contains six tables. The first table shows the transaction data set, which is the one that used by Agrawal etc. (Agrawal, et. al., 1994) to illustrate the identification of association rules. The second and the third tables display the between-item conditional probability and lift values, respectively. The forth table displays the item pairs that have the conditional probability and lift values greater than or equal to the given thresholds, these item pairs are associated item pairs by definition. The fifth table shows the identified association bundles. For comparison, we display the association rules in the sixth table. A comparison between the association bundles and the association rules reveals that the item set {2,3,5} is identified as an association rule but not an association bundle. Check the fourth table we can see the item pair {2,3} and the item pair {3,5} actually have the lift values smaller than 1, which implies that they are having negative association with each other.

We further introduce association bundles in the following four aspects—association measure, threshold setting of measure, supporting algorithm, and main properties—via comparisons between association bundles and association rules.

Association Measure

The conditional probability (confidence) is used as the association measure for association rules (Agrawal, Imielinski & Swami, 1993), and later other measures are introduced (Liu, Hsu and Ma, 1999, Omiecinski 2003). Detailed discussions about association measures can be found in (Tan, Kumar and Srivastava, 2004). Association bundles use the between-item lift and the between-item conditional probabilities as the association measures (Huang, Krneta, Lin and Wu, 2006). The between-item lift guarantees that there is strong positive correlation between items: the between-item conditional probabilities ensure that the prediction

of one item with respect to another is accurate enough to be significant.

Threshold Setting of Measure

The value range of the confidence threshold is defined in [0,1] in association rule mining, which is the value range of the conditional probability. In association bundles, the value ranges for threshold are determined by data. More specifically, the between-item lift threshold *L(beta)* and the between-item conditional probability threshold *T(alpha)* are defined, respectively, as,

$$L(beta)=L_A+ beta * (L_M-L_A),\ beta \text{ is in } [0,1],$$
$$T(alpha)=P_A+ alpha * (P_M-P_A),\ alpha \text{ is in } [0,1],$$

where L_A and L_M are the mean and maximum between-item lifts of all item pairs whose between-item lifts are greater than or equal to 1, P_A and P_M are the mean and maximum between-item conditional probabilities of all item pairs; and beta and alpha are defined as the Strength Level Threshold.

Supporting Algorithm

Identifying "frequent itemsets" is the major step of association rule mining, and quite a few excellent algorithms such as the ECLAT (Zaki, 2000), FP-growth (Han, Pei, Yin & Mao, 2004), Charm (Zaki & Hsiao 2002), Closet (Pei, Han & Mao, 2000) have been proposed. The identification of association bundles does not compute ``frequent itemsets", instead, it contains one scan of data for pair-wise item co-occurrence information, and then a "Maximal Clique Enumeration" under a graph model which maps each item into a vertex and each associated item pair into an edge.

Main Properties

Compactness of association: In an association bundle there are multiple association conditions which are imposed pair-wise on bundle items, whereas in an association rule there is only one association condition which is imposed between rule antecedent and rule consequent.

Rare item problem: Different from association rule mining, association bundle identification avoids the rare item problem. The rare item problem (Mannila, 1998) refers to the mining of association rules involving low frequency items. Since lowering the support threshold to involve low frequency items may result that the number of association rules increases in a ``super-exponential" fashion, it is claimed in (Zheng, Kohavi & Mason, 2001) that "no algorithm can handle them". As such, the rare item problem and the relevant computational explosion problem become a dilemma for association rule mining. Some progresses (Han & Fu, 1995; Liu, Hsu & Ma, 1999; Tao, Murtagh & Farid, 2003; Seno & Karypis, 2005) have been made to address this dilemma. Different from association rules, association bundles impose no frequency threshold upon item(s). Therefore in association bundle identification the rare item problem disappeared - rare items can form association bundles as long as they have a strong between-item association.

Large size bundle identification: An association rule cannot have size larger than the maximum transaction size, because the simultaneous co-occurrence condition (the minimum support) is imposed on rule items. Association bundles have no minimum support requirement, thus can have large size.

FUTURE TRENDS

Association bundles have an association structure that presenting meaningful knowledge uncovered by association rules. With the similar structural analysis approach, other structures of interest can also be explored. For example, with respect to the between-set asymmetric association structure (association rules) and the between-item symmetric association structure (association bundles), the between-all-subset symmetric association structure can present a pattern that has the strongest internal association relationships. This pattern may help revealing meaningful knowledge on applications such as fraud detection, in which the fraud is detected via the identification of strongly associated behaviors. As of association bundles, research on any new pattern must be carried out over all related subjects including pattern meaning exploration, association measure design and supporting algorithm development.

CONCLUSION

In this article we describe the notion of Association Bundle Identification. Association bundles were presented by Huang et. al. (Huang, Krneta, Lin & Wu, 2006) as a new pattern of association for data mining. On applications such as the Market Basket Analysis, association bundles can be compared to, but essentially distinguished from the well-established association rules. Association bundles present meaningful and important associations that association rules unable to identify.

We describe association bundles over four aspects - association structure, association measure, threshold setting, and identification algorithms - and try to clarify these ideas via comparisons between association bundles and association rules.

KEY TERMS AND THEIR DEFINITIONS

Association Bundle: Association bundle is a pattern that has the symmetric between-item association structure. It uses between-item lift and between-item conditional probabilities as the association measures. Its algorithm contains one scan of data set and a maximal clique enumeration problem. It can support marketing applications such as the cross-selling group of items by discounting on one of them.

Association Pattern: An association pattern describes how a group of items are statistically associated together. Association rule is an association pattern of how two sets of items are associated with each other, and association bundle is an association pattern of how individual items are pair-wise associated with each other.

Association Rule: Association rule is a pattern that has the asymmetric between-set association structure. It uses support as the rule significance measure, and confidence as the association measure. Its algorithm computes frequent itemsets. It can support marketing applications such as the shopping recommendation based on in-basket items.

Association Structure: Association structure describes the structural features of the relationships in an association pattern, such as how many relationships are contained in a pattern, whether each relationship is asymmetric or symmetric, between-set or between-item.

Asymmetric Between-set Structure: Association rules have the asymmetric between-set association structure, that is, the association relationship in an association rule exists between two sets of item and it is asymmetric from rule antecedent to rule consequent.

Strength Level Threshold: In association bundle identification, the threshold for association measure takes values in a range determined by data, which is different from the fixed range [0,1] used in association rule mining. When linearly mapping this range into [0,1], the transformed threshold is defined as the Strength Level Threshold.

Symmetric Between-item Structure: Association bundle has the symmetric between-item association structure, that is, the association relationship exists between each pair of individual items and is in a symmetric way.

Association Rule Hiding Methods

INTRODUCTION

The enormous expansion of data collection and storage facilities has created an unprecedented increase in the need for data analysis and processing power. *Data mining* has long been the catalyst for automated and sophisticated data analysis and interrogation. Recent advances in data mining and *knowledge discovery* have generated controversial impact in both scientific and technological arenas. On the one hand, data mining is capable of analyzing vast amounts of information within a minimum amount of time, an analysis that has exceeded the expectations of even the most imaginative scientists of the last decade. On the other hand, the excessive processing power of intelligent algorithms which is brought with this new research area puts at risk sensitive and confidential information that resides in large and distributed data stores.

Privacy and security risks arising from the use of data mining techniques have been first investigated in an early paper by O' Leary (1991). Clifton & Marks (1996) were the first to propose possible remedies to the protection of sensitive data and sensitive knowledge from the use of data mining. In particular, they suggested a variety of ways like the use of controlled access to the data, fuzzification of the data, elimination of unnecessary groupings in the data, data augmentation, as well as data auditing. A subsequent paper by Clifton (2000) made concrete early results in the area by demonstrating an interesting approach for privacy protection that relies on sampling. A main result of Clifton's paper was to show how to determine the right sample size of the public data (data to be disclosed to the public where sensitive information has been trimmed off), by estimating at the same time the error that is introduced from the sampling to the significance of the rules. Agrawal and Srikant (2000) were the first to establish a new research area, the *privacy preserving data mining*, which had as its goal to consider privacy and confidentiality issues originating in the mining of the data. The authors proposed an approach known as *data perturbation* that relies on disclosing a modified database with noisy data instead of the original database. The modified database could produce very similar patterns with those of the original database.

BACKGROUND

One of the main problems which have been investigated within the context of privacy preserving data mining is the so-called *association rule hiding*. Association rule hiding builds on the data mining area of *association rule mining* and studies the problem of hiding sensitive association rules from the data. The problem can be formulated as follows.

Let $I = \{i_1, i_2, \ldots, i_n\}$ be a set of binary literals, called items. Let D be a transactional database, where each transaction T contains a set of items (also called an itemset) from I, such that $T \subseteq I$. A unique identifier TID (stands for transaction id) is associated with each transaction. We assume that the items in an itemset are sorted in lexicographic order. An *association rule* is an implication of the form $X \Rightarrow Y$, where $X \subset I$, $Y \subset I$ and $X \cap Y = \varnothing$. We say that a rule $X \Rightarrow Y$ holds in the database D with *confidence* c if $|X \cup Y|/|X| \geq c$ (where $|X|$ is the cardinality of the set X) and *support* s if $|X \cup Y|/N \geq s$, where N is the number of transactions in D. An association rule mining algorithm proceeds by finding all itemsets that appear frequently enough in the database, so that they can be considered interesting, and by deriving from them all proper association rules that are strong (above a lower confidence level) enough. The association rule hiding problem aims at the prevention of a subset of the association rules from being disclosed during mining. We call these rules *sensitive*, and we argue that in order for a rule to become non-sensitive, its support and confidence must be brought below the minimum support and confidence threshold, so that it escapes mining at the corresponding levels of support and confidence. More formally we can state: Given a database D, a set R of rules mined from database D at a pre-specified threshold of support and confidence, and a subset R_h ($R_h \subset R$) of sensitive rules, the association

rule hiding refers to transforming the database D into a database D' of the same degree (same number of items) as D in such a way that only the rules in R-R_h can be mined from D' at either the pre-specified or even higher thresholds. We should note here that in the association rule hiding problem we consider the publishing of a modified database instead of the secure rules because we claim that a modified database will certainly have higher utility to the data holder compared to the set of secure rules. This claim relies on the fact that either a different data mining approach may be applied to the published data, or a different support and confidence threshold may be easily selected by the data miner, if the data itself is published.

It has been proved (Atallah, Bertino, Elmagarmid, Ibrahim, & Verykios, 1999) that the association rule hiding problem which is also referred to as the *database sanitization problem* is NP-hard. Towards the solution of this problem a number of heuristic and exact techniques have been introduced. In the following section we present a thorough analysis of some of the most interesting techniques which have been proposed for the solution of the association rule hiding problem.

MAIN FOCUS

In the following discussion we present three classes of state of the art techniques which have been proposed for the solution of the association rule hiding problem. The first class contains the *perturbation* approaches which rely on heuristics for modifying the database values so that the sensitive knowledge is hidden. The *use of unknowns* for the hiding of rules comprises the second class of techniques to be investigated in this expository study. The third class contains recent sophisticated approaches that provide a new perspective to the association rule hiding problem, as well as a special class of computationally expensive solutions, the *exact solutions*.

Perturbation Approaches

Atallah, Bertino, Elmagarmid, Ibrahim & Verykios (1999) were the first to propose a rigorous solution to the association rule hiding problem. Their approach was based on the idea of preventing disclosure of sensitive rules by decreasing the support of the itemsets generating the sensitive association rules. This reduced hiding approach is also known as frequent itemset hiding. The heuristic employed in their approach traverses the itemset lattice in the space of items from bottom to top in order to identify these items that need to turn from 1 to 0 so that the support of an itemset that corresponds to a sensitive rule becomes lower than the minimum support threshold. The algorithm sorts the sensitive itemsets based on their supports and then it proceeds by hiding all of the sensitive itemsets one by one. A major improvement over the first heuristic algorithm which was proposed in the previous work appeared in the work of Dasseni, Verykios, Elmagarmid & Bertino (2001). The authors extended the existing association rule hiding technique from using only the support of the generating frequent itemsets to using both the support of the generating frequent itemsets and the confidence of the association rules. In that respect, they proposed three new algorithms that exhibited interesting behavior with respect to the characteristics of the hiding process. Verykios, Elmagarmid, Bertino, Saygin & Dasseni (2004) along the same lines of the first work, presented five different algorithms based on various hiding strategies, and they performed an extensive evaluation of these algorithms with respect to different metrics like the execution time, the number of changes in the original data, the number of non-sensitive rules which were hidden (hiding side effects or false rules) and the number of "ghost" rules which were produced after the hiding. Oliveira & Zaiane (2002) extended existing work by focusing on algorithms that solely remove information so that they create a smaller impact in the database by not generating false or ghost rules. In their work they considered two classes of approaches: the pattern restriction based approaches that remove patterns completely from sensitive transactions, and the item restriction based approaches that selectively remove items from sensitive transactions. They also proposed various performance measures for quantifying the fraction of mining patterns which are preserved after sanitization.

Use of Unknowns

A completely different approach to the hiding of sensitive association rules was taken by employing the use of unknowns in the hiding process (Saygin, Verykios & Elmagarmid, 2002, Saygin, Verykios & Clifton, 2001). The goal of the algorithms that incorporate unknowns in the hiding process was to obscure a given

set of sensitive rules by replacing known values by unknowns, while minimizing the side effects on non-sensitive rules. Note here that the use of unknowns needs a high level of sophistication in order to perform equally well as the perturbation approaches that we presented before, although the quality of the datasets after hiding is higher than that in the perturbation approaches since values do not change behind the scene. Although the work presented under this category is in an early stage, the authors do give arguments as to the difficulty of recovering sensitive rules as well as they formulate experiments that test the side effects on non-sensitive rules. Among the new ideas which were proposed in this work, is the modification of the basic notions of support and confidence in order to accommodate for the use of unknowns (think how an unknown value will count during the computation of these two metrics) and the introduction of a new parameter, the *safety margin*, which was employed in order to account for the distance below the support or the confidence threshold that a sensitive rule needs to maintain. Further studies related to the use of unknown values for the hiding of sensitive rules are underway (Wang & Jafari, 2005).

Recent Approaches

The problem of inverse frequent itemset mining was defined by Mielikainen (2003) in order to answer the following research problem: Given a collection of frequent itemsets and their support, find a transactional database such that the new database precisely agrees with the supports of the given frequent itemset collection while the supports of other itemsets would be less than the predetermined threshold. A recent study (Chen, Orlowska & Li, 2004) investigates the problem of using the concept of inverse frequent itemset mining to solve the association rule hiding problem. In particular, the authors start from a database on which they apply association rule mining. After the association rules have been mined and organized into an itemset lattice, the lattice is revised by taking into consideration the sensitive rules. This means that the frequent itemsets that have generated the sensitive rules are forced to become infrequent in the lattice. Given the itemsets that remain frequent in the lattice after the hiding of the sensitive itemsets, the proposed algorithm tries to reconstruct a new database, the mining of which will produce the given frequent itemsets.

Another study (Menon, Sarkar & Mukherjee 2005) was the first to formulate the association rule hiding problem as an integer programming task by taking into account the occurrences of sensitive itemsets in the transactions. The solution of the integer programming problem provides an answer as to the minimum number of transactions that need to be sanitized for each sensitive itemset to become hidden. Based on the integer programming solution, two heuristic approaches are presented for actually identifying the items to be sanitized.

A border based approach along with a hiding algorithm is presented in Sun & Yu (2005). The authors propose the use of the border of frequent itemsets to drive the hiding algorithm. In particular, given a set of sensitive frequent itemsets, they compute the new (revised) border on which the sensitive itemsets have just turned to infrequent. In this way, the hiding algorithm is forced to maintain the itemsets in the revised positive border while is trying to hide those itemsets in the negative border which have moved from frequent to infrequent. A *maxmin* approach (Moustakides & Verykios, 2006) is proposed that relies on the border revision theory by using the maxmin criterion which is a method in decision theory for maximizing the minimum gain. The maxmin approach improves over the basic border based approach both in attaining hiding results of better quality and in achieving much lower execution times. An exact approach (Gkoulalas-Divanis & Verykios 2006) that is also based on the border revision theory relies on an integer programming formulation of the hiding problem that is efficiently solved by using a Binary Integer Programming approach. The important characteristic of the exact solutions is that they do not create any hiding side effects.

Wu, Chiang & Chen (2007) present a limited side effect approach that modifies the original database to hide sensitive rules by decreasing their support or confidence. The proposed approach first classifies all the valid modifications that can affect the sensitive rules, the non-sensitive rules, and the spurious rules. Then, it uses heuristic methods to modify the transactions in an order that increases the number of hidden sensitive rules, while reducing the number of modified entries. Amiri (2007) presents three data sanitization heuristics that demonstrate high data utility at the expense of computational speed. The first heuristic reduces the support of the sensitive itemsets by deleting a set of supporting transactions. The second heuristic modifies, instead of

deleting, the supporting transactions by removing some items until the sensitive itemsets are protected. The third heuristic combines the previous two by using the first approach to identify the sensitive transactions and the second one to remove items from these transactions, until the sensitive knowledge is hidden.

Still another approach (Oliveira, Zaiane & Saygin, 2004) investigates the distribution of non-sensitive rules for security reasons instead of publishing the perturbed database. The proposed approach presents a rule sanitization algorithm for blocking inference channels that may lead to the disclosure of sensitive rules.

FUTURE TRENDS

Many open issues related to the association rule hiding problem are still under investigation. The emergence of sophisticated exact hiding approaches of extremely high complexity, especially for very large databases, causes the consideration of efficient parallel approaches to be employed for the solution of this problem. A lot more work is in need to provide hiding solutions that take advantage of the use of unknowns. More sophisticated techniques need to emerge regarding the solution of the hiding problem by making use of database reconstruction approaches. Ongoing work considers yet another solution which is to append to the original database a synthetically generated database so that the sensitive knowledge is hidden in the combined database which is disclosed to the public.

CONCLUSION

In the information era, privacy comprises one of the most important issues that need to be thoroughly investigated and resolved before data and information can be given to the public to serve different goals. Privacy is not constrained to personally identifiable information, but it can be equally well refer to business information or other forms of knowledge which can be produced from the processing of the data through data mining and knowledge discovery approaches. The problem of association rule hiding has been in the forefront of the privacy preserving data mining area for more than a decade now. Recently proposed approaches have been creating enormous impact in the area while at the same time open the way to new research problems. Although the systematic work all these years have created a lot of research results, there is still a lot of work to be done. Apart from ongoing work in the field we foresee the need of applying these techniques to operational data warehouses so that we can evaluate in a real environment their effectiveness and applicability. We also envision the necessity of applying knowledge hiding techniques to distributed environments where information and knowledge is shared among collaborators and/or competitors.

KEY TERMS

Association Rule Hiding: The process of lowering the interestingness of an association rule in the database by either decreasing the support or the confidence of the rule, while the number of changes and side effects is minimized.

Database Reconstruction: Generation of a database that exhibits certain statistical behavior. Such a database can be used instead of the original database (i.e., be disclosed to the public) with the added value that privacy is not breached.

Data Sanitization: The process of removing sensitive information from the data, so that they can be made public.

Exact Hiding Approaches: Hiding approaches that provide solutions without side effects, if such solutions exist.

Frequent Itemset Hiding: The process of decreasing the support of a frequent itemset in the database by decreasing the support of individual items that appear in this frequent itemset.

Heuristic Hiding Approaches: Hiding approaches that rely on heuristics in order to become more efficient. These approaches usually behave sub-optimally with respect to the side effects that they create.

Inverse Frequent Itemset Mining: Given a set of frequent itemsets along with their supports, the task of the inverse frequent itemset mining problem is to construct the database which produces the specific set of frequent itemsets as output after mining.

Knowledge Hiding: The process of hiding sensitive knowledge in the data. This knowledge can be in a form that can be mined from a data warehouse through a data mining algorithm in a knowledge discovery in databases setting like association rules, a classification or clustering model, a summarization model etc.

Perturbed Database: A hiding algorithm modifies the original database so that sensitive knowledge (itemsets or rules) is hidden. The modified database is known as perturbed database.

Privacy Preserving Data Mining: The subfield of data mining that is investigating various issues related to the privacy of information and knowledge during the mining of the data.

Sensitive Itemset: A security administrator determines the sensitivity level of a frequent itemset. A frequent itemset that is found above a certain sensitivity level is considered as sensitive. Sensitive itemsets need to be protected by hiding techniques.

Association Rule Mining

INTRODUCTION

Association Rule Mining (ARM) is concerned with how items in a transactional database are grouped together. It is commonly known as market basket analysis, because it can be likened to the analysis of items that are frequently put together in a basket by shoppers in a market. From a statistical point of view, it is a semiautomatic technique to discover correlations among a set of variables.

ARM is widely used in myriad applications, including recommender systems (Lawrence, Almasi, Kotlyar, Viveros, & Duri, 2001), promotional bundling (Wang, Zhou, & Han, 2002), Customer Relationship Management (CRM) (Elliott, Scionti, & Page, 2003), and cross-selling (Brijs, Swinnen, Vanhoof, & Wets, 1999). In addition, its concepts have also been integrated into other mining tasks, such as Web usage mining (Woon, Ng, & Lim, 2002), clustering (Yiu & Mamoulis, 2003), outlier detection (Woon, Li, Ng, & Lu, 2003), and classification (Dong & Li, 1999), for improved efficiency and effectiveness.

CRM benefits greatly from ARM as it helps in the understanding of customer behavior (Elliott et al., 2003). Marketing managers can use association rules of products to develop joint marketing campaigns to acquire new customers. The application of ARM for the cross-selling of supermarket products has been successfully attempted in many cases (Brijs et al., 1999). In one particular study involving the personalization of supermarket product recommendations, ARM has been applied with much success (Lawrence et al., 2001). Together with customer segmentation, ARM helped to increase revenue by 1.8%.

In the biology domain, ARM is used to extract novel knowledge on protein-protein interactions (Oyama, Kitano, Satou, & Ito, 2002). It is also successfully applied in gene expression analysis to discover biologically relevant associations between different genes or between different environment conditions (Creighton & Hanash, 2003).

BACKGROUND

Recently, a new class of problems emerged to challenge ARM researchers: Incoming data is streaming in too fast and changing too rapidly in an unordered and unbounded manner. This new phenomenon is termed data stream (Babcock, Babu, Datar, Motwani, & Widom, 2002).

One major area where the data stream phenomenon is prevalent is the World Wide Web (Web). A good example is an online bookstore, where customers can purchase books from all over the world at any time. As a result, its transactional database grows at a fast rate and presents a scalability problem for ARM. Traditional ARM algorithms, such as Apriori, were not designed to handle large databases that change frequently (Agrawal & Srikant, 1994). Each time a new transaction arrives, Apriori needs to be restarted from scratch to perform ARM. Hence, it is clear that in order to conduct ARM on the latest state of the database in a timely manner, an incremental mechanism to take into consideration the latest transaction must be in place.

In fact, a host of incremental algorithms have already been introduced to mine association rules incrementally (Sarda & Srinivas, 1998). However, they are only incremental to a certain extent; the moment the universal itemset (the number of unique items in a database) (Woon, Ng, & Das, 2001) is changed, they have to be restarted from scratch. The universal

itemset of any online store would certainly be changed frequently, because the store needs to introduce new products and retire old ones for competitiveness. Moreover, such incremental ARM algorithms are efficient only when the database has not changed much since the last mining.

The use of data structures in ARM, particularly the trie, is one viable way to address the data stream phenomenon. Data structures first appeared when programming became increasingly complex during the 1960s. In his classic book, *The Art of Computer Programming* Knuth (1968) reviewed and analyzed algorithms and data structures that are necessary for program efficiency. Since then, the traditional data structures have been extended, and new algorithms have been introduced for them. Though computing power has increased tremendously over the years, efficient algorithms with customized data structures are still necessary to obtain timely and accurate results. This fact is especially true for ARM, which is a computationally intensive process.

The trie is a multiway tree structure that allows fast searches over string data. In addition, as strings with common prefixes share the same nodes, storage space is better utilized. This makes the trie very useful for storing large dictionaries of English words. Figure 1 shows a trie storing four English words *(ape, apple, base,* and *ball).* Several novel trielike data structures have been introduced to improve the efficiency of ARM, and we discuss them in this section.

Amir, Feldman, & Kashi (1999) presented a new way of mining association rules by using a trie to preprocess the database. In this approach, all transactions are mapped onto a trie structure. This mapping involves the extraction of the powerset of the transaction items and the updating of the trie structure. Once built, there is no longer a need to scan the database to obtain support counts of itemsets, because the trie structure contains all their support counts. To find frequent itemsets, the structure is traversed by using depth-first search, and itemsets with support counts satisfying the minimum *support threshold* are added to the set of frequent itemsets.

Drawing upon that work, Yang, Johar, Grama, & Szpankowski (2000) introduced a binary *Patricia trie* to reduce the heavy memory requirements of the preprocessing trie. To support faster support queries, the authors added a set of horizontal pointers to index nodes. They also advocated the use of some form of primary threshold to further prune the structure. However, the compression achieved by the compact Patricia trie comes at a hefty price: It greatly complicates the horizontal pointer index, which is a severe overhead. In addition, after compression, it will be difficult for the Patricia trie to be updated whenever the database is altered.

The *Frequent Pattern-growth* (FP-growth) algorithm is a recent association rule mining algorithm that achieves impressive results (Han, Pei, Yin, & Mao, 2004). It uses a compact tree structure called a *Frequent Pattern-tree* (FP-tree) to store information about frequent 1-itemsets. This compact structure removes the need for multiple database scans and is constructed with only 2 scans. In the first database scan, frequent 1-itemsets are obtained and sorted in support descending order. In the second scan, items in the transactions are first sorted according to the order of the frequent 1-itemsets. These sorted items are used to construct the FP-tree. Figure 2 shows an FP-tree constructed from the database in Table 1.

FP-growth then proceeds to recursively mine FP-trees of decreasing size to generate frequent itemsets

Figure 1. An example of a trie for storing English words

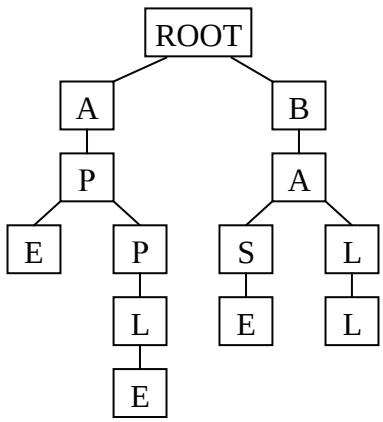

Table 1. A sample transactional database

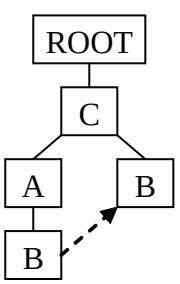
TID	Items
100	*AC*
200	*BC*
300	*ABC*
400	*ABCD*

without candidate generation and database scans. It does so by examining all the *conditional pattern bases* of the FP-tree, which consists of the set of frequent itemsets occurring with the suffix pattern. Conditional FP-trees are constructed from these conditional pattern bases, and mining is carried out recursively with such trees to discover frequent itemsets of various sizes. However, because both the construction and the use of the FP-trees are complex, the performance of FP-growth is reduced to be on par with Apriori at support thresholds of 3% and above. It only achieves significant speed-ups at support thresholds of 1.5% and below. Moreover, it is only incremental to a certain extent, depending on the FP-tree *watermark* (validity support threshold). As new transactions arrive, the support counts of items increase, but their relative support frequency may decrease, too. Suppose, however, that the new transactions cause too many previously infrequent itemsets to become frequent — that is, the watermark is raised too high (in order to make such itemsets infrequent) according to a user-defined level — then the FP-tree must be reconstructed.

The use of lattice theory in ARM was pioneered by Zaki (2000). Lattice theory allows the vast search space to be decomposed into smaller segments that can be tackled independently in memory or even in other machines, thus promoting parallelism. However, they require additional storage space as well as different traversal and construction techniques. To complement the use of lattices, Zaki uses a vertical database format, where each itemset is associated with a list of transactions known as a tid-list (transaction identifier–list). This format is useful for fast frequency counting of itemsets but generates additional overheads because most databases have a horizontal format and would need to be converted first.

Figure 2. An FP-tree constructed from the database in Table 1 at a support threshold of 50%



The Continuous Association Rule Mining Algorithm (CARMA), together with the support lattice, allows the user to change the support threshold and continuously displays the resulting association rules with support and confidence bounds during its first scan/phase (Hidber, 1999). During the second phase, it determines the precise support of each itemset and extracts all the frequent itemsets. CARMA can readily compute frequent itemsets for varying support thresholds. However, experiments reveal that CARMA only performs faster than Apriori at support thresholds of 0.25% and below, because of the tremendous overheads involved in constructing the support lattice.

The adjacency lattice, introduced by Aggarwal & Yu (2001), is similar to Zaki's boolean powerset lattice, except the authors introduced the notion of adjacency among itemsets, and it does not rely on a vertical database format. Two itemsets are said to be adjacent to each other if one of them can be transformed to the other with the addition of a single item. To address the problem of heavy memory requirements, a primary threshold is defined. This term signifies the minimum support threshold possible to fit all the qualified itemsets into the adjacency lattice in main memory. However, this approach disallows the mining of frequent itemsets at support thresholds lower than the primary threshold.

MAIN THRUST

As shown in our previous discussion, none of the existing data structures can effectively address the issues induced by the data stream phenomenon. Here are the desirable characteristics of an ideal data structure that can help ARM cope with data streams:

- It is highly scalable with respect to the size of both the database and the universal itemset.
- It is incrementally updated as transactions are added or deleted.
- It is constructed independent of the support threshold and thus can be used for various support thresholds.
- It helps to speed up ARM algorithms to a certain extent that allows results to be obtained in real-time.

We shall now discuss our novel trie data structure that not only satisfies the above requirements but

also outperforms the discussed existing structures in terms of efficiency, effectiveness, and practicality. Our structure is termed Support-Ordered Trie Itemset (SOTrieIT — pronounced "so-try-it"). It is a dual-level support-ordered trie data structure used to store pertinent itemset information to speed up the discovery of frequent itemsets.

As its construction is carried out before actual mining, it can be viewed as a preprocessing step. For every transaction that arrives, 1-itemsets and 2-itemsets are first extracted from it. For each itemset, the SOTrieIT will be traversed in order to locate the node that stores its support count. Support counts of 1-itemsets and 2-itemsets are stored in first-level and second-level nodes, respectively. The traversal of the SOTrieIT thus requires at most two redirections, which makes it very fast. At any point in time, the SOTrieIT contains the support counts of all 1-itemsets and 2-itemsets that appear in all the transactions. It will then be sorted level-wise from left to right according to the support counts of the nodes in descending order.

Figure 3 shows a SOTrieIT constructed from the database in Table 1. The bracketed number beside an item is its support count. Hence, the support count of itemset {AB} is 2. Notice that the nodes are ordered by support counts in a level-wise descending order.

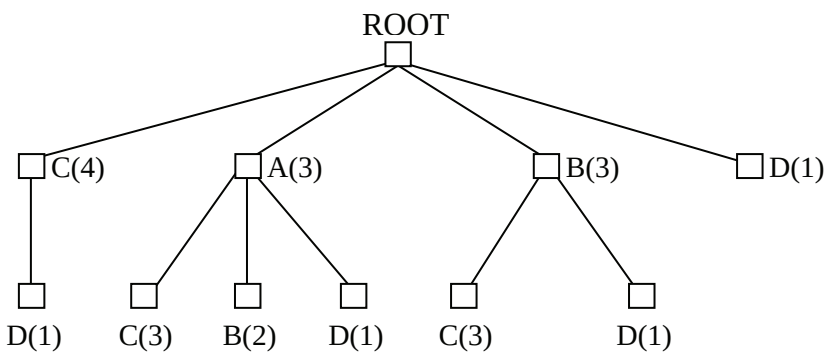
In algorithms such as FP-growth that use a similar data structure to store itemset information, the structure must be rebuilt to accommodate updates to the universal itemset. The SOTrieIT can be easily updated to accommodate the new changes. If a node for a new item in the universal itemset does not exist, it will be created and inserted into the SOTrieIT accordingly. If an item is removed from the universal itemset, all nodes containing that item need only be removed, and the rest of the nodes would still be valid.

Unlike the trie structure of Amir et al. (1999), the SOTrieIT is ordered by support count (which speeds up mining) and does not require the powersets of transactions (which reduces construction time). The main weakness of the SOTrieIT is that it can only discover frequent 1-itemsets and 2-itemsets; its main strength is its speed in discovering them. They can be found promptly because there is no need to scan the database. In addition, the search (depth first) can be stopped at a particular level the moment a node representing a nonfrequent itemset is found, because the nodes are all support ordered.

Another advantage of the SOTrieIT, compared with all previously discussed structures, is that it can be constructed *online*, meaning that each time a new transaction arrives, the SOTrieIT can be incrementally updated. This feature is possible because the SOTrieIT is constructed without the need to know the support threshold; it is support independent. All 1-itemsets and 2-itemsets in the database are used to update the SOTrieIT regardless of their support counts. To conserve storage space, existing trie structures such as the FP-tree have to use thresholds to keep their sizes manageable; thus, when new transactions arrive, they have to be reconstructed, because the support counts of itemsets will have changed.

Finally, the SOTrieIT requires far less storage space than a trie or Patricia trie because it is only two levels deep and can be easily stored in both memory and files. Although this causes some input/output (I/O) overheads, it is insignificant as shown in our extensive experiments. We have designed several algorithms to

Figure 3. A SOTrieIT structure



work synergistically with the SOTrieIT and, through experiments with existing prominent algorithms and a variety of databases, we have proven the practicality and superiority of our approach (Das, Ng, & Woon, 2001; Woon et al., 2001). In fact, our latest algorithm, *FOLD-growth,* is shown to outperform FP-growth by more than 100 times (Woon, Ng, & Lim, 2004).

FUTURE TRENDS

The data stream phenomenon will eventually become ubiquitous as Internet access and bandwidth become increasingly affordable. With keen competition, products will become more complex with customization and more varied to cater to a broad customer base; transaction databases will grow in both size and complexity. Hence, association rule mining research will certainly continue to receive much attention in the quest for faster, more scalable and more configurable algorithms.

CONCLUSION

Association rule mining is an important data mining task with several applications. However, to cope with the current explosion of raw data, data structures must be utilized to enhance its efficiency. We have analyzed several existing trie data structures used in association rule mining and presented our novel trie structure, which has been proven to be most useful and practical. What lies ahead is the parallelization of our structure to further accommodate the ever-increasing demands of today's need for speed and scalability to obtain association rules in a timely manner. Another challenge is to design new data structures that facilitate the discovery of trends as association rules *evolve* over time. Different association rules may be mined at different time points and, by understanding the patterns of changing rules, additional interesting knowledge may be discovered.

KEY TERMS

Apriori: A classic algorithm that popularized association rule mining. It pioneered a method to generate candidate itemsets by using only frequent itemsets in the previous pass. The idea rests on the fact that any subset of a frequent itemset must be frequent as well. This idea is also known as the *downward closure* property.

Itemset: An unordered set of unique items, which may be products or features. For computational efficiency, the items are often represented by integers. A *frequent* itemset is one with a support count that exceeds the support threshold, and a *candidate* itemset is a potential frequent itemset. A *k*-itemset is an itemset with exactly *k* items.

Key: A unique sequence of values that defines the location of a node in a tree data structure.

Patricia Trie: A compressed binary trie. The *Patricia* (Practical Algorithm to Retrieve Information Coded in Alphanumeric) trie is compressed by avoiding one-way branches. This is accomplished by including in each node the number of bits to skip over before making the next branching decision.

SOTrieIT: A dual-level trie whose nodes represent itemsets. The position of a node is ordered by the support count of the itemset it represents; the most frequent itemsets are found on the leftmost branches of the SOTrieIT.

Support Count of an Itemset: The number of transactions that contain a particular itemset.

Support Threshold: A threshold value that is used to decide if an itemset is interesting/frequent. It is defined by the user, and generally, an association rule mining algorithm has to be executed many times before this value can be well adjusted to yield the desired results.

Trie: An *n*-ary tree whose organization is based on *key space* decomposition. In key space decomposition, the key range is equally subdivided, and the splitting position within the key range for each node is predefined.

INTRODUCTION

The concept of Quantitative Structure-Activity Relationship (QSAR), introduced by Hansch and co-workers in the 1960s, attempts to discover the relationship between the structure and the activity of chemical compounds (SAR), in order to allow the prediction of the activity of new compounds based on knowledge of their chemical structure alone. These predictions can be achieved by quantifying the SAR.

Initially, statistical methods have been applied to solve the QSAR problem. For example, pattern recognition techniques facilitate data dimension reduction and transformation techniques from multiple experiments to the underlying patterns of information. Partial least squares (PLS) is used for performing the same operations on the target properties. The predictive ability of this method can be tested using cross-validation on the test set of compounds.

Later, data mining techniques have been considered for this prediction problem. Among data mining techniques, the most popular ones are based on neural networks (Wang, Durst, Eberhart, Boyd, & Ben-Miled, 2004) or on neuro-fuzzy approaches (Neagu, Benfenati, Gini, Mazzatorta, & Roncaglioni, 2002) or on genetic programming (Langdon, &Barrett, 2004). All these approaches predict the activity of a chemical compound, without being able to explain the predicted value.

In order to increase the understanding on the prediction process, descriptive data mining techniques have started to be used related to the QSAR problem. These techniques are based on association rule mining.

In this chapter, we describe the use of association rule-based approaches related to the QSAR problem.

BACKGROUND

Association rule mining, introduced by (Agrawal, Imielinski & Swami, 1993), is defined as finding all the association rules between sets of items in a database that hold with more that a user-given minimum support threshold and a user-given minimum confidence threshold. According to (Agrawal, Imielinski & Swami, 1993) this problem is solved in two steps:

1. Finding all frequent itemsets in the database.
2. For each frequent itemset I, generating all association rules $I' \Rightarrow I \setminus I'$, where $I' \subset I$.

The second problem can be solved in a straightforward manner after the first step is completed. Hence, the problem of mining association rules is reduced to the problem of finding all frequent itemsets. This is not a trivial problem, since the number of possible frequent itemsets is equal to the size of the power set of I, $2^{|I|}$.

There are many algorithms proposed in the literature, most of them based on the Apriori mining method (Agrawal & Srikant, 1994) that relies on a basic property of frequent itemsets: all subsets of a frequent itemset are frequent. This property can also be stated as all supersets of an infrequent itemset are infrequent. There are other approaches, namely the closed-itemset approaches, as Close (Pasquier, Bastide, Taouil & Lakhal, 1999),

CHARM (Zaki & Hsiao, 1999) and Closet (Pei, Han & Mao, 2000). The closed-itemset approaches rely on the application of Formal Concept Analysis to association rule problem that was first mentioned in (Zaki & Ogihara, 1998). For more details on lattice theory see (Ganter & Wille, 1999). Another approach leading to a small number of results is finding representative association rules (Kryszkiewicz, 1998).

The difference between Apriori-based and closed itemset-based approaches consists in the treatment of sub-unitary confidence and unitary confidence association rules, namely Apriori makes no distinction between them, while FCA-based approaches report sub-unitary association rules (also named partial implication rules) structured in a concept lattice and, eventually, the pseudo-intents, a base on the unitary association rules (also named global implications, exhibiting a logical implication behavior). The advantage of a closed itemset approach is the smaller size of the resulting concept lattice versus the number of frequent itemsets, *i.e.* search space reduction.

MAIN THRUST OF THE CHAPTER

While there are many application domains for the association rule mining methods, they have only started to be used in relation to the QSAR problem. There are two main approaches: one that attempts classifying chemical compounds, using frequent sub-structure mining (Deshpande, Kuramochi, Wale, & Karypis, 2005), a modified version of association rule mining, and one that attempts predicting activity using an association rule-based model (Dumitriu, Segal, Craciun, Cocu, & Georgescu, 2006).

Mined Data

For the QSAR problem, the items are called chemical compound descriptors. There are various types of descriptors that can be used to represent the chemical structure of compounds: chemical element presence in a compound, chemical element mass, normalized chemical element mass, topological structure of the molecule, geometrical structure of the molecule etc. Generally, a feature selection algorithm is applied before mining, in order to reduce the search space, as well as the model dimension. We do not focus on feature selection methods in this chapter.

The classification approach uses both the topological representation that sees a chemical compound as an undirected graph, having atoms in the vertices and bonds in the edges and the geometric representation that sees a chemical compound as an undirected graph with 3D coordinates attached to the vertices.

The predictive association-based model approach is applied for organic compounds only and uses typical sub-structure presence/count descriptors (a typical substructure can be, for example, - CH_3 or –CH_2-). It also includes a pre-clustered target item, the activity to be predicted.

Resulting Data Model

The frequent sub-structure mining attempts to build, just like frequent itemsets, frequent connected sub-graphs, by adding vertices step-by step, in an Apriori fashion. The main difference from frequent itemset mining is that graph isomorphism has to be checked, in order to correctly compute itemset support in the database. The purpose of frequent sub-structure mining is the classification of chemical compounds, using a Support Vector Machine-based classification algorithm on the chemical compound structure expressed in terms of the resulted frequent sub-structures.

The predictive association rule-based model considers as mining result only the global implications with predictive capability, namely the ones comprising the target item in the rule's conclusion. The prediction is achieved by applying to a new compound all the rules in the model. Some rules may not apply (rule's premises are not satisfied by the compound's structure) and some rules may predict activity clusters. Each cluster can be predicted by a number of rules. After subjecting the compound to the predictive model, it can yield:

- a "none" result, meaning that the compound's activity can not be predicted with the model,
- a cluster id result, meaning the predicted activity cluster,
- several cluster ids; whenever this situation occurs it can be dealt with in various manners: a vote can be held and the majority cluster id can be declared a winner, or the rule set (the model) can be refined since it is too general.

Contribution of Association Rule-Based Approaches for the QSAR Problem

The main advantage in building a classification or prediction model in terms of association rules is model readability. The QSAR problem requires inter-disciplinary team effort, so an important step in validating a resulting model would be to present it to domain experts. A predictive model with no explanatory capabilities can not express the conceptual relationship structure-activity, it can only express a numerical, difficult to understand, relationship.

FUTURE TRENDS

We are considering that the most challenging trends would manifest in:

- extending the above mentioned approaches to other descriptors;
- associating activity behavior with the compound classes resulted from the classification approach;
- building a predictive model on the activity associated-discovered classes.

Both approaches consider, at one stage or another, compounds described by their sub-structures. Association rule mining has been conceived for the market basket analysis; hence it is particularly well fitted to presence data like the sub-structure presence data taken into account by the mentioned techniques. It would be interesting to see if different types of descriptors are suited for these approaches.

The classification approach does not solve the QSAR problem unless activity items are attached to compound classes. The presence of activity items does not guarantee that prediction would be satisfactory within the classes.

The weakest point of predictive model building for the second approach is the pre-clustering of activity items. Building the model using classes previously discovered by the classification approach, may lead to a more reliable prediction technique.

CONCLUSION

We have introduced the idea of descriptive data mining for the QSAR prediction problem in order to add readability to the prediction process. Since the QSAR problem requires domain expertise readability is extremely important. Association rules have the explanatory capability, but they are better suited for presence data, which is not necessarily the case of chemical structure descriptors. The results obtained so far are promising, but QSAR has proven to be a difficult problem, so achieving satisfactory prediction accuracy would have to rely on a profound knowledge of the application domain.

KEY TERMS

Association Rule: Pair of frequent itemsets (A, B), where the ratio between the support of $A \cup B$ and A itemsets is greater than a predefined threshold, denoted *minconf*.

Closure Operator: Let S be a set and c: $\wp(S) \rightarrow \wp(S)$; c is a *closure operator* on S if $\forall$ X, Y $\subseteq$ S, c satisfies the following properties:

1. extension, $X \subseteq c(X)$;
2. mononicity, if $X \subseteq Y$, then $c(X) \subseteq c(Y)$;
3. idempotency, $c(c(X)) = c(X)$.

Note: $s \circ t$ and $t \circ s$ are closure operators, when s and t are the mappings in a Galois connection.

Concept: The Galois connection of the (***T***, ***I***, ***D***) context, a concept is a pair (X, Y), $X \subseteq \boldsymbol{T}$, $Y \subseteq \boldsymbol{I}$, that satisfies s(X)=Y and t(Y)=X. X is called the *extent* and Y the *intent* of the concept (X,Y).

Context: A triple (***T***, ***I***, ***D***) where ***T*** and ***I*** are sets and $\boldsymbol{D} \subseteq \boldsymbol{T} \times \boldsymbol{I}$. The elements of ***T*** are called *objects* and the elements of ***I*** are called *attributes*. For any $t \in \boldsymbol{T}$ and $i \in \boldsymbol{I}$, we note $t\boldsymbol{D}i$ when *t* is related to *i*, *i.e.* (*t*, *i*) $\in \boldsymbol{D}$.

Frequent Itemset: Itemset with support higher than a predefined threshold, denoted *minsup*.

Galois Connection: Let (***T***, ***I***, ***D***) be a context. Then the mappings

s: $\wp(\boldsymbol{T}) \rightarrow \wp(\boldsymbol{I})$, $s(X) = \{ i \in \boldsymbol{I} \mid (\forall t \in X)\ t\boldsymbol{D}i \}$

t: $\wp(\boldsymbol{I}) \rightarrow \wp(\boldsymbol{T})$, $s(Y) = \{ t \in \boldsymbol{T} \mid (\forall i \in Y)\ t\boldsymbol{D}i \}$

define a *Galois connection* between $\wp(\boldsymbol{T})$ and $\wp(\boldsymbol{I})$, the power sets of ***T*** and ***I***, respectively.

Itemset: Set of items in a Boolean database D, $I=\{i_1, i_2, \ldots i_n\}$.

Itemset Support: The ratio between the number of transactions in D comprising all the items in I and the total number of transactions in D ($support(I) = |\{T_i \in D| (\forall i_j \in I)\ i_j \in T_i \}| / |D|$).

Pseudo-Intent: The set X is a pseudo-intent if $X \neq c(X)$, where c is a closure operator, and for all pseudo-intents $Q \subset X$, $c(Q) \subseteq X$.

Association Rule Mining of Relational Data

Anne Denton
North Dakota State University, USA

Christopher Besemann
North Dakota State University, USA

INTRODUCTION

Most data of practical relevance are structured in more complex ways than is assumed in traditional data mining algorithms, which are based on a single table. The concept of relations allows for discussing many data structures such as trees and graphs. Relational data have much generality and are of significant importance, as demonstrated by the ubiquity of relational database management systems. It is, therefore, not surprising that popular data mining techniques, such as association rule mining, have been generalized to relational data. An important aspect of the generalization process is the identification of challenges that are new to the generalized setting.

BACKGROUND

Several areas of databases and data mining contribute to advances in association rule mining of relational data.

- **Relational data model:** Underlies most commercial database technology and also provides a strong mathematical framework for the manipulation of complex data. Relational algebra provides a natural starting point for generalizations of data mining techniques to complex data types.
- **Inductive Logic Programming, ILP (Džeroski & Lavrač, 2001, pp. 48-73):** Treats multiple tables and patterns as logic programs. Hypothesis for generalizing data to unseen examples are solved using first-order logic. Background knowledge is incorporated directly as a program.
- **Association Rule Mining, ARM (Agrawal & Srikant, 1994):** Identifies associations and correlations in large databases. The result of an ARM algorithm is a set of association rules in the form $A \rightarrow C$. There are efficient algorithms such as Apriori that limit the output to sets of items that occur more frequently than a given threshold.
- **Graph Theory:** Addresses networks that consist of nodes that are connected by edges. Traditional graph theoretic problems typically assume no more than one property per node or edge. Solutions to graph-based problems take into account graph and subgraph isomorphism. For example, a subgraph should only count once per isomorphic instance. Data associated with nodes and edges can be modeled within the relational algebra framework.
- **Link-based Mining (Getoor & Diehl, 2005):** Addresses data containing sets of linked objects. The links are exploited in tasks such as object ranking, classification, and link prediction. This work considers multiple relations in order to represent links.

Association rule mining of relational data incorporates important aspects of these areas to form an innovative data mining area of important practical relevance.

MAIN THRUST OF THE CHAPTER

Association rule mining of relational data is a topic that borders on many distinct topics, each with its own opportunities and limitations. Traditional association rule mining allows extracting rules from large data sets without specification of a consequent. Traditional predictive modeling techniques lack this generality and only address a single class label. Association rule mining techniques can be efficient because of the pruning opportunity provided by the downward closure property of support, and through the simple structure of the resulting rules (Agrawal & Srikant, 1994).

When applying association rule mining to relational data, these concepts cannot easily be transferred. This

can be seen particularly easily for data with an underlying graph structure. Graph theory has been developed for the special case of relational data that represent connectivity between nodes or objects with no more than one label. A commonly studied pattern mining problem in graph theory is frequent subgraph discovery (Kuramochi & Karypis, 2004). Challenges in gaining efficiency differ substantially in frequent subgraph discovery compared with data mining of single tables: While downward closure is easy to achieve in single-table data, it requires advanced edge disjoint mining techniques in graph data. On the other hand, while the subgraph isomorphism problem has simple solutions in a graph setting, it cannot easily be discussed in the context of relational joined tables.

This chapter attempts to view the problem of relational association rule mining from the perspective of these and other data mining areas, and highlights challenges and solutions in each case.

General Concept

Two main challenges have to be addressed when applying association rule mining to relational data. Combined mining of multiple tables leads to a search space that is typically large even for moderately sized tables. Performance is, thereby, commonly an important issue in relational data mining algorithms. A less obvious problem lies in the skewing of results (Jensen & Neville, 2007, Getoor & Diehl, 2005). Unlike single-table data, relational data records cannot be assumed to be independent.

One approach to relational data mining is to convert the data from a multiple table format to a single table format using methods such as relational joins and aggregation queries. The relational join operation combines each record from one table with each occurrence of the corresponding record in a second table. That means that the information in one record is represented multiple times in the joined table. Data mining algorithms that operate either explicitly or implicitly on joined tables, thereby, use the same information multiple times. This also applies to algorithms in which tables are joined on-the-fly by identifying corresponding records as they are needed. The relational learning task of transforming multiple relations into propositional or single-table format is also called propositionalization (Kramer et al., 2001). We illustrate specific issues related to reflexive relationships in the next section on relations that represent a graph.

A variety of techniques have been developed for data mining of relational data (Džeroski & Lavrač, 2001). A typical approach is called inductive logic programming, ILP. In this approach relational structure is represented in the form of Prolog queries, leaving maximum flexibility to the user. ILP notation differs from the relational algebra notation; however, all relational operators can be represented in ILP. The approach thereby does not limit the types of problems that can be addressed. It should, however, also be noted that relational database management systems are developed with performance in mind and Prolog-based environments may present limitations in speed.

Application of ARM within the ILP setting corresponds to a search for frequent Prolog (Datalog) queries as a generalization of traditional association rules (Dehaspe & Toivonen, 1999). An example of association rule mining of relational data using ILP (Dehaspe & Toivonen, 2001) could be shopping behavior of customers where relationships between customers are included in the reasoning as in the rule:

{customer(X), parent(X,Y)}→{buys(Y, cola)},

which states that if *X* is a parent then their child *Y* will buy a *cola*. This rule covers tables for the parent, buys, and customer relationships. When a pattern or rule is defined over multiple tables, a relational key is defined as the unit to which queries must be rolled up (usually using the Boolean existential function). In the customer relationships example a key could be "customer", so support is based on the number of customers that support the rule. Summarizations such as this are also needed in link-based classification tasks since individuals are often considered the unknown input examples (Getoor & Diehl, 2005). Propositionalization methods construct features by traversing the relational link structure. Typically, the algorithm specifies how to place the constructed attribute into a single table through the use of aggregation or "roll-up" functions (Kramer et al., 2001). In general, any relationship of a many-to-many type will require the use of aggregation when considering individual objects since an example of a pattern can extend to arbitrarily many examples of a larger pattern. While ILP does not use a relational joining step as such, it does also associate individual objects with multiple occurrences of corresponding

objects. Problems related to skewing are, thereby, also encountered in this approach.

An alternative to the ILP approach is to apply the standard definition of association rule mining to relations that are joined using the relational join operation. While such an approach is less general it is often more efficient since the join operation is highly optimized in standard database systems. It is important to note that a join operation typically changes the support of an item set, and any support calculation should therefore be based on the relation that uses the smallest number of join operations (Cristofor & Simovici, 2001).

Defining rule interest is an important issue in any type of association rule mining. In traditional association rule mining the problem of rule interest has been addressed in a variety of work on redundant rules, including closed set generation (Zaki, 2000). Additional rule metrics such as lift and conviction have been defined (Brin et al., 1997). In relational association rule mining the problem has been approached by the definition of a deviation measure (Dehaspe & Toivonen, 2001). Relational data records have natural dependencies based on the relational link structure. Patterns derived by traversing the link structure will also include dependencies. Therefore it is desirable to develop algorithms that can identify these natural dependencies. Current relational and graph-based pattern mining does not consider intra-pattern dependency. In general it can be noted that relational data mining poses many additional problems related to skewing of data compared with traditional mining on a single table (Jensen & Neville, 2002).

Relations that Represent a Graph

One type of relational data set has traditionally received particular attention, albeit under a different name. A relation representing a relationship between entity instances of the same type, also called a reflexive relationship, can be viewed as the definition of a unipartite graph. Graphs have been used to represent social networks, biological networks, communication networks, and citation graphs, just to name a few. Traditional graph-based approaches focus on connectivity only and are discussed in the related research section.

Recent work extends the field of graph-based patterns to multiple properties on nodes (Oyama et al., 2002; Besemann et al., 2004; Rahal et al., 2006; Besemann et al., 2006; Besemann et al., 2007). Other recent work studies tree based patterns that can represent general graphs by repeating node labels in the tree (Goethals et al., 2005). These graph-based approaches differ from the previous relational approaches in that they do not consider a universal key or record type as the unit of support counts. For example, in (Besemann et al., 2004) the rows for each join definition are considered the transactions therefore the universal key is the join "shape" itself. Relational approaches "roll-up" to a common level such as single nodes. Thus graph-based rule discovery must be performed in a level-by-level basis based on each shape or join operation and by the number of items.

A typical example of an association rule mining problem in graphs is mining of annotation data of proteins in the presence of a protein-protein interaction graph (Oyama et al., 2002). Associations are extracted that relate functions and localizations of one protein with those of interacting proteins. Oyama et al. use association rule mining, as applied to joined relations, for this work. Another example could be association rule mining of attributes associated with scientific publications on the graph of their mutual citations (Rahal et al., 2006).

A problem of the straight-forward approach of mining joined tables directly becomes obvious upon further study of the rules: In most cases the output is dominated by rules that involve the same item as it occurs in different entity instances that participate in a relationship. In the example of protein annotations within the protein interaction graph this is expressed in rules like:

{protein(A), protein(B), interaction(A, B), location(A, nucleus)}→{location(B, nucleus)}

that states if one of two interacting proteins is in the nucleus then the other protein will also be in the nucleus. Similarities among relational neighbors have been observed more generally for relational databases (Macskassy & Provost, 2003). It can be shown that filtering of output is not a consistent solution to this problem, and items that are repeated for multiple nodes should be eliminated in a preprocessing step (Besemann et al., 2004). This is an example of a problem that does not occur in association rule mining of a single table and requires special attention when moving to multiple relations. The example also highlights the

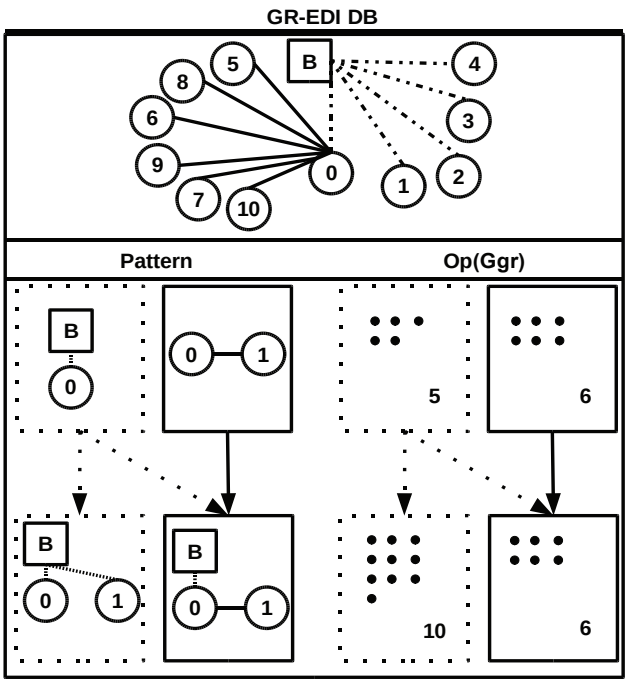
need to discuss what the differences between sets of items of related objects are.

A main problem in applying association rule mining to relational data that represents a graph is the lack of downward closure for graph-subgraph relationships. Edge disjoint instance mining techniques (Kuramochi & Karypis, 2005; Vanetik, 2006; Chen et al, 2007) have been used in frequent subgraph discovery. As a generalization, graphs with sets of labels on nodes have been addressed by considering the node – data relationship as a bipartite graph. Initial work combined the bipartite graph with other graph data as if it were one input graph (Kuramochi & Karypis, 2005). It has been shown in (Besemann & Denton, 2007) that it is beneficial to not include the bipartite graph in the determination of edge disjointness and that downward closure can still be achieved. However, for this to be true, some patterns have to be excluded from the search space. In the following this problem will be discussed in more detail.

Graphs in this context can be described in the form: $G(V, E, L_V, T_V, T_E)$ where the graph vertices $V = \{N \cup D\}$ are composed of entity nodes N and descriptors nodes D. Descriptor nodes correspond to attributes for the entities. The graph edges are $E = \{U \cup B\}$ where $U \subseteq (N \times N)$ is a unipartite relationship between entities and $B \subseteq (N \times D)$ is a bipartite relationship between entities and descriptors. A labeling function L assigns symbols as labels for vertices. Finally T_V and T_E denote the type of vertices and edges as entity or descriptor and unipartite or bipartite respectively. In this context, patterns, which can later be used to build association rules, are simply subgraphs of the same format.

Figure 1 shows a portion of the search space for the GR-EDI algorithm by Besemann and Denton. Potential patterns are arranged in a lattice where child nodes differ from parents by one edge. The left portion describes graph patterns in the space. As mentioned earlier, edge-disjoint instance mining (EDI) approaches allow for downward closure of patterns in the lattice with respect to support. The graph of edge disjoint instances is given for each pattern in the right of the figure. At the level shown, all instances are disjoint therefore the resulting instance graph is composed of individual nodes. This is the case since no pattern contains more than one unipartite (solid) edge and the EDI constraint is only applied to unipartite edges in this case. Dashed boxes indicate patterns that are not guaranteed to meet conditions for the monotone frequency property required for downward closure.

Figure 1. Illustration of need for specifying new pattern constraints when removing edge-disjointness requirement for bipartite edges



As shown, an instance for a pattern with no unipartite edges can be arbitrarily extended to instances of a larger pattern. In order to solve this problem, a pattern constraint must be introduced that requires valid patterns to at least have one unipartite edge connected to each entity node.

Related Research Areas

A related area of research is graph-based pattern mining. Traditional graph-based pattern mining does not produce association rules but rather focuses on the task of frequent subgraph discovery. Most graph-based methods consider a single label or attribute per node. When there are multiple attributes, the data are either modeled with zero or one label per node or as a bipartite graph. One graph-based task addresses multiple graph transactions where the data are a set of graphs (Inokuchi et al, 2000; Yan and Han, 2002; Kuramochi & Karypis, 2004; Hasan et al, 2007). Since each record or transaction is a graph, a subgraph pattern is counted once for each graph in which it exists at least once. In that sense transactional methods are not much different than single-table item set methods.

Single graph settings differ from transactional settings since they contain only one input graph rather than a set of graphs (Kuramochi & Karypis, 2005; Vanetik, 2006; Chen et al, 2007). They cannot use simple existence of a subgraph as the aggregation function; otherwise the pattern supports would be either one or zero. If all examples were counted without aggregation then the problem would no longer satisfy downward closure. Instead, only those instances are counted as discussed in the previous section.

In relational pattern mining multiple items or attributes are associated with each node and the main challenge is to achieve scaling with respect to the number of items per node. Scaling to large subgraphs is usually less relevant due to the "small world" property of many types of graphs. For most networks of practical interest any node can be reached from almost any other by means of no more than some small number of edges (Barabasi & Bonabeau, 2003). Association rules that involve longer distances are therefore unlikely to produce meaningful results.

There are other areas of research on ARM in which related transactions are mined in some combined fashion. Sequential pattern or episode mining (Agrawal & Srikant 1995; Yan, Han, & Afshar, 2003) and inter-transaction mining (Tung et al., 1999) are two main categories. Generally the interest in association rule mining is moving beyond the single-table setting to incorporate the complex requirements of real-world data.

FUTURE TRENDS

The consensus in the data mining community of the importance of relational data mining was recently paraphrased by Dietterich (2003) as "I.i.d. learning is dead. Long live relational learning". The statistics, machine learning, and ultimately data mining communities have invested decades into sound theories based on a single table. It is now time to afford as much rigor to relational data. When taking this step it is important to not only specify generalizations of existing algorithms but to also identify novel questions that may be asked that are specific to the relational setting. It is, furthermore, important to identify challenges that only occur in the relational setting, including skewing due to traversal of the relational link structure and correlations that are frequent in relational neighbors.

CONCLUSION

Association rule mining of relational data is a powerful frequent pattern mining technique that is useful for several data structures including graphs. Two main approaches are distinguished. Inductive logic programming provides a high degree of flexibility, while mining of joined relations is a fast technique that allows the study of problems related to skewed or uninteresting results. The potential computational complexity of relational algorithms and specific properties of relational data make its mining an important current research topic. Association rule mining takes a special role in this process, being one of the most important frequent pattern algorithms.

KEY TERMS

Antecedent: The set of items A in the association rule $A \rightarrow C$.

Apriori: Association rule mining algorithm that uses the fact that the support of a non-empty subset of an item set cannot be smaller than the support of the item set itself.

Association Rule: A rule of the form $A \rightarrow C$ meaning "if the set of items A is present in a transaction, then the set of items C is likely to be present too". A typical example constitutes associations between items purchased at a supermarket.

Confidence: The confidence of a rule $A \rightarrow C$ is support($A \cup C$) / support(A) that can be viewed as the sample probability Pr($C|A$).

Consequent: The set of items C in the association rule $A \rightarrow C$.

Entity-Relationship Model (E-R-Model): A model to represent real-world requirements through entities, their attributes, and a variety of relationships between them. E-R-Models can be mapped automatically to the relational model.

Inductive Logic Programming (ILP): Research area at the interface of machine learning and logic programming. Predicate descriptions are derived from examples and background knowledge. All examples, background knowledge and final descriptions are represented as logic programs.

Redundant Association Rule: An association rule is redundant if it can be explained based entirely on one or more other rules.

Relational Database: A database that has relations and relational algebra operations as underlying mathematical concepts. All relational algebra operations result in relations as output. A join operation is used to combine relations. The concept of a relational database was introduced by E. F. Codd at IBM in 1970.

Relation: A mathematical structure similar to a table in which every row is unique, and neither rows nor columns have a meaningful order.

Support: The support of an item set is the fraction of transactions or records that have all items in that item set. Absolute support measures the count of transactions that have all items.

Association Rules and Statistics

INTRODUCTION

A manager would like to have a dashboard of his company without manipulating data. Usually, statistics have solved this challenge, but nowadays, data have changed (Jensen, 1992); their size has increased, and they are badly structured (Han & Kamber, 2001). A recent method—data mining—has been developed to analyze this type of data (Piatetski-Shapiro, 2000). A specific method of data mining, which fits the goal of the manager, is the extraction of association rules (Hand, Mannila & Smyth, 2001). This extraction is a part of attribute-oriented induction (Guyon & Elisseeff, 2003).

The aim of this paper is to compare both types of extracted knowledge: association rules and results of statistics.

BACKGROUND

Statistics have been used by people who want to extract knowledge from data for one century (Freeman, 1997). Statistics can describe, summarize and represent the data. In this paper data are structured in tables, where lines are called objects, subjects or transactions and columns are called variables, properties or attributes. For a specific variable, the value of an object can have different types: quantitative, ordinal, qualitative or binary. Furthermore, statistics tell if an effect is significant or not. They are called inferential statistics.

Data mining (Srikant, 2001) has been developed to precede a huge amount of data, which is the result of progress in digital data acquisition, storage technology, and computational power. The association rules, which are produced by data-mining methods, express links on database attributes. The knowledge brought by the association rules is shared in two different parts. The first describes general links, and the second finds specific links (knowledge nuggets) (Fabris & Freitas, 1999; Padmanabhan & Tuzhilin, 2000). In this article, only the first part is discussed and compared to statistics. Furthermore, in this article, only data structured in tables are used for association rules.

MAIN THRUST

The problem differs with the number of variables. In the sequel, problems with two, three, or more variables are discussed.

Two Variables

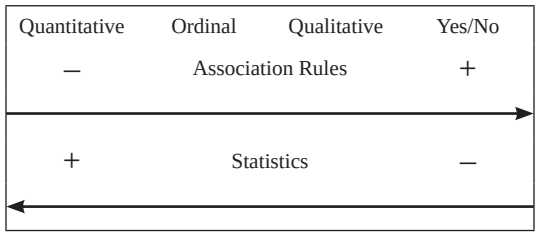
The link between two variables (A and B) depends on the coding. The outcome of statistics is better when data are quantitative. A current model is linear regression. For instance, the salary (S) of a worker can be expressed by the following equation:

$$S = 100\ Y + 20000 + \varepsilon \quad (1)$$

where Y is the number of years in the company, and ε is a random number. This model means that the salary of a newcomer in the company is $20,000 and increases by $100 per year.

The association rule for this model is: $Y \rightarrow S$. This means that there are a few senior workers with a small paycheck. For this, the variables are translated into binary variables. Y is not the number of years, but the property has seniority, which is not quantitative but of type Yes/No. The same transformation is applied to the salary S, which becomes the property "has a big salary."

Figure 1. Coding and analysis methods



Therefore, these two methods both provide the link between the two variables and have their own instruments for measuring the quality of the link. For statistics, there are the tests of regression model (Baillargeon, 1996), and for association rules, there are measures like support, confidence, and so forth (Kodratoff, 2001). But, depending on the type of data, one model is more appropriate than the other (Figure 1).

Three Variables

If a third variable E, the experience of the worker, is integrated, the equation (1) becomes:

$$S = 100\ Y + 2000\ E + 19000 + \varepsilon \qquad (2)$$

E is the property "has experience." If E=1, a new experienced worker gets a salary of $21,000, and if E=0, a new non-experienced worker gets a salary of $19,000. The increase of the salary, as a function of seniority (Y), is the same in both cases of experience.

$$S = 50\ Y + 1500\ E + 50\ E \acute{}\ Y + 19500 + \varepsilon \qquad (3)$$

Now, if E=1, a new experienced worker gets a salary of $21,000, and if E=0, a new non-experienced worker gets a salary of $19,500. The increase of the salary, as a function of seniority (Y), is $50 higher for experienced workers. These regression models belong to a linear model of statistics (Prum, 1996), where, in the equation (3), the third variable has a particular effect on the link between Y and S, called *interaction* (Winer, Brown & Michels, 1991).

The association rules for this model are:

- $Y \rightarrow S$, $E \rightarrow S$ for the equation (2)
- $Y \rightarrow S$, $E \rightarrow S$, $YE \rightarrow S$ for the equation (3)

The statistical test of the regression model allows to choose with or without interaction (2) or (3). For the association rules, it is necessary to prune the set of three rules, because their measures do not give the choice between a model of two rules and a model of three rules (Zaki, 2000; Zhu, 1998).

More Variables

With more variables, it is difficult to use statistical models to test the link between variables (Megiddo & Srikant, 1998). However, there are still some ways to group variables: clustering, factor analysis, and taxonomy (Govaert, 2003). But the complex links between variables, like interactions, are not given by these models and decrease the quality of the results.

Comparison

Table 1 briefly compares statistics with the association rules. Two types of statistics are described: by tests and by taxonomy. Statistical tests are applied to a small amount of variables and the taxonomy to a great

Table 1. Comparison between statistics and association rules

	Statistics		Data mining

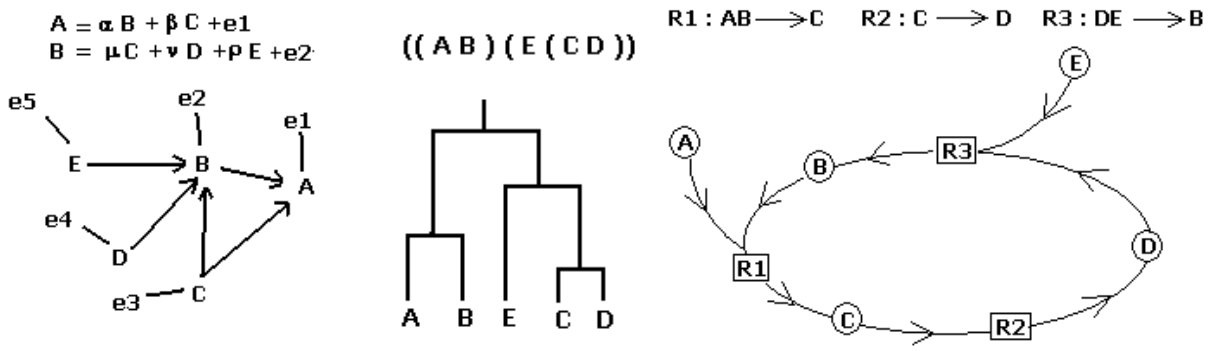
Complex Link	**Yes (-)**	**No (+)**	**No (-)**

Figure 2. a) Regression equations b) Taxonomy c) Association rules



(a) (b) (c)

amount of variables. In statistics, the decision is easy to make out of test results, unlike association rules, where a difficult choice on several indices thresholds has to be performed. For the level of knowledge, the statistical results need more interpretation relative to the taxonomy and the association rules.

Finally, graphs of the regression equations (Hayduk, 1987), taxonomy (Foucart, 1997), and association rules (Gras & Bailleul, 2001) are depicted in Figure 2.

FUTURE TRENDS

With association rules, some researchers try to find the right indices and thresholds with stochastic methods. More development needs to be done in this area. Another sensitive problem is the set of association rules that is not made for deductive reasoning. One of the most common solutions is the pruning to suppress redundancies, contradictions and loss of transitivity. Pruning is a new method and needs to be developed.

CONCLUSION

With association rules, the manager can have a fully detailed dashboard of his or her company without manipulating data. The advantage of the set of association rules relative to statistics is a high level of knowledge. This means that the manager does not have the inconvenience of reading tables of numbers and making interpretations. Furthermore, the manager can find knowledge nuggets that are not present in statistics.

The association rules have some inconvenience; however, it is a new method that still needs to be developed.

KEY TERMS

Attribute-Oriented Induction: Association rules, classification rules, and characterization rules are written with attributes (i.e., variables). These rules are obtained from data by induction and not from theory by deduction.

Badly Structured Data: Data, like texts of corpus or log sessions, often do not contain explicit variables. To extract association rules, it is necessary to create variables (e.g., keyword) after defining their values (frequency of apparition in corpus texts or simply apparition/non apparition).

Interaction: Two variables, A and B, are in interaction if their actions are not seperate.

Linear Model: A variable is fitted by a linear combination of other variables and interactions between them.

Pruning: The algorithms of extraction for the association rule are optimized in computationality cost but not in other constraints. This is why a suppression has to be performed on the results that do not satisfy special constraints.

Structural Equations: System of several regression equations with numerous possibilities. For instance, a same variable can be made into different equations, and a latent (not defined in data) variable can be accepted.

Taxonomy: This belongs to clustering methods and is usually represented by a tree. Often used in life categorization.

Tests of Regression Model: Regression models and analysis of variance models have numerous hypothesis, e.g. normal distribution of errors. These constraints allow to determine if a coefficient of regression equation can be considered as null with a fixed level of significance.

Audio and Speech Processing for Data Mining

Zheng-Hua Tan
Aalborg University, Denmark

INTRODUCTION

The explosive increase in computing power, network bandwidth and storage capacity has largely facilitated the production, transmission and storage of multimedia data. Compared to alpha-numeric database, non-text media such as audio, image and video are different in that they are unstructured by nature, and although containing rich information, they are not quite as expressive from the viewpoint of a contemporary computer. As a consequence, an overwhelming amount of data is created and then left unstructured and inaccessible, boosting the desire for efficient content management of these data. This has become a driving force of multimedia research and development, and has lead to a new field termed multimedia data mining. While text mining is relatively mature, mining information from non-text media is still in its infancy, but holds much promise for the future.

In general, data mining the process of applying analytical approaches to large data sets to discover implicit, previously unknown, and potentially useful information. This process often involves three steps: data preprocessing, data mining and postprocessing (Tan, Steinbach, & Kumar, 2005). The first step is to transform the raw data into a more suitable format for subsequent data mining. The second step conducts the actual mining while the last one is implemented to validate and interpret the mining results.

Data preprocessing is a broad area and is the part in data mining where essential techniques are highly dependent on data types. Different from textual data, which is typically based on a written language, image, video and some audio are inherently non-linguistic. Speech as a spoken language lies in between and often provides valuable information about the subjects, topics and concepts of multimedia content (Lee & Chen, 2005). The language nature of speech makes information extraction from speech less complicated yet more precise and accurate than from image and video. This fact motivates content based speech analysis for multimedia data mining and retrieval where audio and speech processing is a key, enabling technology (Ohtsuki, Bessho, Matsuo, Matsunaga, & Kayashi, 2006). Progress in this area can impact numerous business and government applications (Gilbert, Moore, & Zweig, 2005). Examples are discovering patterns and generating alarms for intelligence organizations as well as for call centers, analyzing customer preferences, and searching through vast audio warehouses.

BACKGROUND

With the enormous, ever-increasing amount of audio data (including speech), the challenge now and in the future becomes the exploration of new methods for accessing and mining these data. Due to the non-structured nature of audio, audio files must be annotated with structured metadata to facilitate the practice of data mining. Although manually labeled metadata to some extent assist in such activities as categorizing audio files, they are insufficient on their own when it comes to more sophisticated applications like data mining. Manual transcription is also expensive and in many cases outright impossible. Consequently, automatic metadata generation relying on advanced processing technologies is required so that more thorough annotation and transcription can be provided. Technologies for this purpose include audio diarization and automatic speech recognition. Audio diarization aims at annotating audio data through segmentation, classification and clustering while speech recognition is deployed to transcribe speech. In addition to these is event detection, such as, for example, applause detection in sports recordings. After audio is transformed into various symbolic streams, data mining techniques can be applied to the streams to find patterns and associations, and information retrieval techniques can be applied for the purposes of indexing, search and retrieval. The procedure is analogous to video data mining and retrieval (Zhu, Wu, Elmagarmid, Feng, & Wu, 2005; Oh, Lee, & Hwang, 2005).

Diarization is the necessary, first stage in recognizing speech mingled with other audios and is an important field in its own right. The state-of-the-art system has achieved a speaker diarization error of less than 7% for broadcast news shows (Tranter & Reynolds, 2006).

A recent, notable research project on speech transcription is the Effective Affordable Reusable Speech-To-Text (EARS) program (Chen, Kingsbury, Mangu, Povey, Saon, Soltau, & Zweig, 2006). The EARS program focuses on automatically transcribing natural, unconstrained human-human speech from broadcasts and telephone conversations in multiple languages. The primary goal is to generate rich and accurate transcription both to enable computers to better detect, extract, summarize, and translate important information embedded in the speech and to enable humans to understand the speech content by reading transcripts instead of listening to audio signals. To date, accuracies for broadcast news and conversational telephone speech are approximately 90% and 85%, respectively. For reading or dictated speech, recognition accuracy is much higher, and depending on several configurations, it can reach as high as 99% for large vocabulary tasks.

Progress in audio classification and categorization is also appealing. In a task of classifying 198 sounds into 16 classes, (Lin, Chen, Truong, & Chang, 2005) achieved an accuracy of 97% and the performance was 100% when considering Top 2 matches. The 16 sound classes are alto-trombone, animals, bells, cello-bowed, crowds, female, laughter, machines, male, oboe, percussion, telephone, tubular-bells, violin-bowed, violin-pizz and water.

The technologies at this level are highly attractive for many speech data mining applications. The question we ask here is what is speech data mining? The fact is that we have areas close to or even overlapping with it, such as spoken document retrieval for search and retrieval (Hansen, Huang, Zhou, Seadle, Deller, Gurijala, Kurimo, & Angkititrakul, 2005). At this early stage of research, the community does not show a clear intention to segregate them, though. The same has happened with text data mining (Hearst, 1999). In this chapter we define speech data mining as the nontrivial extraction of hidden and useful information from masses of speech data. The same applies to audio data mining. Interesting information includes trends, anomalies and associations with the purpose being primarily for decision making. An example is mining spoken dialog to generate alerts.

MAIN FOCUS

In this section we discuss some key topics within or related to speech data mining. We cover audio diarization, robust speech recognition, speech data mining and spoken document retrieval. Spoken document retrieval is accounted for since the subject is so closely related to speech data mining, and the two draw on each other by sharing many common preprocessing techniques.

Audio Diarization

Audio diarization aims to automatically segment an audio recording into homogeneous regions. Diarization first segments and categorizes audio as speech and non-speech. Non-speech is a general category covering silence, music, background noise, channel conditions and so on. Speech segments are further annotated through speaker diarization which is the current focus in audio diarization. Speaker diarization, also known as "Who Spoke When" or speaker segmentation and clustering, partitions speech stream into uniform segments according to speaker identity.

A typical diarization system comprises such components as speech activity detection, change detection, gender and bandwidth identification, speaker segmentation, speaker clustering, and iterative re-segmentation or boundary refinement (Tranter & Reynolds, 2006). Two notable techniques applied in this area are Gaussian mixture model (GMM) and Bayesian information criterion (BIC), both of which are deployed through the process of diarization. The performance of speaker diarization is often measured by diarization error rate which is the sum of speaker error, missed speaker and false alarm speaker rates.

Diarization is an important step for further processing such as audio classification (Lu, Zhang, & Li, 2003), audio clustering (Sundaram & Narayanan, 2007), and speech recognition.

Robust Speech Recognition

Speech recognition is the process of converting a speech signal to a word sequence. Modern speech recognition systems are firmly based on the principles of statistical pattern recognition, in particular the use of hidden Markov models (HMMs). The objective is to find the most likely sequence of words $\hat{W}$, given the observation data Y which are feature vectors extracted

from an utterance. It is achieved through the following Bayesian decision rule:

$$\hat{W} = \arg\max_{W} P(W \mid Y) = \arg\max_{W} P(W)P(Y \mid W)$$

where $P(W)$ is the a priori probability of observing some specified word sequence W and is given by a language model, for example tri-grams, and $P(Y|W)$ is the probability of observing speech data Y given word sequence W and is determined by an acoustic model, often being HMMs.

HMM models are trained on a collection of acoustic data to characterize the distributions of selected speech units. The distributions estimated on training data, however, may not represent those in test data. Variations such as background noise will introduce mismatches between training and test conditions, leading to severe performance degradation (Gong, 1995). Robustness strategies are therefore demanded to reduce the mismatches. This is a significant challenge placed by various recording conditions, speaker variations and dialect divergences. The challenge is even more significant in the context of speech data mining, where speech is often recorded under less control and has more unpredictable variations. Here we put an emphasis on robustness against noise.

Noise robustness can be improved through feature-based or model-based compensation or the combination of the two. Feature compensation is achieved through three means: feature enhancement, distribution normalization and noise robust feature extraction. Feature enhancement attempts to clean noise-corrupted features, as in spectral subtraction. Distribution normalization reduces the distribution mismatches between training and test speech; cepstral mean subtraction and variance normalization are good examples. Noise robust feature extraction includes improved mel-frequency cepstral coefficients and completely new features. Two classes of model domain methods are model adaptation and multi-condition training (Xu, Tan, Dalsgaard, & Lindberg, 2006).

Speech enhancement unavoidably brings in uncertainties and these uncertainties can be exploited in the HMM decoding process to improve its performance. Uncertain decoding is such an approach in which the uncertainty of features introduced by the background noise is incorporated in the decoding process by using a modified Bayesian decision rule (Liao & Gales, 2005). This is an elegant compromise between feature-based and model-based compensation and is considered an interesting addition to the category of joint feature and model domain compensation which contains well-known techniques such as missing data and weighted Viterbi decoding.

Another recent research focus is on robustness against transmission errors and packet losses for speech recognition over communication networks (Tan, Dalsgaard, & Lindberg, 2007). This becomes important when there are more and more speech traffic through networks.

Speech Data Mining

Speech data mining relies on audio diarization, speech recognition and event detection for generating data description and then applies machine learning techniques to find patterns, trends, and associations.

The simplest way is to use text mining tools on speech transcription. Different from written text, however, textual transcription of speech is inevitably erroneous and lacks formatting such as punctuation marks. Speech, in particular spontaneous speech, furthermore contains hesitations, repairs, repetitions, and partial words. On the other hand, speech is an information-rich media including such information as language, text, meaning, speaker identity and emotion. This characteristic lends a high potential for data mining to speech, and techniques for extracting various types of information embedded in speech have undergone substantial development in recent years.

Data mining can be applied to various aspects of speech. As an example, large-scale spoken dialog systems receive millions of calls every year and generate terabytes of log and audio data. Dialog mining has been successfully applied to these data to generate alerts (Douglas, Agarwal, Alonso, Bell, Gilbert, Swayne, & Volinsky, 2005). This is done by labeling calls based on subsequent outcomes, extracting features from dialog and speech, and then finding patterns. Other interesting work includes semantic data mining of speech utterances and data mining for recognition error detection.

Whether speech summarization is also considered under this umbrella is a matter of debate, but it is nevertheless worthwhile to refer to it here. Speech summarization is the generation of short text summaries of speech (Koumpis & Renals, 2005). An intuitive approach is to apply text-based methods to speech

transcription while more sophisticated approaches combine prosodic, acoustic and language information with textual transcription.

Spoken Document Retrieval

Spoken document retrieval is turned into a text information retrieval task by using a large-vocabulary continuous speech recognition (LVCSR) system to generate a textual transcription. This approach has shown good performance for high-quality, close-domain corpora, for example broadcast news, where a moderate word error rate can be achieved. When word error rate is below one quarter, spoken document retrieval systems are able to get retrieval accuracy similar to using human reference transcriptions because query terms are often long words that are easy to recognize and are often repeated several times in the spoken documents. However, the LVCSR approach presents two inherent deficiencies: vocabulary limitations and recognition errors. First, this type of system can only process words within the predefined vocabulary of the recognizer. If any out-of-vocabulary words appear in the spoken documents or in the queries, the system cannot deal with them. Secondly, speech recognition is error-prone and has an error rate of typically ranging from five percent for clean, close-domain speech to as much as 50 percent for spontaneous, noisy speech, and any errors made in the recognition phase cannot be recovered later on as speech recognition is an irreversible process. To resolve the problem of high word error rates, recognition lattices can be used as an alternative for indexing and search (Chelba, Silva, & Acero, 2007). The key issue in this field is indexing, or more generally, the combination of automatic speech recognition and information retrieval technologies for optimum overall performance.

Search engines have recently experienced a great success in searching and retrieving text documents. Nevertheless the World Wide Web is very silent with only primitive audio search mostly relying on surrounding text and editorial metadata. Content based search for audio material, more specifically spoken archives, is still an uncommon practice and the gap between audio search and text search performance is significant. Spoken document retrieval is identified as one of the key elements of next-generation search engines.

FUTURE TRENDS

The success of speech data mining highly depends on the progress of audio and speech processing. While the techniques have already shown good potentials for data mining applications, further advances are called for. To be applied to gigantic data collected under diverse conditions, faster and more robust speech recognition systems are required.

At present hidden Markov model is the dominating approach for automatic speech recognition. A recent trend worth noting is the revisit of template-based speech recognition, which is an aged, almost obsolete paradigm. It has now been put into a different perspective and framework and is gathering momentum. In addition to this are knowledge based approaches and cognitive science oriented approaches.

In connection with diarization, it is foreseen that there should be a wider scope of studies to cover larger and broader databases, and to gather more diversity of information including emotion, speaker identities and characteristics.

Data mining is often used for surveillance applications, where real-time or near real-time operation is mandatory while at present many systems and approaches work in a batch mode or far from real-time.

Another topic under active research is music data mining for detecting melodic or harmonic patterns from music data. Main focuses are on feature extraction, similarity measures, categorization and clustering, pattern extraction and knowledge representation.

Multimedia data in general contains several different types of media. Information fusion from multiple media has been less investigated and should be given more attention in the future.

CONCLUSION

This chapter reviews audio and speech processing technologies for data mining with an emphasis on speech data mining. The status and the challenges of various related techniques are discussed. The underpinning techniques for mining audio and speech are audio diarization, robust speech recognition, and audio classification and categorization. These techniques have reached a level where highly attractive data

mining applications can be deployed for the purposes of prediction and knowledge discovery. The field of audio and speech data mining is still in its infancy, but it has received attention in security, commercial and academic fields.

KEY TERMS

Audio Diarization: A process of segmenting an audio recording into homogeneous regions.

Audio Classification: A process of determining to which predefined class an audio file or segment belongs. It is fundamentally a pattern recognition problem.

Audio Clustering: A process of partitioning a set of audio files or segments into subsets or clusters such that audio content in each cluster share come common characteristics. This is done on the basis of some defined distance or similarity measure.

Automatic Speech Recognition: A process of converting a speech signal to a word sequence.

Metadata: A set of structured descriptions about data, or simply "data about data". Metadata is exploited to facilitate the management and use of data.

Pattern Discovery: A sub-discipline of data mining concerned with defining and detecting local anomalies in a given set of data, in contrast with modeling the entire data set.

Robust Speech Recognition: A field of research aimed at reinforcing the capability of speech recognition systems in coping well with variations in their operating environments.

Speech Data Mining: A process of extracting hidden and useful information from masses of speech data. In the process information like patterns, trends and anomalies are detected primarily for the purpose of decision making.

Audio Indexing

Gaël Richard
Ecole Nationale Supérieure des Télécommunications (TELECOM ParisTech), France

INTRODUCTION

The enormous amount of unstructured audio data available nowadays and the spread of its use as a data source in many applications are introducing new challenges to researchers in information and signal processing. The continuously growing size of digital audio information increases the difficulty of its access and management, thus hampering its practical usefulness. As a consequence, the need for content-based audio data parsing, indexing and retrieval techniques to make the digital information more readily available to the user is becoming ever more critical.

The lack of proper indexing and retrieval systems is making de facto useless significant portions of existing audio information (and obviously audiovisual information in general). In fact, if generating digital content is easy and cheap, managing and structuring it to produce effective services is clearly not. This applies to the whole range of content providers and broadcasters which can amount to terabytes of audio and audiovisual data. It also applies to the audio content gathered in private collection of digital movies or music files stored in the hard disks of conventional personal computers.

In summary, the goal of an audio indexing system will then be to automatically extract high-level information from the digital raw audio in order to provide new means to navigate and search in large audio databases. Since it is not possible to cover all applications of audio indexing, the basic concepts described in this chapter will be mainly illustrated on the specific problem of musical instrument recognition.

BACKGROUND

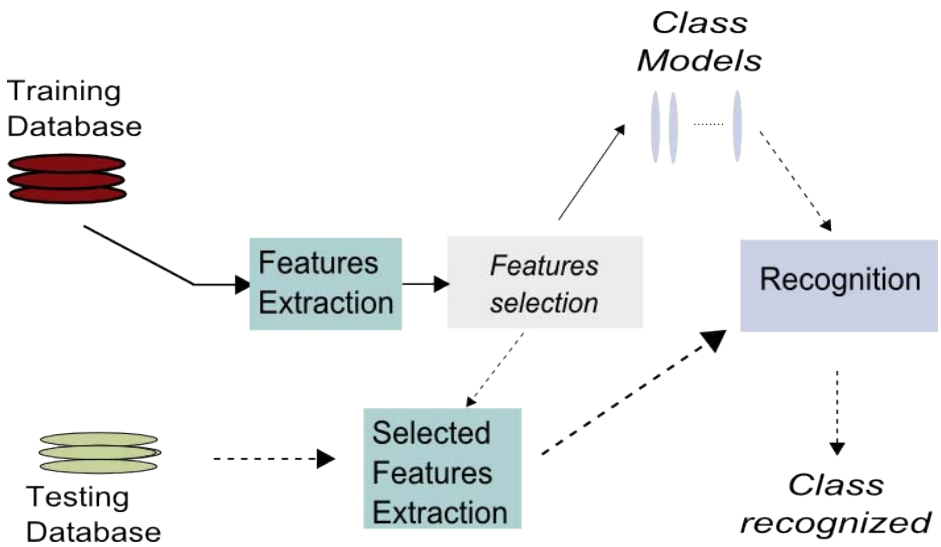
Audio indexing was historically restricted to word spotting in spoken documents. Such an application consists in looking for pre-defined words (such as name of a person, topics of the discussion etc…) in spoken documents by means of Automatic Speech Recognition (ASR) algorithms (see (Rabiner, 1993) for fundamentals of speech recognition). Although this application remains of great importance, the variety of applications of audio indexing now clearly goes beyond this initial scope. In fact, numerous promising applications exist ranging from automatic broadcast audio streams segmentation (Richard & et al., 2007) to automatic music transcription (Klapuri & Davy, 2006). Typical applications can be classified in three major categories depending on the potential users (Content providers, broadcasters or end-user consumers). Such applications include:

- Intelligent browsing of music samples databases for composition (Gillet & Richard, 2005), video scenes retrieval by audio (Gillet & et al., 2007) and automatic playlist production according to user preferences (for **content providers**).
- Automatic podcasting, automatic audio summarization (Peeters & et al., 2002), automatic audio title identification and smart digital DJing (for **broadcasters**).
- Music genre recognition (Tzanetakis & Cook, 2002), music search by similarity (Berenzweig & et al., 2004), personal music database intelligent browsing and query by humming (Dannenberg & et al. 2007) (for **consumers**).

MAIN FOCUS

Depending on the problem tackled different architectures are proposed in the community. For example, for musical tempo estimation and tracking traditional architectures will include a decomposition module which aims at splitting the signal into separate frequency bands (using a filterbank) and a periodicity detection module which aims at estimating the periodicity of a detection function built from the time domain envelope of the signal in each band (Scheirer, 1998)(Alonso & et al., 2007). When tempo or beat tracking is necessary, it will be coupled with onset detection techniques (Bello & et al., 2006) which aim at locating note onsets in

Figure 1. A typical architecture for a statistical audio indexing system based on a traditional bag-of frames approach. In a problem of automatic musical instrument recognition, each class represents an instrument or a family of instruments.



the musical signal. Note that the knowledge of note onset positions allows for other important applications such as Audio-to-Audio alignment or Audio-to-Score alignment.

However a number of different audio indexing tasks will share a similar architecture. In fact, a typical architecture of an audio indexing system includes two or three major components: A feature extraction module sometimes associated with a feature selection module and a classification or decision module. This typical "bag-of-frames" approach is depicted in Figure 1.

These modules are further detailed below.

Feature Extraction

The *feature extraction module* aims at representing the audio signal using a reduced set of features that well characterize the signal properties. The features proposed in the literature can be roughly classified in four categories:

- Temporal features: These features are directly computed on the time domain signal. The advantage of such features is that they are usually straightforward to compute. They include amongst others the crest factor, temporal centroid, zero-crossing rate and envelope amplitude modulation.
- Cepstral features: Such features are widely used in speech recognition or speaker recognition due to a clear consensus on their appropriateness for these applications. This is duly justified by the fact that such features allow to estimate the contribution of the filter (or vocal tract) in a source-filter model of speech production. They are also often used in audio indexing applications since many audio sources also obey a source filter model. The usual features include the Mel-Frequency Cepstral Coefficients (MFCC), and the Linear-Predictive Cepstral Coefficients (LPCC).
- Spectral features: These features are usually computed on the spectrum (magnitude of the Fourier Transform) of the time domain signal. They include the first four spectral statistical moments, namely the spectral centroid, the spectral width, the spectral asymmetry defined from the spectral skewness, and the spectral kurtosis describing the peakedness/flatness of the spectrum. A number of spectral features were also defined in the framework of MPEG-7 such as for example the MPEG-7 Audio Spectrum Flatness and Spectral Crest Factors which are processed over a number of frequency bands (ISO, 2001). Other features

proposed include the Spectral slope, the the spectral variation and the frequency cutoff. Some specific parameters were also introduced by (Essid & al. 2006a) for music instrument recognition to capture in a rough manner the power distribution of the different harmonics of a musical sound without recurring to pitch-detection techniques: the Octave Band Signal Intensities and Octave Band Signal Intensities Ratios.

- Perceptual features: Typical features of this class include the relative specific loudness representing a sort of equalization curve of the sound, the sharpness - as a perceptual alternative to the spectral centroid based on specific loudness measures- and the spread, being the distance between the largest specific loudness and the total loudness.

For all these features, it is also rather common to consider their variation over time through their first and second derivatives.

It is also worth to mention that due to their different dynamic it is often necessary to normalize each feature. A commonly used transformation scheme consists in applying a linear transformation to each computed feature to obtain centered and unit variance features. This normalization scheme is known to be more robust to outliers than a mapping of the feature dynamic range to a predefined interval such as [-1 : 1]. More details on most of these common features can be found in (Peeters, 2004) and in (Essid, 2005).

Features Selection

As mentioned above, when a large number of features is chosen, it becomes necessary to use *feature selection techniques* to reduce the size of the feature set (Guyon & Eliseeff, 2003). Feature selection techniques will consist in selecting the features that are the most discriminative for separating the different classes. A popular scheme is based on the Fisher Information Criterion which is expressed as the ratio of the inter-class spread to the intra-class spread. As such, a high value of the criterion for a given feature corresponds to a high separability of the class. The appropriate features can therefore be chosen by selecting those with the highest ratios.

Classification

The *classification module* aims at classifying or labelling a given audio segment. This module usually needs a training step where the characteristics of each class are learned. Popular supervised classification approaches for this task include K-nearest neighbours, Gaussian Mixture Models, Support Vector Machines (SVM) and Hidden Markov models (Burges, 1998), (Duda & al., 2000).

For example, in a problem of automatic musical instrument recognition (Essid & al., 2006a), a state of the art system will compute a large number of features (over 500), use feature selection and combine multiple binary SVM classifiers. When a large number of instruments is considered (or when polyphonic music involving more than one instrument playing at a time, as in (Eggink and Brown, 2004)), hierarchical approaches aiming first at recognising an instrument family (or group of instruments) are becoming very efficient (Essid & al. 2006b).

FUTURE TRENDS

Future trends in audio indexing are targeting robust and automatic extraction of high level semantic information in polyphonic music signals. Such information for a given piece of music could include the main melody line; the musical emotions carried by the musical piece, its genre or tonality; the number and type of musical instruments that are active. All these tasks which have already interesting solutions for solo music (e.g. for mono-instrumental music) become particularly difficult to solve in the context of real recordings of polyphonic and multi-instrumental music. Amongst the interesting directions, a promising path is provided by methods that try to go beyond the traditional "bag-of-frames" approach described above. In particular, sparse representation approaches that rely on a signal model (Leveau & al. 2008) or techniques based on mathematical decomposition such as Non-Negative Matrix factorization (Bertin & al. 2007) have already obtained very promising results in Audio-to-Score transcription tasks.

CONCLUSION

Nowadays, there is a continuously growing interest of the community for audio indexing and Music Information Retrieval (MIR). If a large number of applications already exist, this field is still in its infancy and a lot of effort is still needed to bridge the "semantic gap" between a low-level representation that a machine can obtain and the high level interpretation that a human can achieve.

KEY TERMS

Features: Features aimed at capturing one or several characteristics of the incoming signal. Typical features include the energy, the Mel-frequency cepstral coefficients.

Frequency Cutoff (or Roll-off): Computed as the frequency below which 99% of the total spectrum energy is concentrated.

Mel-Frequency Cepstral Coefficients (MFCC): are very common features in audio indexing and speech recognition applications. It is very common to keep only the first few coefficients (typically 13) so that they mostly represent the spectral envelope of the signal.

Musical Instrument Recognition: The task to automatically identify from a music signal which instruments are playing. We often distinguish the situation where a single instrument is playing with the more complex but more realistic problem of recognizing all instruments of real recordings of polyphonic music.

Non-Negative Matrix Factorization: This technique permits to represent the data (e.g. the magnitude spectrogram) as a linear combination of elementary spectra, or atoms and to find from the data both the decomposition and the atoms of this decomposition (see [Lee & al., 2001] for more details).

Octave Band Signal Intensities: These features are computed as the log-energy of the signal in overlapping octave bands.

Octave Band Signal Intensities Ratios: These features are computed as the logarithm of the energy ratio of each subband to the previous (e.g. lower) subband.

Semantic Gap: Refers to the gap between the low-level information that can be easily extracted from a raw signal and the high level semantic information carried by the signal that a human can easily interpret.

Sparse Representation Based on a Signal Model: Such methods aim at representing the signal as an explicit linear combination of sound sources, which can be adapted to better fit the analyzed signal. This decomposition of the signal can be done using elementary sound templates of musical instruments.

Spectral Centroid: Spectral centroid is the first statistical moment of the magnitude spectrum components (obtained from the magnitude of the Fourier transform of a signal segment).

Spectral Slope: Obtained as the slope of a line segment fit to the magnitude spectrum.

Spectral Variation: Represents the variation of the magnitude spectrum over time.

Support Vector Machines: Support Vector Machines (SVM) are powerful classifiers arising from Structural Risk Minimization Theory that have proven to be efficient for various classification tasks, including speaker identification, text categorization and musical instrument recognition.

An Automatic Data Warehouse Conceptual Design Approach

INTRODUCTION

Within today's competitive economic context, information acquisition, analysis and exploitation became strategic and unavoidable requirements for every enterprise. Moreover, in order to guarantee their persistence and growth, enterprises are forced, henceforth, to capitalize expertise in this domain.

Data warehouses (DW) emerged as a potential solution answering the needs of storage and analysis of large data volumes. In fact, a DW is a database system specialized in the storage of data used for decisional ends. This type of systems was proposed to overcome the incapacities of OLTP (On-Line Transaction Processing) systems in offering analysis functionalities. It offers integrated, consolidated and temporal data to perform decisional analyses. However, the different objectives and functionalities between OLTP and DW systems created a need for a development method appropriate for DW.

Indeed, data warehouses still deploy considerable efforts and interests of a large community of both software editors of decision support systems (DSS) and researchers (Kimball, 1996; Inmon, 2002). Current software tools for DW focus on meeting end-user needs. OLAP (On-Line Analytical Processing) tools are dedicated to multidimensional analyses and graphical visualization of results (*e.g.*, Oracle Discoverer®); some products permit the description of DW and Data Mart (DM) schemes (*e.g.*, Oracle Warehouse Builder®). One major limit of these tools is that the schemes must be built beforehand and, in most cases, manually. However, such a task can be tedious, error-prone and time-consuming, especially with heterogeneous data sources.

On the other hand, the majority of research efforts focuses on particular aspects in DW development, *cf.*, multidimensional modeling, physical design (materialized views (Moody & Kortnik, 2000), index selection (Golfarelli, Rizzi, & Saltarelli 2002), schema partitioning (Bellatreche & Boukhalfa, 2005)) and more recently applying data mining for a better data interpretation (Mikolaj, 2006; Zubcoff, Pardillo & Trujillo, 2007). While these practical issues determine the performance of a DW, other just as important, conceptual issues (*e.g.*, requirements specification and DW schema design) still require further investigations. In fact, few propositions were put forward to assist in and/or to automate the design process of DW, *cf.*, (Bonifati, Cattaneo, Ceri, Fuggetta & Paraboschi, 2001; Hahn, Sapia & Blaschka, 2000; Phipps & Davis 2002; Peralta, Marotta & Ruggia, 2003).

This chapter has a twofold objective. First, it proposes an intuitive, tabular format to assist decision maker in formulating their OLAP requirements. It proposes an automatic approach for the conceptual design of DW/DM schemes, starting from specified OLAP requirements. Our automatic approach is composed of four steps: *Acquisition of OLAP requirements*, *Generation of star/constellation schemes*, *DW schema generation*, and *Mapping the DM/DW onto data sources*. In addition, it relies on an algorithm that transforms tabular OLAP requirements into DM modelled either as a star or a constellation schema. Furthermore, it applies a set of mapping rules between the data sources and the DM schemes. Finally, it uses a set of unification rules

that merge the generated DM schemes and construct the DW schema.

BACKGROUND

There are several proposals to automate certain tasks of the DW design process (Hahn, Sapia & Blaschka, 2000). In (Peralta, Marotta & Ruggia, 2003), the authors propose a rule-based mechanism to automate the construction of the DW logical schema. This mechanism accepts the DW conceptual schema and the source databases. That is, it supposes that the DW conceptual schema already exists. In addition, being a bottom-up approach, this mechanism lacks a conceptual design methodology that takes into account the user requirements which are crucial in the DW design.

In (Golfarelli, Maio & Rizzi, 1998), the authors propose how to derive a DW conceptual schema from Entity-Relationship (E/R) schemes. The conceptual schema is represented by a Dimensional-Fact Model (DFM). In addition, the translation process is left to the designer, with only interesting strategies and cost models presented. Other proposals, similar to (Marotta & Ruggia 2002; Hahn, Sapia & Blaschka, 2000) also generate star schemes and suppose that the data sources are E/R schemes. Although the design steps are based on the operational data sources, the end-users' requirements are neglected. Furthermore, the majority of these works use a graphical model for the Data Source (DS) from which they generate the DM schema; that is, they neither describe clearly how to obtain the conceptual graphical models from the DS, nor how to generate the multidimensional schemes.

Other works relevant to automated DW design mainly focus on the conceptual design, *e.g.*, (Hüsemann, Lechtenbörger & Vossen 2000) and (Phipps & Davis 2002) who generate the conceptual schema from an E/R model. However, these works do not focus on a conceptual design methodology based on users' requirements and are, in addition, limited to the E/R DS model.

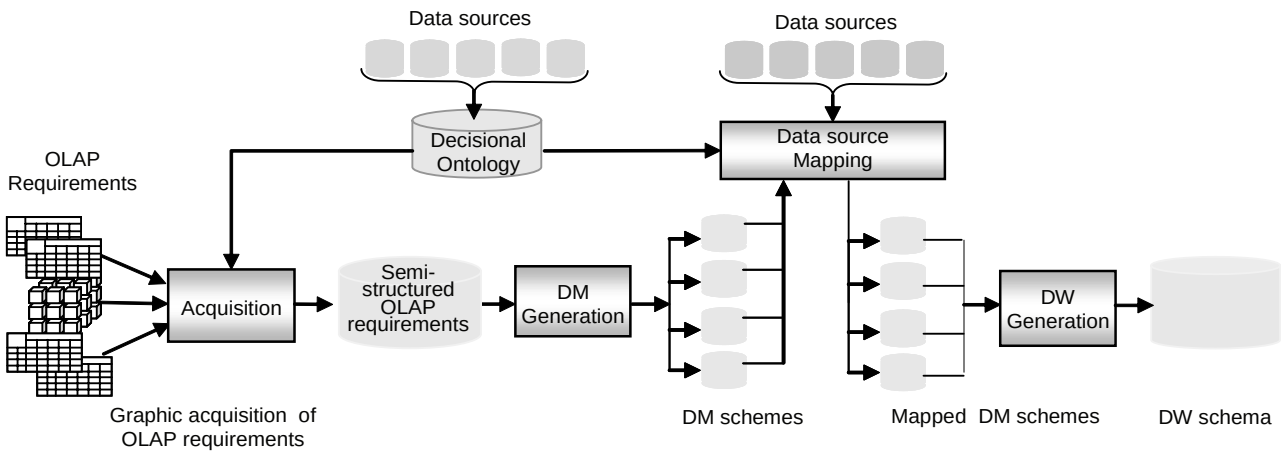
MAIN FOCUS

We propose an automatic approach to design DW/DM schemes from precisely specified OLAP requirements. This approach (Figure 1) is composed of four steps: *i) Acquisition of OLAP requirements* specified as two/n-dimensional fact sheets producing "semi-structured" OLAP requirements, *ii) Generation of star/constellation schemes* by merging the semi-structured OLAP requirements, *iii) DW generation schema* by fusion of DM schemes, and *iv) Mapping the DM/DW* to the data sources.

OLAP Requirement Acquisition

Decisional requirements can be formulated in various manners, but most generally they are expressed in natural language sentences. In our approach, which aims at a computer aided design, we propose to collect these requirements in a format familiar to the decision

Figure 1. DW design starting from OLAP requirements



makers: structured sheets. As illustrated in Figure 2, our generic structure defines the *fact* to be analyzed its *domain*, its *measures* and its analysis *dimensions*. We call this structure "2D-F sheet", acronym for Two-Dimensional Fact sheet. To analyze a fact with *n* (*n*>2) dimensions, we may need to use several 2D-F sheets simultaneously or hide one dimension at a time to add a new one to the sheet to obtain *nD-F* sheet. With this format, the OLAP requirements can be viewed as a set of 2/nD-F sheets, each defining a fact and two/n analysis dimensions.

We privileged this input format because it is familiar and intuitive to decision makers. As illustrated in Figure 1, the requirement acquisition step uses a decisional ontology specific to the application domain. This ontology supplies the basic elements and their multidimensional semantic relations during the acquisition. It assists the decisional user in formulating their needs and avoiding naming and relational ambiguities of dimensional concepts (Nabli, Feki & Gargouri 2006).

Example: Figure 3 depicts a 2D-F sheet that analyzes the *SALE* fact of the *commercial* domain. The measure *Qty* depends of the dimensions *Client* and *Date*.

The output of the acquisition step is a set of sheets defining the facts to be analyzed, their measures and dimensions, dimensional attributes, etc. These specified requirements, called semi-structured OLAP requirements, are the input of the next step: DM generation.

DM Schema Generation

A DM is subject-oriented and characterized by its multidimensional schema made up of facts measured along analysis dimensions. Our approach aims at constructing the DM schema starting from OLAP requirements specified as a set of 2/nD-F sheets. Each sheet can be seen as a partial description (i.e., multidimensional view) of a DM schema. Consequently, for a given domain, the complete multidimensional schemes of the DMs are derived from all the sheets specified in the acquisition step. For this, we have defined a set of algebraic operators to derive automatically the DM schema (Nabli, Feki & Gargouri, 2005).

This derivation is done in two complementary phases according to whether we want to obtain star or constellation schemes:

1. *Generation of star schemes*, which groups sheets referring to the same domain and describing the same fact. It then merges all the sheets identified within a group to build a star.

Figure 2. Generic structure of 2D-F sheet

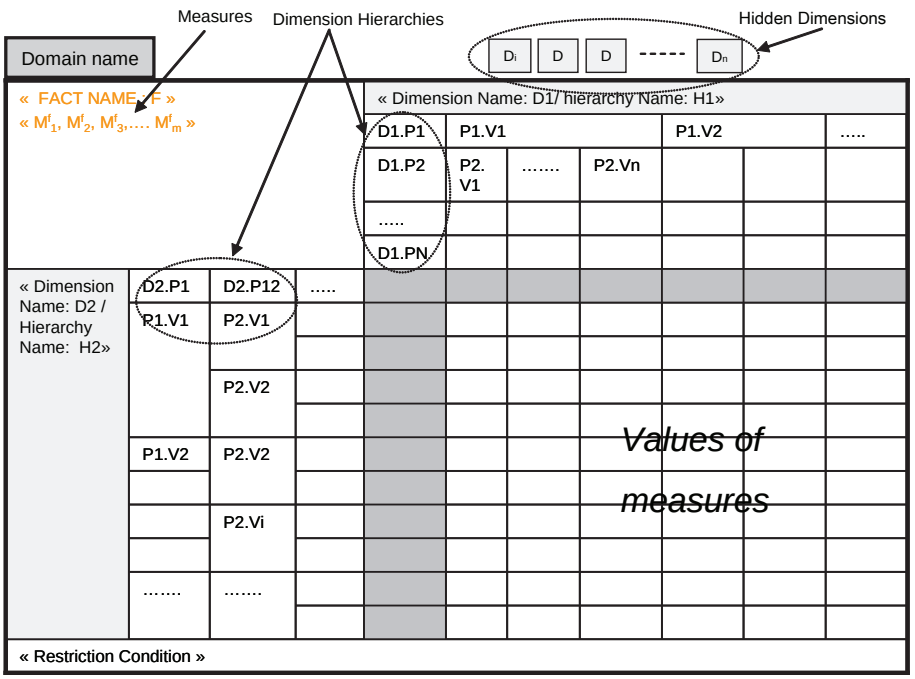


Figure 3. T1. 2D-F sheet for the SALE fact

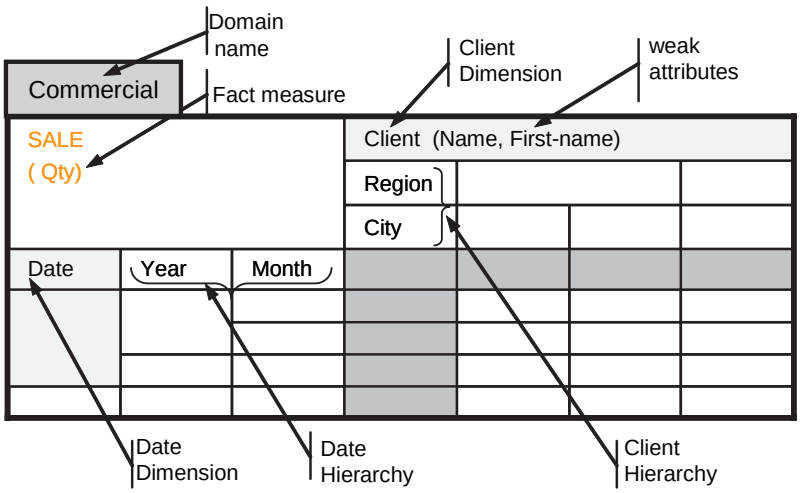


Box 1.

Star_Generation
Begin
Given *t* *n*D-F sheets analyzing *f* facts belonging to *m* analysis domains (*m*<=*t*).
Partition the *t* sheets into the *m* domains, to obtain G_{dom1}, G_{dom2},….., G_{domm} sets of sheets.
For each G_{domi} (i=1..*m*)
Begin
1.1. Partition the sheets in G_{domi} by facts into G^{F1}_{domi},…… , G^{Fk}_{domi} (k<=f)
1.2. For each G^{Fj}_{domi} (j=1..k)
Begin
1.2.1. For each sheet s ∈ G^{Fj}_{domi}
For each dimension d ∈ dim(s)
Begin
- Complete the hierarchy of d to obtain a maximal hierarchy.
- Add an identifier Id^d as an attribute.
End
1.2.2. Collect measures $Mes^{Fj} = \bigcup_{s \in G^{Fj}_{domi}} meas(s)$
1.2.3. Create the structure of a fact F for F_j with Mes^{Fj}.
1.2.4. Collect dimensions $Dim^{Fj} = \bigcup_{s \in G^{fj}_{domi}} \dim(s)$
1.2.4.1. For each d ∈ Dim^{Fj}
Begin
- Determine hierarchies $hier_d^{Fj} = \bigcup_{s \in G^{Fj}_{domi}} \bigcup_{d \in \dim(s)} hier(d)$
- Create the structure of a dimension D for d with $hier^{Fj}_d$.
- Associate D with F.
End
End
End.

2. *Generation of constellation schemes,* which integrates star schemes relevant to the same domain and that may have common dimensions.

To present the algorithms of these two types of schema generation, we will use the following notation.

– *Dim(s):* the set of dimensions in an nD-F sheet *s*,
– *Hier(d):* the hierarchy of a dimension *d*,
– *Meas(s):* the set of measures in an nD-F sheet *s*.

Star Schema Generation

The algorithm shown in Box 1 (Nabli, Soussi, Feki, Ben-Abdallah & Gargouri, 2005) generates star schemes. In this algorithm, the *t* nD-F sheets are first partitioned into domains; this ensures that each star schema is generated for one domain. In turn, this will reduce the number of comparisons used in the constellation schema generation phase (see next section). A star schema is constructed for each fact (F_j) in steps 3.2.2. to 3.2.5.

Example: Let us extend the previous *SALE* example with the two additional sheets shown in Figure 4. The

Figure 4. T2 and T3 two sheets for the SALE fact

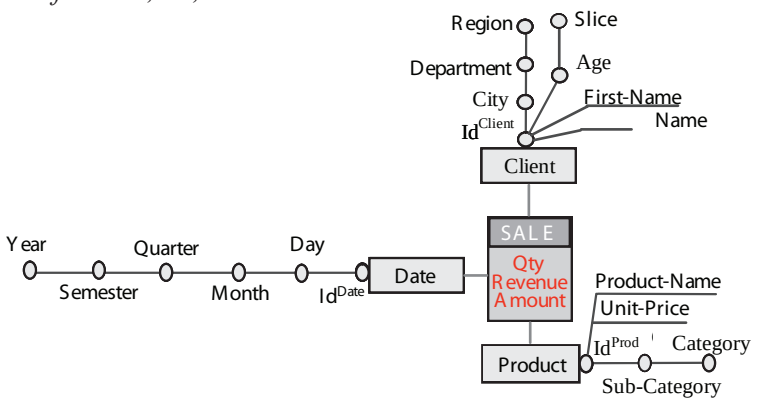
Commercial **T2**

SALE (Qty, Amount)				Product (unit-price, prod-name) /H_category			
				category			
Date H_Year	Year	Quarter	Month				

Commercial **T3**

SALE (Qty, Revenue)				Client (Name, First-name)/H_age			
				Age			
				Slice			
Date H_Year	Year	Semester	Month				

Figure 5. Star schema built from T1, T2, and T3 sheets



star schema resulting from applying our algorithm is shown in Figure 5.

Note that Id^{Date}, Id^{Client} and Id^{Prod} were added as attributes to identify the dimensions. In addition, several attributes were added to complete the dimension hierarchies. This addition was done in step 3.2.1. of the algorithm.

Constellation Schema Generation

In the above phase, we have generated a star schema for each fact in the same analysis domain. These latter have to be merged to obtain star/constellation schemes. For this, we adapt the *similarity factor* of (Feki, 2004) to measure the pertinence of schemes to be integrated, *i.e.*, the number of their common dimensions.

Given S_i and S_k two star schemes in the same analysis domain, their similarity factor $Sim(S_i, S_k)$ is calculated on the basis of n and m which are the number of dimensions in S_i and S_k respectively, and p which is the number of their common dimensions:

$$Sim(S_i, S_K) = \begin{cases} \alpha \quad if\,(n = p) \wedge (n < m); \\ p\,/\,(n + m - p)\; otherwise. \end{cases}$$

Informally, $Sim(S_i, S_k)$ highlights the case where all the dimensions of S_i are included in S_k. To dismiss the trivial case of S_i is having only the *Date* dimension (present in all schemes), the designer should fix the threshold α to a value strictly greater than 0.5.

In addition, to enhance the quality of the integration result, we define a matrix of similarities *MS* to measure the similarity between each pair of multidimensional schemes. This matrix is used to decide which schemes should be integrated first.

Given n star schemes of the same analysis domain $S_1, S_2, \ldots, S_n$. Each schema, defined by a name, analyzes a fact and has a set of dimensions. The *stopcondition* is a Boolean expression, *true* if either the size of *MS* becomes 1 or all the values in *MS* are lower than a threshold set by the designer. Let us extend our previous example with the additional star S2 (Figure 6).

The five steps of the DM schema construction are:

a. Construct the matrix of similarities *MS*
b. Find all the occurrences of the maximum *max* in *MS*
c. Construct a constellation by merging all schemes having the maximum similarity *max*
d. Re-dimension *MS* by:
   - Dropping rows and columns of the merged schemes
   - Adding one row and one column for the newly constructed schema
e. If <*stopcondition*> then exit, else return to step a.

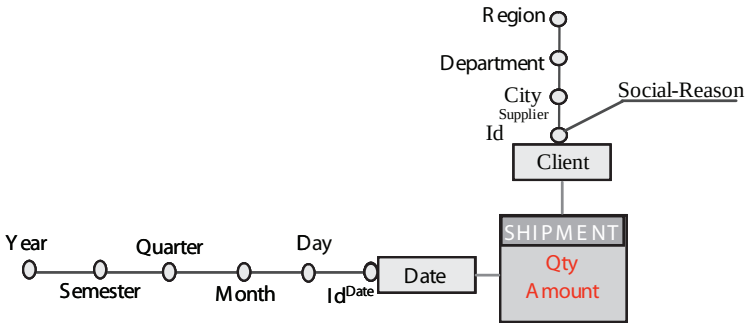
The similarity matrix for *S1* and *S2* contains the single value *Sim(S1, S2) = 0.75.*

The constellation schema resulting from applying the above five steps is depicted by Figure 7.

DM-DS Mapping

The DW is built from several data sources (DS) while its schema is built from the DM schemes. Thus, the DM schemes must be mapped to the DS schemes. In our approach, the DM-DS mapping adapts the heuristics proposed by (Golfarelli, Maio & Rizzi , 1998; Bonifati, Cattaneo, Ceri, Fuggetta & Paraboschi, 2001) to map each element (i.e., fact, dimension…) of the DM

Figure 6. S2 star schema



schemes to one or more elements (entity, relation, attribute…) of the DS schemes.

Our DM-DS mapping is performed in three steps: first, it identifies from the DS schema potential facts (PF), and matches facts in the DM schemes with identified PF. Secondly, for each mapped fact, it looks for DS attributes that can be mapped to measures in the DM schemes. Finally, for each fact that has potential measures, it searches DS attributes that can be mapped to dimensional attributes in the DM schemes.

A DM element may be derived from several identified potential elements. In addition, the same element can be mapped to several identified potential elements. It may also happen that a DM element is different from all potential elements, which might require OLAP requirement revision.

Fact Mapping

Fact mapping aims to find for each DM fact (Fd) the corresponding DS elements. For this, we first identify DS elements that could represent potentiel facts (PF). Then, we confront the set of Fd with all identified PF. The result of this step is a set of (Fd, PF) pairs for which the measures and dimensions must be confronted to accept or reject the mapping (cf. validation mapping step).

Fact Identification

Each entity of the DS verifying one of the following two rules becomes a potential fact:

F1: An *n-ary* relationship in the DS with numerical attribute with $n \geq 2$;

F2: An entity with at least one numerical attribute not included in its identifier.

Fact Matching

An ontology dedicated to decisional system is used to find for each fact in the DM schema all corresponding potential facts. In this step, we may encounter one problematic case: a DM fact has no corresponding PF. Here the designer must intervene.

Note that, when a DM fact has several corresponding PF, all mappings are retained until the measures and dimensions are identified.

Measure Mapping

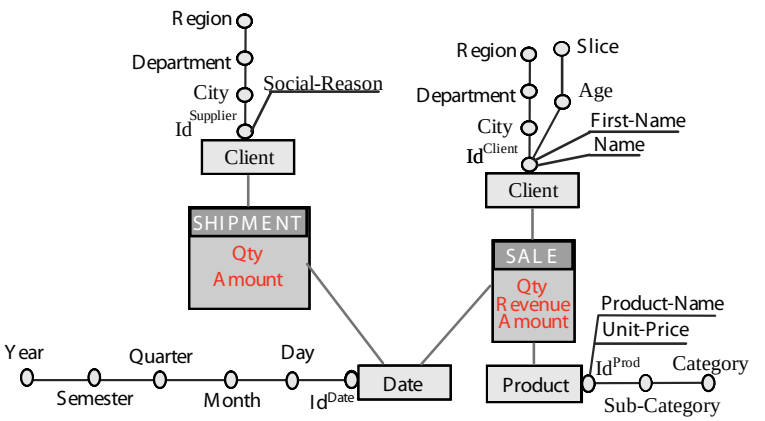
For each (Fd, PF) determined in the previous step, we identify the potential measures of PF and confront them with those of Fd.

Measure Identification

Since measures are numerical attributes, they will be searched within potential facts (PF) and "parallel" entities; they will be qualified as potential measures (PM). The search order is:

1. A non-key numerical attribute of PF
2. A non-key numerical attribute of parallel entities to PF
3. A numerical attribute of the entities related to PF by a "one-to-one" link first, followed by those related to PF by a "one-to-many" link
4. Repeat step 3 for each entity found in step 3

Figure 7. Constellation schema built from the stars in Figures 5 and 6



Measure Matching
Given the set of potential measures of each PF, we use a decisional ontology to find the corresponding measures in Fd. A DM measure may be derived from several identified PM. The identified PM that are matched to fact Fd measures are considered the measures of the PF.

In this step, we eliminate all (Fd, PF) for which no correspondence between their measures is found.

Dimension Mapping
This step identifies potential dimension attributes and confronts them with those of Fd, for each (Fd, PF) retained in the measure mapping phase.

Dimension Attribute Identification
Each attribute, not belonging to any potential measures and verifying the following two rules, becomes a potential dimension (PD) attribute:

D1: An attribute in a potential fact PF
D2: An attribute of an entity related to a PF via a "one-to-one" or "one-to-many" link. The entity relationships take into account the transitivity

Note that, the order in which the entities are considered determines the hierarchy of the dimension attributes. Thus, we consult the attributes in the following order:

1. An attribute of PF, if any
2. An attribute of the entities related to PF by a "one-to-one" link initially, followed by the attributes of the entities related to PF by "one-to-many" link
3. Repeat step 2 for each entity found in step 2

Dimension Matching
Given the set of PD attribute, we use a decisional ontology to find the corresponding attribute in Fd. If we can match the identifier of a dimension *d* with a PD attributes, this later is considered as a PD associated to PF.

In this step, we eliminate all (Fd, PF) for which no correspondence between their dimensions is found.

DM-DS Mapping Validation
The crucial step is to specify how the ideal requirements can be mapped to the real system. The validation may also give the opportunity to consider new analysis aspects that did not emerge from user requirements, but that the system may easily make available. When a DM has one corresponding potential fact, the mapping is retained. Whereas, when a DM fact has several corresponding potential facts {(Fd, PF)}, the measures of Fd are the union of the measures of all PF. This is argued by the fact that the identification step associates each PM with only one potential fact; hence, all sets of measures are disjoint. Multiple correspondences of dimensions are treated in the same way.

Data Warehouse Generation

Our approach distinguishes two storage spaces: the DM and the DW designed by two different models. The DMs have multidimensional models, to support OLAP analysis, whereas the DW is structured as a conventional database. We found the UML class diagram appropriate to represent the DW schema.

The DM schema integration is accomplished in the DW generation step (see Figure 1) that operates in two complementary phases:

1. Transform each DM schema (i.e. stars and constellations) into an UML class diagram.
2. Merge the UML class diagrams. This merger produces the DW schema independent of any data structure and content.

Recall that a dimension is made up of hierarchies of attributes. The attributes are organized from the finest to the highest granularity. Some attributes belong to the dimension but not to hierarchies; these attributes are called weak attributes, they serve to label results.

The transformation of DM schemes to UML class diagrams uses a set of rules among which we list the following five rules (For further details, the reader is referred to Feki, 2005):

Rule 1: *Transforming a dimension d into classes* − Build a class for every non-terminal attribute of each hierarchy of d.
Rule 2: *Assigning attributes to classes* − A class built from an attribute *a* gathers this attribute, the weak attributes associated to *a*, and the terminal attributes that are immediately related to *a* and not having weak attributes.
Rule 3: *Linking classes* − Each class *Ci* built from attribute at level *i* of a hierarchy *h*, is con-

nected via a composition link to the class C_{i-1}, of the same hierarchy, if any.

Rule 4: *Transforming facts into associations* − A fact table is transformed into an association linking the finest level classes derived from its dimensions. Measures of the fact become attributes of the association.

Note that the above four rules apply only to non-date dimension. Rule 5 deals with the date dimension:

Rule 5: *Transforming date dimension* – A date dimension is integrated into each of its related fact classes as a full-date, *i.e.*, detailed date.

FUTURE TRENDS

We are currently verifying the completeness of the set of DM to DW schema transformation rules; the proof proceeds by induction on the schema structure. In addition, we are examining how to adapt our approach to a model-driven development approach like MDA (Model Driven Architecture) of OMG (OMG, 2002) (Mazón & Trujillo, 2007). Such an alignment will allow us to formalize better the transformations among the models. In addition, it can benefit from the decisional ontology as a starting Computation Independent Model (CIM). The decisional end-user instantiates the decisional elements from this ontology in order to formulate their particular requirements as nD-F; thus, the nD-F can be regarded as a form of Platform Independent Model (PIM). This later can be transformed, through our set of transformations, to derive a DM/DW schema.

CONCLUSION

This work lays the grounds for an automatic, systematic approach for the generation of data mart and data warehouse conceptual schemes. It proposed a standard format for OLAP requirement acquisition, and defined an algorithm that transforms automatically the OLAP requirements into multidimensional data mart schemes. In addition, it outlined the mapping rules between the data sources and the data marts schemes. Finally, it defined a set of unification rules that merge the generated data mart schemes to construct the data warehouse schema.

KEY TERMS

Decisional Ontology: A decisional ontology is a representation of knowledge dedicated to the decisional systems. It is a referential of multidimensional concepts of a field, their semantic and multidimensional relations.

Maximal Hierarchy: A hierarchy is called *maximal* if it cannot be extended upwards or downwards by including another attribute.

Multidimensional Model: data are modelled as dimensional schemes composed of a set of facts, dimensions and hierarchies. It can be either a star or a constellation.

OLAP Requirement Model: a tabular, two/n-dimensional fact sheet (2/nD-F) that describes a fact F in a domain, its measures, and its two (n) dimensions of analysis.

Parallel Entities: Two entities *E1* and *E2* are "parallel" if the set of entities related to *E1* by a one-to-one link is included in the set of entities related to *E2* by one-to-one links.

Schema Integration: Merges multidimensional schemes with a high similarity factor in order to build a constellation schema that enables drill across analyses.

Similarity Factor: a ratio that reflects the number of common dimensions between two multidimensional schemes.

INTRODUCTION

Starting with a vast number of unstructured or semi-structured documents, text mining tools analyze and sift through them to present to users more valuable information specific to their information needs. The technologies in text mining include information extraction, topic tracking, summarization, categorization/classification, clustering, concept linkage, information visualization, and question answering [Fan, Wallace, Rich, & Zhang, 2006]. In this chapter, we share our hands-on experience with one specific text mining task — text classification [Sebastiani, 2002].

Information occurs in various formats, and some formats have a specific structure or specific information that they contain: we refer to these as *`genres'*. Examples of information genres include news items, reports, academic articles, etc. In this paper, we deal with a specific genre type, course syllabus.

A course syllabus is such a genre, with the following commonly-occurring fields: title, description, instructor's name, textbook details, class schedule, etc. In essence, a course syllabus is the skeleton of a course. Free and fast access to a collection of syllabi in a structured format could have a significant impact on education, especially for educators and life-long learners. Educators can borrow ideas from others' syllabi to organize their own classes. It also will be easy for life-long learners to find popular textbooks and even important chapters when they would like to learn a course on their own. Unfortunately, searching for a syllabus on the Web using Information Retrieval [Baeza-Yates & Ribeiro-Neto, 1999] techniques employed by a generic search engine often yields too many non-relevant search result pages (i.e., noise) — some of these only provide guidelines on syllabus creation; some only provide a schedule for a course event; some have outgoing links to syllabi (e.g. a course list page of an academic department). Therefore, a well-designed classifier for the search results is needed, that would help not only to filter noise out, but also to identify more relevant and useful syllabi.

This chapter presents our work regarding automatic recognition of syllabus pages through text classification to build a syllabus collection. Issues related to the selection of appropriate features as well as classifier model construction using both generative models (Naïve Bayes – NB [John & Langley, 1995; Kim, Han, Rim, & Myaeng, 2006]) and discriminative counterparts (Support Vector Machines – SVM [Boser, Guyon, & Vapnik, 1992]) are discussed. Our results show that SVM outperforms NB in recognizing true syllabi.

BACKGROUND

There has been recent interest in collecting and studying the syllabus genre. A small set of digital library course syllabi was manually collected and carefully analyzed, especially with respect to their reading lists, in order to define the digital library curriculum [Pomerantz, Oh, Yang, Fox, & Wildemuth, 2006]. In the MIT OpenCourseWare project, 1,400 MIT course syllabi were manually collected and made publicly available, which required a lot of work by students and faculty.

Some efforts have already been devoted to automating the syllabus collection process. A syllabus acquisition approach similar to ours is described in [Matsunaga, Yamada, Ito, & Hirokaw, 2003]. However, their work differs from ours in the way syllabi are identified. They crawled Web pages from Japanese universities and sifted through them using a thesaurus with common words which occur often in syllabi. A decision tree was used to classify syllabus pages and entry pages (for example, a page containing links to all the syllabi of a particular course over time). Similarly, [Thompson, Smarr, Nguyen, & Manning, 2003] used a classification approach to classify education resources – especially syllabi, assignments, exams, and tutorials. Using the word features of each document, the authors were able to achieve very good performance (F_1 score: 0.98). However, this result is based upon their relative clean data set, only including the four kinds of education resources, which still took efforts to collect. We, on the other hand, to better apply to a variety of data domains, test and report our approach on search results for syllabi on the Web.

In addition, our genre feature selection work is also inspired by research on genre classification, which aims to classify data according to genre types by selecting features that distinguish one genre from another, i.e., identifying home pages in sets of web pages [Kennedy & Shepherd, 2005].

MAIN FOCUS

A text classification task usually can be accomplished by defining classes, selecting features, preparing a training corpus, and building a classifier. In order to build quickly an initial collection of CS syllabi, we obtained more than 8000 possible syllabus pages by programmatically searching using Google [Tungare et al., 2007]. After randomly examining the result set, we found it to contain many documents that were not truly syllabi: we refer to this as noise. To help with the task of properly identifying true syllabi, we defined true syllabi and false syllabi, and then selected features specific to the syllabus genre. We randomly sampled the collection to prepare a training corpus of size 1020. All 1020 files were in one of the following formats: HTML, PDF, PostScript, or Text. Finally, we applied Naïve Bayes, Support Vector Machines, and its variants to learn classifiers to produce the syllabus repository.

Class Definition

A syllabus component is one of the following: course code, title, class time, class location, offering institute, teaching staff, course description, objectives, web site, prerequisite, textbook, grading policy, schedule, assignment, exam, or resource. A true syllabus is a page that describes a course by including most of these syllabus components, which can be located in the current page or be obtained by following outgoing links. A false syllabus (or noise) is a page for other purposes (such as an instructor's homepage with a link to syllabi for his/her teaching purpose) instead of describing a course.

The two class labels were assigned by three team members to the 1020 samples with unanimous agreement. A skewed class distribution was observed in the sample set with 707 true syllabus and 313 false syllabus pages. We used this sample set as our training corpus.

Feature Selection

In a text classification task, a document is represented as a vector of features usually from a high dimensional space that consists of unique words occurring in documents. A good feature selection method reduces the feature space so that most learning algorithms can handle and contribute to high classification accuracy. We applied three feature selection methods in our study: general feature selection, genre-specific feature selection, and a hybrid of the two.

1. *General Features* - In a study of feature selection methods for text categorization tasks [Yang & Pedersen, 1997], the authors concluded that Document Frequency (DF) is a good choice since

its performance was similar to the one deemed best such as Information Gain and Chi Square, and it is simple and efficient. Therefore, we chose DF as our general feature selection method. In our previous work [Yu et al., 2008], we concluded that a DF threshold of 30 is a good setting to balance the computation complexity and classification accuracy. With such a feature selection setting, we obtained 1754 features from 63963 unique words in the training corpus.

2. *Genre Features* - Each defined class has its own characteristics other than general features. Many keywords such as 'grading policy' occur in a true syllabus probably along with a link to the content page. On the other hand, a false syllabus might contain syllabus keyword without enough keywords related to the syllabus components. In addition, the position of a keyword within a page matters. For example, a keyword within the anchor text of a link or around the link would suggest a syllabus component outside the current page. A capitalized keyword at the beginning of a page would suggest a syllabus component with a heading in the page. Motivated by the above observations, we manually selected 84 features to classify our data set into the four classes. We used both content and structure features for syllabus classification, as they have been found useful in the detection of other genres [Kennedy & Shepherd, 2005]. These features mainly concern the occurrence of keywords, the positions of keywords, and the co-occurrence of keywords and links. Details of these features are in [Yu et al., 2008].

After extracting free text from these documents, our training corpus consisted of 63963 unique terms, We represented it by the three kinds of feature attributes: 1754 unique general features, 84 unique genre features, and 1838 unique features in total. Each of these feature attributes has a numeric value between 0.0 and 1.0.

Classifiers

NB and SVM are two well-known best performing supervised learning models in text classification applications [Kim, Han, Rim, & Myaeng, 2006; Joachims, 1998]. NB, a simple and efficient approach, succeeds in various data mining tasks, while SVM, a highly complex one, outperforms NB especially in text mining tasks [Kim, Han, Rim, & Myaeng, 2006]. We describe them below.

1. *Naïve Bayes* - Naïve Bayes classifier can be viewed as a Bayesian network where feature attributes X_1, X_2, …, X_n are conditionally independent given the class attribute C [John & Langley, 1995]. Let C be a random variable and X be a vector of random variables X_1, X_2, …, X_n. The probability of a document *x* being in class *c* is calculated using Bayes' rule as below. The document will be classified into the most probable class.

$$p(C = c \mid X = x) = \frac{p(X = x \mid C = c)\, p(C = c)}{p(X = x)}$$

Since feature attributes (x_1, x_2, ..., x_n) represent the document *x,* and they are assumed to be conditionally independent, we can obtain the equation below.

$$p(X = x \mid C = c) = \prod_i p(X_i = x_i \mid C = c)$$

An assumption to estimate the above probabilities for numeric attributes is that the value of such an attribute follows a normal distribution within a class. Therefore, we can estimate $p(X_i = x_i \mid C = c)$ by using the mean and the standard deviation of such a normal distribution from the training data.

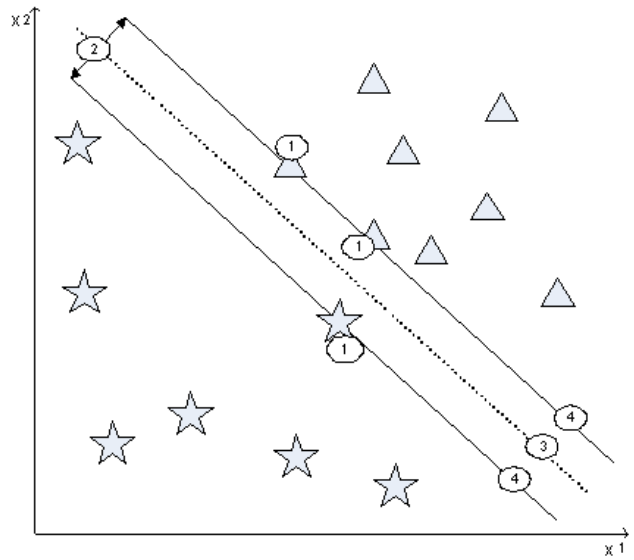
Such an assumption for the distribution may not hold for some domains. Therefore, we also applied the kernel method from [John & Langley, 1995] to estimate the distribution of each numeric attribute in our syllabus classification application.

2. *Support Vector Machines* - It is a two-class classifier (Figure 1) that finds the hyperplane maximizing the minimum distance between the hyperplane and training data points [Boser, Guyon, & Vapnik, 1992]. Specifically, the hyperplane $\omega^T x + \gamma$ is found by minimizing the objective function:

$$\frac{1}{2} \| \omega \|^2 \text{ such that } D(A\omega - e\gamma) \geq e$$

The margin is

Figure 1. Support Vector Machines where the hyperplane (3) is found to separate two classes of objects (represented here by stars and triangles, respectively) by considering the margin (i.e., distance) (2) of two support hyperplanes (4) defined by support vectors (1). An special case is depicted here that each object only has two feature variables x1 and x2.



$$\frac{2}{\|\omega\|^2}.$$

D is a vector of classes of training data, i.e., each item in *D* is +1 or −1. *A* is the matrix of feature values of training data. *e* is the vector of ones. After ω and γ are estimated from training data, a testing item *x* will be classified as +1 if

$\omega^T x + \gamma > 0$ and −1 otherwise.

The soft margin hyperplane [Cortes & Vapnik, 1995] was proposed to allow for the case where the training data points cannot be split without errors. The modified objective function is

$$\frac{1}{2}\|\omega\|^2 + \sum_i \varepsilon_i \text{ such that } D(A\omega - e\gamma) \geq e - \xi$$

where $\xi = (\varepsilon_1 \ldots \varepsilon_n)^T$ and ε_i measures the degree of misclassification of the *i*th training data point during the training. It considers minimizing the errors while maximizing the margins.

In some cases, it is not easy to find the hyperplane in the original data space, in which case the original data space has to be transformed into a higher dimensional space by applying kernels [Boser, Guyon, & Vapnik, 1992]. Common used kernels include polynomial, radial basis function, Gaussian radial basis function, and sigmoid. In our comparative study, we only tested SVM with a polynomial kernel. In addition, sequential minimal optimization (SMO) [Platt, 1999], a fast nonlinear optimization method, was employed during the training process to accelerate training.

Evaluation Results and Discussions

Evaluation Setups - We applied the classification models discussed above (five settings in total implemented with the Weka package [Witten & Frank, 2005]) on the training corpus with the three different feature sets. In the rest of this paper, we refer to the SVM implemented using the SMO simply as *'SMO'* for short; the one with the polynomial kernel as *'SMO-K'*, Naïve Bayes with numeric features estimated by Gaussian distribution as *'NB'*, and the one with kernel as *'NB-K'*. We used tenfold cross validation to estimate the classification performance as measured by F_1. Tenfold cross validation estimates the average classification performance by splitting a training corpus into ten parts and averaging the performance in ten runs, each run with nine of these as a training set and the rest as a testing set. F_1 is a measure that trades off precision and recall. It provides an overall measure of classification performance. For

each class, the definitions of the measures are as follows. A higher F_1 value indicates better classification performance.

- Precision is the percentage of the correctly classified positive examples among all the examples classified as positive.
- Recall is the percentage of the correctly classified positive examples among all the positive examples.
- $$F_1 = \frac{2 \times \Pr ecision \times \mathrm{Re} call}{\Pr ecision + \mathrm{Re} call}$$

(2) *Findings and Discussions* – The following are the main four findings from our experiments.

First, SVM outperforms NB in syllabus classification in the average case (Figure 2). On average, SMO performed best at the F_1 score of 0.87, 15% better than NB in terms of the true syllabus class and 1% better in terms of the false syllabus class. The best setting for our task is SMO with the genre feature selection method, which achieved an F_1 score of 0.88 in recognizing true syllabi and 0.71 in recognizing false syllabi.

Second, the kernel settings we tried in the experiments were not helpful in the syllabus classification task. Figure 2 indicates that SMO with kernel settings perform rather worse than that without kernels.

Third, the performance with genre features settings outperforms those with general features settings and hybrid feature settings. Figure 3 shows this performance pattern in the SMO classifier setting; other classifiers show the same pattern. We also found that the performance with hybrid features settings is dominated by the general features among them. It is probably because the number of the genre features is very small, compared to the number of general features. Therefore, it might be useful to test new ways of mixing genre features and general features to take advantage of both of them more effectively.

Finally, at all settings, better performance is achieved in recognizing true syllabi than in recognizing false syllabi. We analyzed the classification results with the best setting and found that 94 of 313 false syllabi were classified as true ones mistakenly. It is likely that the skewed distribution in the two classes makes classifiers favor true syllabus class given an error-prone data point. Since we probably provide no appropriate information if we misclassify a true syllabus as a false one, our better performance in the true syllabus class is satisfactory.

FUTURE WORK

Although general search engines such as Google meet people's basic information needs, there are still possibilities for improvement, especially with genre-specific search. Our work on the syllabus genre successfully indicates that machine learning techniques can contribute to genre-specific search and classification. In the future, we plan to improve the classification accuracy from multiple perspectives such as defining

Figure 2. Classification performance of different classifiers on different classes measured in terms of F_1

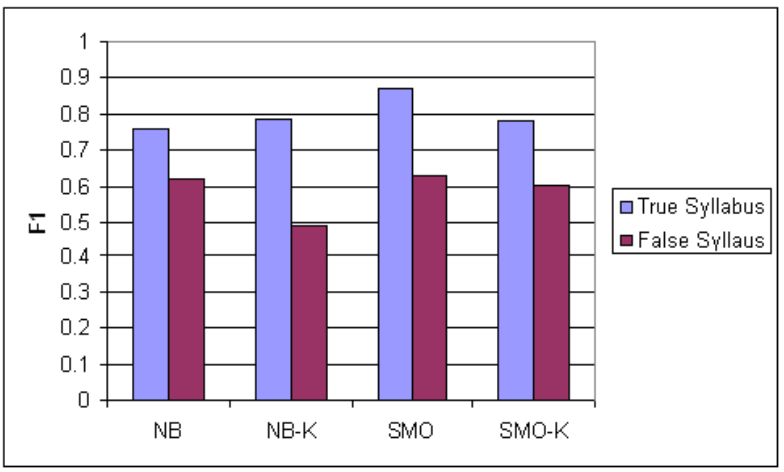


Figure 3. Classification performance of SMO on different classes using different feature selection methods measured in terms of F_1

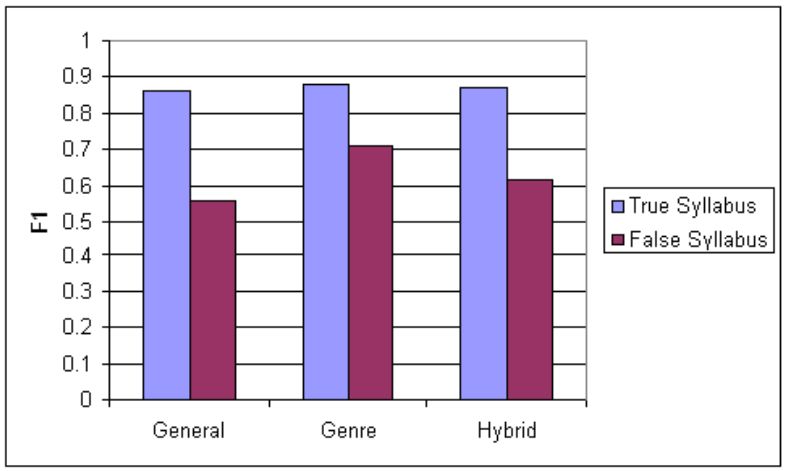

more genre-specific features and applying many more state-of-the-art classification models.

Our work on automatically identifying syllabi among a variety of publicly available documents will also help build a large-scale educational resource repository for the academic community. We are obtaining more syllabi to grow our current repository by manual submissions to our repository website, http://syllabus.cs.vt.edu, from people who would like to share their educational resources with one another.

CONCLUSION

In this chapter, we presented our work on automatically identifying syllabi from search results on the Web. We proposed features specific to the syllabus genre and compared them with general features obtained by the document frequency method. Our results showed the promising future of genre-specific feature selection methods regarding the computation complexity and improvement space. We also employed state-of-the-art machine learning techniques for automatic classification. Our results indicated that support vector machines were a good choice for our syllabus classification task.

KEY TERMS

False Syllabus: A page that does not describe a course.

Feature Selection: A method to reduce the high dimensionality of the feature space by selecting features that are more representative than others. In text classification, usually the feature space consists of unique terms occurring in the documents.

Genre: Information presented in a specific format, often with certain fields and subfields associated closely with the genre; e.g. syllabi, news reports, academic articles, etc.

Model Testing: A procedure performed after model training that applies the trained model to a different data set and evaluates the performance of the trained model.

Model Training: A procedure in supervised learning that generates a function to map inputs to desired outputs. In text classification, a function is generated to map a document represented by features into known classes.

Naïve Bayes (NB) Classifiers: A classifier modeled as a Bayesian network where feature attributes are conditionally independent of class attributes.

Support Vector Machines (SVM): A supervised machine learning approach used for classification and regression to find the hyperplane maximizing the minimum distance between the plane and the training data points.

Syllabus Component: One of the following pieces of information: course code, title, class time, class location, offering institute, teaching staff, course description,

objectives, web site, prerequisite, textbook, grading policy, schedule, assignment, exam, or resource.

Text Classification: The problem of automatically assigning predefined classes to text documents.

True Syllabus: A page that describes a course; it includes many of the syllabus components described above, which can be located in the current page or be obtained by following outgoing links.

Automatic Music Timbre Indexing

Xin Zhang
University of North Carolina at Charlotte, USA

Zbigniew W. Ras
University of North Carolina, Charlotte, USA

INTRODUCTION

Music information indexing based on timbre helps users to get relevant musical data in large digital music databases. Timbre is a quality of sound that distinguishes one music instrument from another among a wide variety of instrument families and individual categories. The real use of timbre-based grouping of music is very nicely discussed in (Bregman, 1990).

Typically, an uncompressed digital music recording, in form of a binary file, contains a header and a body. A header stores file information such as length, number of channels, rate of sample frequency, etc. Unless being manually labeled, a digital audio recording has no description on timbre, pitch or other perceptual properties. Also, it is a highly nontrivial task to label those perceptual properties for every piece of music object based on its data content. Lots of researchers have explored numerous computational methods to identify the timbre property of a sound. However, the body of a digital audio recording contains an enormous amount of integers in a time-order sequence. For example, at a sample frequency rate of 44,100Hz, a digital recording has 44,100 integers per second, which means, in a one-minute long digital recording, the total number of the integers in the time-order sequence will be 2,646,000, which makes it a very big data item. Being not in form of a record, this type of data is not suitable for most traditional data mining algorithms.

Recently, numerous features have been explored to represent the properties of a digital musical object based on acoustical expertise. However, timbre description is basically subjective and vague, and only some subjective features have well defined objective counterparts, like brightness, calculated as gravity center of the spectrum. Explicit formulation of rules of objective specification of timbre in terms of digital descriptors will formally express subjective and informal sound characteristics. It is especially important in the light of human perception of sound timbre. Time-variant information is necessary for correct classification of musical instrument sounds because quasi-steady state, where the sound vibration is stable, is not sufficient for human experts. Therefore, evolution of sound features in time should be reflected in sound description as well. The discovered temporal patterns may better express sound features than static features, especially that classic features can be very similar for sounds representing the same family or pitch, whereas changeability of features with pitch for the same instrument makes sounds of one instrument dissimilar. Therefore, classical sound features can make correct identification of musical instruments independently on the pitch very difficult and erroneous.

BACKGROUND

Automatic content extraction is clearly needed and it relates to the ability of identifying the segments of audio in which particular predominant instruments were playing. Instruments having rich timbre are known to produce overtones, which result in a sound with a group of frequencies in clear mathematical relationships (so-called harmonics). Most western instruments produce harmonic sounds. Generally, identification of musical information can be performed for audio samples taken from real recordings, representing waveform, and for MIDI (Musical Instrument Digital Interface) data. MIDI files give access to highly structured data. So, research on MIDI data may basically concentrate on higher level of musical structure, like key or metrical information. Identifying the predominant instruments, which are playing in the multimedia segments, is

even more difficult. Defined by ANSI as the attribute of auditory sensation, timbre is rather subjective: a quality of sound, by which a listener can judge that two sounds, similarly presented and having the same loudness and pitch, are different. Such definition is subjective and not of much use for automatic sound timbre classification. Therefore, musical sounds must be very carefully parameterized to allow automatic timbre recognition. There are a number of different approaches to sound timbre (Balzano, 1986; Cadoz, 1985). Dimensional approach to timbre description was proposed by (Bregman, 1990). Sets of acoustical features have been successfully developed for timbre estimation in monophonic sounds where mono instruments were playing. However, none of those features can be successfully applied to polyphonic sounds, where two or more instruments were playing at the same time, since those features represent the overlapping sound harmonics as a whole instead of individual sound sources.

This has brought the research interest into Blind Source Separation (BBS) and independent component analysis (ICA) for musical data. BBS is to estimate original sound sources based on signal observations without any knowledge on the mixing and filter procedure. ICA is to separate sounds by linear models of matrix factorization based on the assumption that each sound source is statistically independent. Based on the fact that harmonic components have significant energy, harmonics tracking together with Q-Constant Transform and Short Time Fourier Transform have been applied to sound separation (Dziubinski, Dalka and Kostek 2005; Herrera, Peeters and Dubnov 2003; Zhang and Ras 2006B). The main steps in those researches include processing polyphonic sounds into monophonic sounds, extracting features from the resultant monophonic sounds, and then performing classification.

MAIN FOCUS

Current research in timbre recognition for polyphonic sounds can be summarized into three steps: sound separation, feature extraction and classification. Sound separation has been used to process polyphonic sounds into monophonic sounds by isolating sound sources; features have been used to represent the sound behaviors in different domains; then, classification shall be performed based on the feature values by various classifiers.

Sound Separation

In a polyphonic sound with multiple pitches, multiple sets of harmonics from different instrument sources are overlapping with each other. For example, in a sound mix where a sound in 3A of clarinet and a sound in 4C of violin were played at the same time, there are two sets of harmonics: one set is distributed near several integer multiples of 440Hz; the other spreads around integer multiples of 523.25Hz. Thus, the j^{th} harmonic peak of the k^{th} instrument can be estimated by searching a local peak in the vicinity of an integer multiple of the fundamental frequency. Consequently, k predominant instruments will result in k sets of harmonic peaks. Then, we can merge the resultant sets of harmonic peaks together to form a sequence of peaks H_p^j in an ascending order by the frequency, where three possible situations should be taken into consideration for each pair of neighbor peaks: the two immediate peak neighbors are from the same sound source; the two immediate peak neighbors are from two different sound sources; part of one of the peak and the other peak are from the same sound source. The third case is due to two overlapping peaks, where the frequency is the multiplication of the fundamental frequencies of two different sound sources. In this scenario, the system first partitions the energy between the two sound sources according to the ratio of the previous harmonic peaks of those two sound sources. Therefore, only the heterogeneous peaks should be partitioned. A clustering algorithm has been used for separation of energy between two immediate heterogeneous neighbor peaks. Considering the wide range of the magnitude of harmonic peaks, we may apply a coefficient to linearly scale each pair of immediate neighbor harmonic peaks to a virtual position along the frequency axis by a ratio of the magnitude values of the two harmonic peaks. Then the magnitude of each point between the two peaks is proportionally computed in each peak. For fast computation, a threshold for the magnitude of each FFT point has been applied, where only points with significant energy had been computed by the above formulas. We assume that a musical instrument is not predominant only when its total harmonic energy is significantly smaller than the average of the total harmonic energy of all sound sources. After clustering the energy, each FFT point in the analysis window has been assigned k coefficients, for each predominant instrument accordingly.

Feature Extraction

Methods in research on automatic musical instrument sound classification go back to last few years. So far, there is no standard parameterization used as a classification basis. The sound descriptors used are based on various methods of analysis in time domain, spectrum domain, time-frequency domain and cepstrum with Fourier Transform for spectral analysis being most common, such as Fast Fourier Transform, Short-time Fourier Transform, Discrete Fourier Transform, and so on. Also, wavelet analysis gains increasing interest for sound and especially for musical sound analysis and representation. Based on recent research performed in this area, MPEG proposed an MPEG-7 standard, in which it described a set of low-level sound temporal and spectral features. However, a sound segment of note played by a music instrument is known to have at least three states: transient state, quasi-steady state and decay state. Vibration pattern in a transient state is known to significantly differ from the one in a quasi-steady state. Temporal features in differentiated states enable accurate instrument estimation.

These acoustic features can be categorized into two types in terms of size:

- **Acoustical instantaneous features in time series:** A huge matrix or vector, where data in each row describe a frame, such as Power Spectrum Flatness, and Harmonic Peaks, etc. The huge size of data in time series is not suitable for current classification algorithms and data mining approaches.
- **Statistical summation of those acoustical features:** A small vector or single value, upon which classical classifiers and analysis approaches can be applied, such as Tristimulus (Pollard and Jansson, 1982), Even/Odd Harmonics (Kostek and Wieczorkowska, 1997), averaged harmonic parameters in differentiated time domain (Zhang and Ras, 2006A), etc.

Machine Learning Classifiers

The classifiers, applied to the investigations on musical instrument recognition and speech recognition, represent practically all known methods: Bayesian Networks (Zweig, 1998; Livescu and Bilmes, 2003), Decision Tree (Quinlan, 1993; Wieczorkowska, 1999), K-Nearest Neighbors algorithm (Fujinaga and McMillan 2000; Kaminskyj and Materka 1995), Locally Weighted Regression (Atkeson and Moore, 1997), Logistic Regression Model (le Cessie and Houwelingen, 1992), Neural Networks (Dziubinski, Dalka and Kostek 2005) and Hidden Markov Model (Gillet and Richard 2005), etc. Also, hierarchical classification structures have been widely used by researchers in this area (Martin and Kim, 1998; Eronen and Klapuri, 2000), where sounds have been first categorized to different instrument families (e.g. the String Family, the Woodwind Family, the Percussion Family, etc), and then been classified into individual categories (e.g. Violin, Cello, Flute, etc.)

FUTURE TRENDS

The classification performance relies on sound items of the training dataset and the multi-pitch detection algorithms. More new temporal features in time-variation against background noise and resonance need to be investigated. Timbre detection of sounds with overlapping in homogeneous pitches from different instruments can be a very interesting and challenging area.

CONCLUSION

Timbre detection is one of the most important sub-tasks for content based indexing. In Automatic Music Timbre Indexing, timbre is estimated based on computation of the content of audio data in terms of acoustical features by machine learning classifiers. An automatic music timbre indexing system should have at least the following components: sound separation, feature extraction, and hierarchical timbre classification. We observed that sound separation based on multi-pitch trajectory significantly isolated heterogeneous harmonic sound sources in different pitches. Carefully designed temporal parameters in the differentiated time-frequency domain together with the MPEG-7 low-level descriptors have been used to briefly represent subtle sound behaviors within the entire pitch range of a group of western orchestral instruments. The results of our study also showed that Bayesian Network had a significant better performance than Decision Tree, Locally Weighted Regression and Logistic Regression Model.

KEY TERMS

Automatic Indexing: Automatically identifies precise, relevant clips of content within audio sources.

Feature Extraction: The process of generating a set of descriptors or characteristic attributes from a binary musical file.

Harmonic: A set of component pitches in mathematical relationship with the fundamental frequency.

Hierarchical Classification: Classification in a top-down order. First identify musical instrument family types, and then categorize individual or groups of instruments within the instrument family.

Machine Learning: A study of computer algorithms that improve their performance automatically based on previous results.

MPEG-7: A Multimedia Content Description Interface standardizes descriptions for audio-visual content by Moving Picture Experts Group.

Quasi-Steady State: A steady state where frequencies are in periodical patterns.

Short-Time Fourier Transform: By using an analysis window, e.g., a hamming window, signal is evaluated with elementary functions that are localized in time and frequency domains simultaneously.

Sound Separation: The process of isolating sound sources within a piece of sound.

Timbre: Describes those characteristics of sound, which allow the ear to distinguish one instrument from another.

Time-Frequency Domain: A time series of analysis windows, where patterns are described in frequency domain.

A Bayesian Based Machine Learning Application to Task Analysis

Shu-Chiang Lin
Purdue University, USA

Mark R. Lehto
Purdue University, USA

INTRODUCTION

Many task analysis techniques and methods have been developed over the past decades, but identifying and decomposing a user's task into small task components remains a difficult, impractically time-consuming, and expensive process that involves extensive manual effort (Sheridan, 1997; Liu, 1997; Gramopadhye and Thaker, 1999; Annett and Stanton, 2000; Bridger, 2003; Stammers and Shephard, 2005; Hollnagel, 2006; Luczak et al., 2006; Morgeson et al., 2006). A practical need exists for developing automated task analysis techniques to help practitioners perform task analysis efficiently and effectively (Lin, 2007). This chapter summarizes a Bayesian methodology for task analysis tool to help identify and predict the agents' subtasks from the call center's naturalistic decision making's environment.

BACKGROUND

Numerous computer-based task analysis techniques have been developed over the years (Gael, 1988; Kirwan and Ainsworth, 1992; Wickens and Hollands, 2000; Hollnagel, 2003; Stephanidis and Jacko, 2003; Diaper and Stanton, 2004; Wilson and Corlett, 2005; Salvendy, 2006; Lehto and Buck, 2008). These approaches are similar in many ways to methods of knowledge acquisition commonly used during the development of expert systems (Vicente, 1999; Schraagen et al., 2000; Elm et al., 2003; Shadbolt and Burton, 2005). Several taxonomies exist to classify knowledge elicitation approaches. For example, Lehto et al. (1992) organize knowledge elicitation methods (including 140 computer-based tools), identified in an extensive review of 478 articles, into three categories: manual methods, interactive or semi-automated methods, and automated or machine learning methods. Manual methods such as protocol analysis or knowledge organization are especially useful as an initial approach because they can be used to effectively retrieve structure and formalize knowledge components, resulting in a knowledge base that is accurate and complete (Fujihara, et al., 1997). Studies such as Trafton et al. (2000) have shown this technique can capture the essence of qualitative mental models used in complex visualization and other tasks. The drawbacks of this technique are similar to those of classic task analysis techniques in that they involve extensive manual effort and may interfere with the expert's ability to perform the task. Semi-automated methods generally utilize computer programs to simplify applications of the manual methods of knowledge acquisition. The neural network model is one of the methods in common use today, especially when learning and recognition of patterns are essential (Bhagat, 2005). A neural network can self-update its processes to provide better estimates and results with further training. However, one arguable disadvantage is that this approach may require considerable computational power should the problem be somewhat complex (Dewdney, 1997).

Automated methods or machine learning based methods primarily focus on learning from recorded data rather than through direct acquisition of knowledge from human experts. Many variations of commonly used machine learning algorithms can be found in the literature. In general, the latter approach learns from examples-guided deductive/inductive processes to infer rules applicable to other similar situations (Shalin, et al., 1988; Jagielska et al., 1999; Wong & Wang, 2003; Alpaydın, 2004; Huang et al., 2006; Bishop, 2007).

MAIN FOCUS

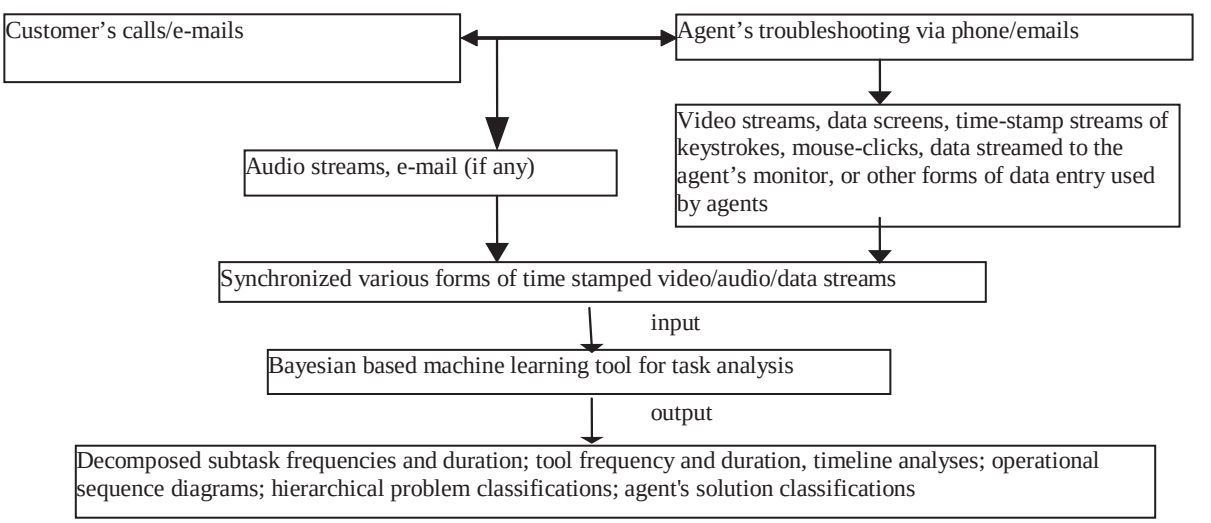
The Bayesian framework provides a potentially more applicable method of task analysis compared to competing approaches such as neural networks, natural language processing methods, or linguistic models. Two Bayesian methods are often proposed: naïve Bayes and fuzzy Bayes. Over the decades, studies such as those of Bookstein, (1985), Evans and Karwowski (1987), Lehto and Sorock (1996), Chatterjee (1998), Yamamoto and Sagisaka (1999), Zhu and Lehto (1999), Qiu and Agogino (2001), Hatakeyama et al. (2003), Zhou and Huang (2003), Leman and Lehto (2003), Wellman et al. (2004), and Bolstad (2004) have shown that statistical machine learning within the framework of fuzzy Bayes can be more efficient when the assumptions of independence are violated. McCarthy (2002) found that fuzzy Bayes gave the highest success rate for print defect classification compared to ID3, C4.5, and individual keyword comparison algorithms. Noorinaeini and Lehto (2007) compare the accuracy of three Singular Value Decomposition (SVD) based Bayesian/Regression models and conclude that all three models are capable of learning from human experts to accurately categorize cause-of-injury codes from injury narrative.

Case studies have contributed to both theoretical and empirical research in the naturalistic decision making environment (Zsambok, 1997; Klein, 1998; Todd & Gigerenzer, 2001; Hutton et al, 2003). The following discussion presents a brief case study illustrating the application of a Bayesian method to task analysis. This particular study here focuses on describing what takes place in a call center, when the customer calls to report various problems and the knowledge agent helps troubleshoot remotely. In this example, the conversation between agent and customer was recorded and manipulated to form a knowledge database as input to the Bayesian based machine learning tool.

Model Development

Figure 1 illustrates important elements of the dialog between a call center knowledge agent and customer. The arrows indicate data flow. The dialog between the customer and the knowledge agent can be recorded using several methods. For example, if the customer uses e-mail, these conversations are directly available in written form. The knowledge agent's troubleshooting processes similarly could be recorded in video streams, data screens, time-stamp streams of keystrokes, mouse-clicks, data streamed to the agent's monitor, or various forms of data entry used by agents. These data streams can be synchronized with a time-stamp as input for the Bayesian based machine learning tool.

Figure 1, Model of Bayesian based machine learning tool for task analysis[1]



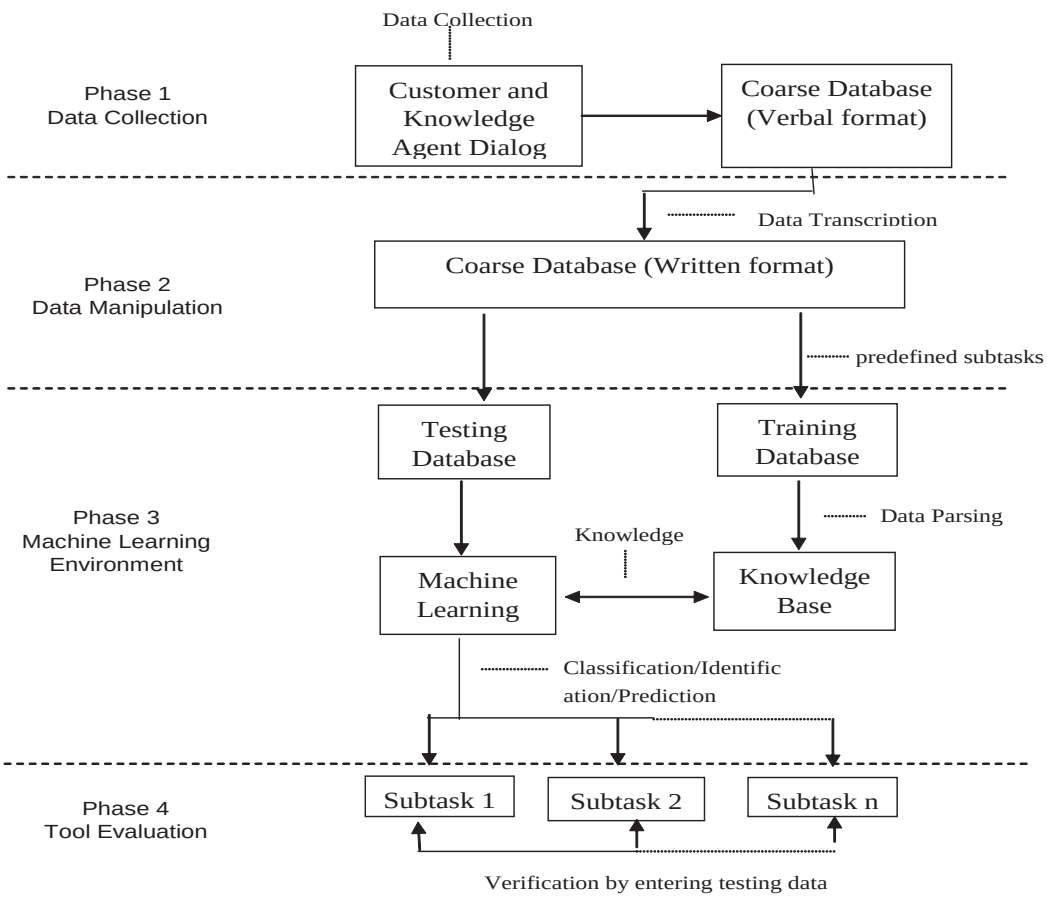
The anticipated output of the tool could be a set of decomposed subtasks/tools with associated frequencies and duration, timeline analyses, operational sequence diagrams, product hierarchical problem classifications such as software issues, hardware issues, network issues, media issues, or print quality issues, and agent solution classifications such as dispatching an on-site technician, sending out parts, or escalating the problem to the attention of product engineers. Potential benefits of this approach might include more efficient and effective integration of the human element into system operations, better allocation of task functions, human-computer interface redesigns, and revisions of agent training materials.

Methodology

As illustrated in Figure 2, the process followed to implement this methodology consists of four phases:

1. Recorded phone conversations between the customer and the knowledge agent are transcribed into a written format. Preferably this data is collected from several knowledge agents using a non-intrusive process. Following such an approach in the field will produce a large amount of realistic and naturalistic case-based information, which is unlikely to be obtained through lab-controlled methodologies that require making assumptions

Figure 2, Four phases to the development of Bayesian based machine learning tool[2]



that have arguably little face validity. Such as approach also helps balance out the effect of many biasing factors such as individual differences among the knowledge agents, unusual work activities followed by a particular knowledge agent, or sampling problems related to collecting data from only a few or particular groups of customers with specific questions.

2. The next step is to document the agents' troubleshooting process and define the subtask categories. The assigned subtasks can then be manually assigned into either the training set or testing set. Development of subtask definitions will normally require inputs from human experts. In addition to the use of transcribed verbal protocols, the analyst might consider using synchronized forms of time stamped video/audio/data streams.
3. In our particular study, the fuzzy Bayes model was developed (Lin, 2006) during the text mining process to describe the relation between the verbal protocol data and assigned subtasks. For fuzzy Bayes method, the expression below is used to classify subtasks into categories:

$$P(S_i \mid E) = MAX_j \frac{P(E_j \mid S_i)P(S_i)}{P(E_j)}$$

where $P(S_i|E)$ is the posterior probability of subtask S_i is true given the evidence E (words used by the agent and the customer) is present,
$P(E_j|S_i)$ is the conditional probability of obtaining the evidence E_j given that the subtask S_i is true,
$P(S_i)$ is the prior probability of the subtask being true prior to obtaining the evidence E_j, and
"MAX" is used to assign the maximum value of calculated $P(E_j|S_i)*P(S_i)/P(E_j)$.
When agent performs subtask A_i, words used by the agent and the customer are expressed by word vectors

$WA_i = (WA_{i1}, WA_{i2}, \ldots, WA_{iq})$ and $WC_i = (WC_{i1}, WC_{i2}, \ldots, WC_{iq})$ respectively,

where $WA_{i1}, WA_{i2}, \ldots, WA_{iq}$ are the q words in the i^{th} agent's dialog/narrative;
$WC_{i1}, WC_{i2}, \ldots, WC_{iq}$ are the q words in the i^{th} customer's dialog/narrative.
A_i is considered potentially relevant to WA_i, WC_{i-1}, and WC_i for i greater than 1.

The posterior probability of subtask A_i is calculated as follows:

$P(A_i|WA_i,WC_i,WC_{i-1})=MAX[P(WA_i|A_i)*P(A_i)/P(WA_i), P(WC_i|A_i)*P(A_i)/P(WC_i), P(WC_{i-1}|A_i)*P(A_i)/P(WC_{i-1})]$
$=MAX[MAX_j[P(WA_{ij}|A_i)*P(A_i)/P(WA_{ij})], MAX_j[P(WC_{ij}|A_i)*P(A_i)/P(WC_{ij})], MAX_j[P(WC_{(i-1)j}|A_i)*P(A_i)/P(WC_{(i-1)j})]]$ for j=1,2,….q

To develop the model, keywords were first parsed from the training set to form a knowledge base. The Bayesian based machine learning tool then learned from the knowledge base. This involved determines combinations of words appearing in the narratives that could be candidates for subtask category predictors. These words were then used to predict subtask categories, which was the output of the fuzzy Bayes model.

4. The fuzzy Bayes model was tested on the test set and the model performance was evaluated in terms of hit rate, false alarm rate, and sensitivity value. The model training and testing processes were repeated ten times to allow cross-validation of the accuracy of the predicted results. The testing results showed that the average hit rate (56.55%) was significantly greater than the average false alarm rate (0.64%), and a sensitivity value of 2.65 greater than zero.

FUTURE TRENDS

The testing results reported above suggest that the fuzzy Bayesian based model is able to learn and accurately predict subtask categories from the telephone conversation between the customers and the knowledge agents. These results are encouraging given the complexity of the tasks addressed. That is, the problem domain included 24 different agents, 55 printer models, 75 companies, 110 customers, and over 70 technical issues. Future studies are needed to further evaluate model performance that includes topics such as alternative groupings of subtasks and words, as well as use of word sequences. Other research opportunities include further development and exploration of a variety of Bayesian models, as well as comparison of model

performance to classification algorithms such as ID3 and C4.5. Researchers also might explore implementation of the Bayesian based model to other service industries. For example, in health care applications, a similar tool might be used to analyze tasks performed by clerks or nursing staff.

CONCLUSION

Bayesian based machine learning methods can be combined with classic task analysis methods to help practitioners analyze tasks. Preliminary results indicate this approach successfully learned how to predict subtasks from the telephone conversations between customers and call center agents. These results support the conclusion that Bayesian methods can serve as a practical methodology in the field of important research area of task analysis as well as other areas of naturalistic decision making.

KEY TERMS

Bayesian Inference: A type of statistical inference that uses Bayes' Rule to compute the posterior probability that the hypothesis is true, given the various sources of evidence is present.

Naïve Bayesian: A type of Bayesian inference that assumes evidences are conditionally independent given that the hypothesis is true and seeks to aggregate these evidences.

Database Indexing: A type of data structure that groups and classifies the data according to their criteria such as subject, words, and/or cross index for rapid access to records in the database.

Fuzzy Bayesian: A type of Bayesian inference that makes dependence assumptions of the evidences and reflects on the strongest evidence presented with no consideration given to negative evidence while co-occurrence of positive evidence is not aggregated.

Knowledge Acquisition: Means of extracting human thought processes as input data essential for the construction of knowledge-based systems

Machine Learning: Techniques and algorithms that allow computers to learn from recorded data rather than through direct acquisition of knowledge from human experts.

Naturalistic Decision Making: People use their experience to make decisions in field settings that often involve uncertain, dynamic, and information-rich problems with time constraints.

Task Analysis: A systematic identification and decomposition of a user's task into a number of small task components.

Text Mining: The process of parsing, filtering, categorizing, clustering, and analyzing the text to extract the relevance, usefulness, interestingness, and novelty of the text.

Behavioral Pattern–Based Customer Segmentation

Yinghui Yang
University of California, Davis, USA

INTRODUCTION

Customer segmentation is the process of dividing customers into distinct subsets (segments or clusters) that behave in the same way or have similar needs. Because each segment is fairly homogeneous in their behavior and needs, they are likely to respond similarly to a given marketing strategy. In the marketing literature, market segmentation approaches have often been used to divide customers into groups in order to implement different strategies. It has been long established that customers demonstrate heterogeneity in their product preferences and buying behaviors (Allenby & Rossi 1999) and that the model built on the market in aggregate is often less efficient than models built for individual segments. Much of this research focuses on examining how variables such as demographics, socioeconomic status, personality, and attitudes can be used to predict differences in consumption and brand loyalty. Distance-based clustering techniques, such as k-means, and parametric mixture models, such as Gaussian mixture models, are two main approaches used in segmentation. While both of these approaches have produced good results in various applications, they are not designed to segment customers based on their behavioral patterns.

There may exist natural behavioral patterns in different groups of customers or customer transactions (e.g. purchase transactions, Web browsing sessions, etc.). For example, a set of behavioral patterns that distinguish a group of wireless subscribers may be as follows: Their call duration during weekday mornings is short, and these calls are within the same geographical area. They call from outside the home area on weekdays and from the home area on weekends. They have several "data" calls on weekdays.

The above set of three behavioral patterns may be representative of a group of consultants who travel frequently and who exhibit a set of common behavioral patterns. This example suggests that there may be natural clusters in data, characterized by a set of typical behavioral patterns. In such cases, appropriate "behavioral pattern-based segmentation" approaches can constitute an intuitive method for grouping customer transactions.

BACKGROUND

The related work can be categorized into the following groups.

Market Segmentation

Since the concept emerged in the late 1950s, segmentation has been one of the most researched topics in the marketing literature. There have been two dimensions of segmentation research: segmentation bases and methods. A segmentation basis is defined as a set of variables or characteristics used to assign potential customers to homogenous groups. Research in segmentation bases focuses on identifying effective variables for segmentation, such as socioeconomic status, loyalty, and price elasticity (Frank et al 1972). Cluster analysis has historically been the most well-known method for market segmentation (Gordon 1980). Recently, much of market segmentation literature has focused on the technology of identifying segments from marketing data through the development and application of finite mixture models (see Böhning (1995) for a review). In general model-based clustering (Fraley & Raftery 1998; Fraley & Raftery 2002), the data is viewed as coming from a mixture of probability distributions, each representing a different cluster.

Pattern-Based Clustering

The definition of pattern-based clustering can vary. Some use this term to refer to clustering of patterns, e.g. pictures and signals. Others discover patterns from

the objects they are clustering and use the discovered patterns to help clustering the objects. In the second scenario, the definition of a pattern can vary as well. Wang et al (2002) considers two objects to be similar if they exhibit a coherent pattern on a subset of dimensions. The definition of a pattern is based on the correlation between attributes of objects to be clustered. Some other approaches use itemsets or association rules (Agrawal et al., 1995) as the representation of patterns. Han et al., (1997) addresses the problem of clustering-related customer transactions in a market basket database. Frequent itemsets used to generate association rules are used to construct a weighted hypergraph. Each frequent itemset is a hyperedge in the weighted hypergraph, and the weight of the hyperedge is computed as the average of the confidences for all possible association rules that can be generated from the itemset. Then, a hypergraph partitioning algorithm from Karypis et al., (1997) is used to partition the items such that the sum of the weights of hyperedges that are cut due to the partitioning is minimized. The result is a clustering of items (not transactions) that occur together in the transactions. Finally, the item clusters are used as the description of the cluster and a scoring metric is used to assign customer transactions to the best item cluster. Fung et al., (2003) used itemsets for document clustering. The intuition of their clustering criterion is that there are some frequent itemsets for each cluster (topic) in the document set, and different clusters share few frequent itemsets. A frequent itemset is a set of words that occur together in some minimum fraction of documents in a cluster. Therefore, a frequent itemset describes something common to many documents in a cluster. They use frequent itemsets to construct clusters and to organize clusters into a topic hierarchy. Yiu & Mamoulis (2003) uses projected clustering algorithms to find clusters in hidden subspaces. They realized the analogy between mining frequent itemsets and discovering the relevant subspace for a given cluster. They find projected clusters by mining frequent itemsets. Wimalasuriya et al., (2007) applies the technique of clustering based on frequent-itemsets in the domain of bio-informatics, especially to obtain clusters of genes based on Expressed Sequence Tags that make up the genes. Yuan et al., (2007) discovers frequent itemsets from image databases and feeds back discovered patterns to tune the similarity measure in clustering.

One common aspect among various pattern-based clustering methods is to define the similarity and/or the difference of objects/patterns. Then the similarity and difference are used in the clustering algorithms. The similarity and difference can be defined pairwise (between a pair of objects), or globally (e.g. within a cluster or between clusters). In the main focus section, we focus on the ones that are defined globally and discuss how these pattern-based clustering methods can be used for segmenting customers based on their behavioral patterns.

MAIN FOCUS OF THE CHAPTER

Segmenting Customers Based on Behavioral Patterns

The systematic approach to segment customers or customer transactions based on behavioral patterns is one that clusters customer transactions such that behavioral patterns generated from each cluster, while similar to each other within the cluster, are very different from the behavioral patterns generated from other clusters. Different domains may have different representations for what behavioral patterns are and for how to define similarity and difference between sets of behavioral patterns. In the wireless subscribers example described in the introduction, rules are an effective representation for behavioral patterns generated from the wireless call data; however, in a different domain, such as time series data on stock prices, representations for patterns may be based on "shapes" in the time series. It is easy to see that traditional distance-based clustering techniques and mixture models are not well suited to learning clusters for which the fundamental characterization is a set of patterns such as the ones above.

One reason that behavioral pattern-based clustering techniques can generate natural clusters from customer transactions is that such transactions often have natural categories that are not directly observable from the data. For example, Web transactions may be for work, for entertainment, shopping for self, shopping for gifts, transactions made while in a happy mood and so forth. But customers do not indicate the situation they are in before starting a transaction. However, the set of patterns corresponding to transactions in each category will be different. Transactions at work may be quicker and more focused, while transactions for entertainment may be long and across a broader set of sites. Hence, grouping transactions such that the patterns generated

from each cluster are very different from those generated from another cluster may be an effective method for learning the natural categorizations.

Behavioral Pattern Representation: Itemset

Behavioral patterns first need to be represented properly before they can be used for clustering. In many application domains, itemset is a reasonable representation for behavioral patterns. We illustrate how to use itemsets to represent behavioral patterns by using Web browsing data as an example. Assume we are analyzing Web data at a session level (continuous clicks are grouped together to form a session for the purpose of data analysis.). Features are first created to describe the session. The features can include those about time (e.g., average time spent per page), quantity (e.g., number of sites visited), and order of pages visited (e.g., first site) and therefore include both categorical and numeric types. A conjunction of atomic conditions on these attributes (an "itemset") is a good representation for common behavioral patterns in the Web data. For example, {starting_time = morning, average_time_page < 2 minutes, num_cate gories = 3, total_time < 10 minutes} is a behavioral pattern that may capture a user's specific "morning" pattern of Web usage that involves looking at multiple sites (e.g., work e-mail, news, finance) in a focused manner such that the total time spent is low. Another common pattern for this (same) user may be {starting_time = night, most_visted_category = games}, reflecting the user's typical behavior at the end of the day.

Behavioral patterns from other domains (e.g. shopping patterns in grocery stores) can be represented in a similar fashion. The attribute and value pair (starting_time = morning) can be treated as an item, and the combination of such items form an itemset (or a pattern). When we consider a cluster that contains objects with similar behavior patterns, we expect these objects in the cluster share many patterns (a list of itemsets).

Clustering Based on Frequent Itemsets

Clustering based on frequent-itemsets is recognized as a distinct technique and is often categorized under frequent-pattern based clustering methods (Han & Kamber 2006). Even though not a lot of existing research in this area addresses the problem of clustering based on behavioral patterns, the methods can potentially be modified for this purpose. Wang et al (1999) introduces a clustering criterion suggesting that there should be many large items within a cluster and little overlapping of such items across clusters. They then use this criterion to search for a good clustering solution. Wang et al (1999) also points out that, for transaction data, methods using pairwise similarity, such as k-means, have problems in forming a meaningful cluster. For transactions that come naturally in collection of items, it is more meaningful to use item/rule-based methods. Since we can represent behavioral patterns into a collection of items, we can potentially modify Wang et al (1999) so that there are many large items within a cluster and little overlapping of such items across clusters. Yang et al (2002) addresses a similar problem as that in Wang et al (1999), and does not use any pairwise distance function. They study the problem of categorical data clustering and propose a global criterion function that tries to increase the intra-cluster overlapping of transaction items by increasing the height-to-width ratio of the cluster histogram. The drawback of Wang et al (1999) and Yang et al (2002) for behavioral pattern based clustering is that they are not able to generate a set of large itemsets (a collection of behavioral patterns) within a cluster. Yang & Padmanabhan (2003, 2005) define a global goal and use this goal to guide the clustering process. Compared to Wang et al (1999) and Yang et al (2002), Yang & Padmanabhan (2003, 2005) take a new perspective of associating itemsets with behavior patterns and using that concept to guide the clustering process. Using this approach, distinguishing itemsets are identified to represent a cluster of transactions. As noted previously in this chapter behavioral patterns describing a cluster are represented by a set of itemsets (for example, a set of two itemsets {weekend, second site = eonline.com} and {weekday, second site = cnbc.com}. Yang & Padmanabhan (2003, 2005) allow the possibility to find a set of itemsets to describe a cluster instead of just a set of items, which is the focus of other item/itemsets-related work. In addition, the algorithms presented in Wang et al (1999) and Yang et al (2002) are very sensitive to the initial seeds that they pick, while the clustering results in Yang & Padmanabhan (2003, 2005) are stable. Wang et al (1999) and Yang et al (2002) did not use the concept of pattern difference and similarity.

The Framework for Behavioral Pattern-Based Clustering

Consider a collection of customer transactions to be clustered $\{ T_1, T_2, \ldots, T_n \}$. A clustering C is a partition $\{ C_1, C_2, \ldots, C_k \}$ of $\{ T_1, T_2, \ldots, T_n \}$ and each C_i is a cluster. The goal is to maximize the difference between clusters and the similarity of transactions within clusters. In words, we cluster to maximize a quantity M, where M is defined as follows:

$$M(C_1, C_2, ..., C_k) = Difference\ (C_1, C_2, ..., C_k) + \sum_{i=1}^{k} Similarity\ (C_i)$$

Here we only give specific definition for the difference between two clusters. This is sufficient, since hierarchical clustering techniques can be used to cluster the transactions repeatedly into two groups in such a way that the process results in clustering the transactions into an arbitrary number of clusters (which is generally desirable because the number of clusters does not have to be specified up front). The exact definition of difference and similarity will depend on the specific representation of behavioral patterns. Yang & Padmanabhan (2003, 2005) focus on clustering customers' Web transactions and uses itemsets as the representation of behavioral patterns. With the representation given, the difference and similarity between two clusters are defined as follows:

For each pattern P_a considered, we calculate the support of this pattern in cluster C_i and the support of the pattern in cluster C_j, then compute the relative difference between these two support values and aggregate these relative differences across all patterns. The support of a pattern in a cluster is the proportion of the transactions containing that pattern in the cluster. The intuition behind the definition of difference is that the support of the patterns in one cluster should be different from the support of the patterns in the other cluster if the underlying behavioral patterns are different. Here we use the relative difference between two support values instead of the absolute difference. Yang & Padmanabhan (2007) proves that under certain natural distributional assumptions the difference metric above is maximized when the correct clusters are discovered.

Here, the goal of the similarity measure is to capture how similar transactions are *within* each cluster. The heuristic is that, if transactions are more similar to each other, then they can be assumed to share more patterns. Hence, one approach is to use the number of strong patterns generated as a proxy for the similarity. If itemsets are used to represent patterns, then the number of frequent itemsets in a cluster can be used as a proxy for similarity.

The Clustering Algorithm

The ideal algorithm will be one that maximizes M (defined in previous section). However, for the objective function defined above, if there are n transactions and two clusters that we are interested in learning, the number of possible clustering schemes to examine is 2^n. Hence, a heuristic approach is called for. Yang & Padmanabhan (2003, 2005) provide two different clustering algorithms. The main heuristic used in the hierarchical algorithm presented in Yang & Padmanabhan (2005) is as follows. For each pattern, the data is divided into two parts such that all records containing that pattern are in one cluster and the remaining are in the other cluster. The division maximizing the global objective M is chosen. Further divisions are conducted following similar heuristic. The experiments in Yang & Padmanabhan (2003, 2005) indicate that the behavioral pattern-based customer segmentation approach is highly effective.

FUTURE TRENDS

Firms are increasingly realizing the importance of understanding and leveraging customer-level data, and critical business decision models are being built upon analyzing such data. Nowadays, massive amount of data is being collected for customers reflecting their behavioral patterns, so the practice of analyzing such data to identify behavioral patterns and using the patterns discovered to facilitate decision making is becoming more and more popular. Utilizing behavioral patterns for segmentation, classification, customer retention, targeted marketing, etc. is on the research agenda. For different application domains, the representations of behavioral patterns can be different. Different algorithms need to be designed for different pattern representations in different domains. Also, given the representation of the behavioral patterns, similarity and difference may also need to be defined differently. These all call for more research in this field.

CONCLUSION

As mentioned in the introduction, the existence of natural categories of customer behavior is intuitive, and these categories influence the transactions observed. Behavioral pattern-based clustering techniques, such as the one described in this chapter, can be effective in learning such natural categories and can enable firms to understand their customers better and build more accurate customer models. A notable strength of the behavioral pattern-based approach is the ability to explain the clusters and the differences between clusters.

KEY TERMS

Customer/Market Segmentation: The process of dividing customers/market into distinct subsets (segments) that behave in the same way or have similar needs.

Gaussian Mixture Models: A method used for clustering. It assumes that data comes from a distribution that is a combination of several Gaussian distributions.

Itemset: A set of items. It's often used in association rule mining. The occurrence frequency of an itemset (a set of items) is the number of transactions that contain the itemset. A frequent itemset is one that occurs often (with high frequency or support).

K-Means Clustering Algorithm: An algorithm to cluster objects based on attributes into k partitions. It assigns each object to the cluster whose center is nearest. It follows several iterations of assignments until convergence.

Model-Based Clustering: A type of clustering method. The data is viewed as coming from a mixture of probability distributions, each representing a different cluster.

Segmentation Basis: A segmentation basis is defined as a set of variables or characteristics used to assign potential customers to homogenous groups.

Web Browsing Sessions: A Web browsing session contains a list of consecutive clicks within a span of 30 minutes.

Best Practices in Data Warehousing

Les Pang
University of Maryland University College, USA

INTRODUCTION

Data warehousing has been a successful approach for supporting the important concept of knowledge management—one of the keys to organizational success at the enterprise level. Based on successful implementations of warehousing projects, a number of lessons learned and best practices were derived from these project experiences. The scope was limited to projects funded and implemented by federal agencies, military institutions and organizations directly supporting them.

Projects and organizations reviewed include the following:

- Census 2000 Cost and Progress System
- Defense Dental Standard System
- Defense Medical Logistics Support System Data Warehouse Program
- Department of Agriculture Rural Development Data Warehouse
- Department of Defense (DoD) Computerized Executive Information System
- Department of Energy, Lawrence Livermore National Laboratory, Enterprise Reporting Workbench
- Department of Health and Human Services, Health Care Financing Administration (HFCA) Teraplex Integration Center
- Environmental Protection Agency (EPA) Envirofacts Warehouse
- Federal Bureau of Investigation (FBI) Investigative Data Warehouse
- Federal Credit Union
- Internal Revenue Service (IRS) Compliance Data Warehouse
- Securities and Exchange Commission (SEC) Data Warehouse
- U.S. Army Operational Testing and Evaluation Command
- U.S. Coast Guard Executive Information System
- U.S. Navy Type Commander's Readiness Management System

BACKGROUND

Data warehousing involves the consolidation of data from various transactional data sources in order to support the strategic needs of an organization. This approach links the various silos of data that is distributed throughout an organization. By applying this approach, an organization can gain significant competitive advantages through the new level of corporate knowledge.

Various agencies in the Federal Government attempted to implement a data warehousing strategy in order to achieve data interoperability. Many of these agencies have achieved significant success in improving internal decision processes as well as enhancing the delivery of products and services to the citizen. This chapter aims to identify the best practices that were implemented as part of the successful data warehousing projects within the federal sector.

MAIN THRUST

Each best practice (indicated in **boldface**) and its rationale are listed below. Following each practice is a description of illustrative project or projects (indicated in *italics*), which support the practice.

Ensure the Accuracy of the Source Data to Maintain the User's Trust of the Information in a Warehouse

The user of a data warehouse needs to be confident that the data in a data warehouse is timely, precise, and complete. Otherwise, a user that discovers suspect data in warehouse will likely cease using it, thereby reduc-

ing the return on investment involved in building the warehouse. Within government circles, the appearance of suspect data takes on a new perspective.

HUD Enterprise Data Warehouse - Gloria Parker, HUD Chief Information Officer, spearheaded data warehousing projects at the Department of Education and at HUD. The HUD warehouse effort was used to profile performance, detect fraud, profile customers, and do "what if" analysis. Business areas served include Federal Housing Administration loans, subsidized properties, and grants. She emphasizes that the *public trust* of the information is critical. Government agencies do not want to jeopardize our public trust by putting out bad data. Bad data will result in major ramifications not only from citizens but also from the government auditing arm, the General Accounting Office, and from Congress (Parker, 1999).

EPA Envirofacts Warehouse - The Envirofacts data warehouse comprises of information from 12 different environmental databases for facility information, including toxic chemical releases, water discharge permit compliance, hazardous waste handling processes, Superfund status, and air emission estimates. Each program office provides its own data and is responsible for maintaining this data. Initially, the Envirofacts warehouse architects noted some data integrity problems, namely, issues with accurate data, understandable data, properly linked data and standardized data. The architects had to work hard to address these key data issues so that the public can trust that the quality of data in the warehouse (Garvey, 2003).

U.S. Navy Type Commander Readiness Management System – The Navy uses a data warehouse to support the decisions of its commanding officers. Data at the lower unit levels is aggregated to the higher levels and then interfaced with other military systems for a joint military assessment of readiness as required by the Joint Chiefs of Staff. The Navy found that it was spending too much time to determine its readiness and some of its reports contained incorrect data. The Navy developed a user friendly, Web-based system that provides quick and accurate assessment of readiness data at all levels within the Navy. "The system collects, stores, reports and analyzes mission readiness data from air, sub and surface forces" for the Atlantic and Pacific Fleets. Although this effort was successful, the Navy learned that data originating from the lower levels still needs to be accurate. The reason is that a number of legacy systems, which serves as the source data for the warehouse, lacked validation functions (Microsoft, 2000).

Standardize the Organization's Data Definitions

A key attribute of a data warehouse is that it serves as "a single version of the truth." This is a significant improvement over the different and often conflicting versions of the truth that come from an environment of disparate silos of data. To achieve this singular version of the truth, there needs to be consistent definitions of data elements to afford the consolidation of common information across different data sources. These consistent data definitions are captured in a data warehouse's metadata repository.

DoD Computerized Executive Information System (CEIS) is a 4-terabyte data warehouse holds the medical records of the 8.5 million active members of the U.S. military health care system who are treated at 115 hospitals and 461 clinics around the world. The Defense Department wanted to convert its fixed-cost health care system to a managed-care model to lower costs and increase patient care for the active military, retirees and their dependents. Over 12,000 doctors, nurses and administrators use it. Frank Gillett, an analyst at Forrester Research, Inc., stated that, "What kills these huge data warehouse projects is that the human beings don't agree on the definition of data. Without that . . . all that $450 million [cost of the warehouse project] could be thrown out the window" (Hamblen, 1998).

Be Selective on What Data Elements to Include in the Warehouse

Users are unsure of what they want so they place an excessive number of data elements in the warehouse. This results in an immense, unwieldy warehouse in which query performance is impaired.

Federal Credit Union - The data warehouse architect for this organization suggests that users know which data they use most, although they will not always admit to what they use least (Deitch, 2000).

Select the Extraction-Transformation-Loading (ETL) Strategy Carefully

Having an effective ETL strategy that extracts data from the various transactional systems, transforms the data to a common format, and loads the data into a relational or multidimensional database is the key to a successful data warehouse project. If the ETL strategy is not effective, it will mean delays in refreshing the data warehouse, contaminating the data warehouse with dirty data, and increasing the costs in maintaining the warehouse.

IRS Compliance Warehouse supports research and decision support, allows the IRS to analyze, develop, and implement business strategies for increasing voluntary compliance, improving productivity and managing the organization. It also provides projections, forecasts, quantitative analysis, and modeling. Users are able to query this data for decision support.

A major hurdle was to transform the large and diverse legacy online transactional data sets for effective use in an analytical architecture. They needed a way to process custom hierarchical data files and convert to ASCII for local processing and mapping to relational databases. They ended up with developing a script program that will do all of this. ETL is a major challenge and may be a "showstopper" for a warehouse implementation (Kmonk, 1999).

Leverage the Data Warehouse to Provide Auditing Capability

An overlooked benefit of data warehouses is its capability of serving as an archive of historic knowledge that can be used as an audit trail for later investigations.

U.S. Army Operational Testing and Evaluation Command (OPTEC) is charged with developing test criteria and evaluating the performance of extremely complex weapons equipment in every conceivable environment and condition. Moreover, as national defense policy is undergoing a transformation, so do the weapon systems, and thus the testing requirements. The objective of their warehouse was to consolidate a myriad of test data sets to provide analysts and auditors with access to the specific information needed to make proper decisions.

OPTEC was having "fits" when audit agencies, such as the General Accounting Office (GAO), would show up to investigate a weapon system. For instance, if problems with a weapon show up five years after it is introduced into the field, people are going to want to know what tests were performed and the results of those tests. A warehouse with its metadata capability made data retrieval much more efficient (Microsoft, 2000).

Leverage the Web and Web Portals for Warehouse Data to Reach Dispersed Users

In many organizations, users are geographically distributed and the World Wide Web has been very effective as a gateway for these dispersed users to access the key resources of their organization, which include data warehouses and data marts.

U.S. Army OPTEC developed a Web-based front end for its warehouse so that information can be entered and accessed regardless of the hardware available to users. It supports the geographically dispersed nature of OPTEC's mission. Users performing tests in the field can be anywhere from Albany, New York to Fort Hood, Texas. That is why the browser client the Army developed is so important to the success of the warehouse (Microsoft, 2000).

DoD Defense Dental Standard System supports more than 10,000 users at 600 military installations worldwide. The solution consists of three main modules: Dental Charting, Dental Laboratory Management, and Workload and Dental Readiness Reporting. The charting module helps dentists graphically record patient information. The lab module automates the workflow between dentists and lab technicians. The reporting module allows users to see key information though Web-based online reports, which is a key to the success of the defense dental operations.

IRS Compliance Data Warehouse includes a Web-based query and reporting solution that provides high-value, easy-to-use data access and analysis capabilities, be quickly and easily installed and managed, and scale to support hundreds of thousands of users. With this portal, the IRS found that portals provide an effective way to access diverse data sources via a single screen (Kmonk, 1999).

Make Warehouse Data Available to All Knowledgeworkers (Not Only to Managers)

The early data warehouses were designed to support upper management decision-making. However, over time, organizations have realized the importance of knowledge sharing and collaboration and its relevance to the success of the organizational mission. As a result, upper management has become aware of the need to disseminate the functionality of the data warehouse throughout the organization.

IRS Compliance Data Warehouse supports a diversity of user types—economists, research analysts, and statisticians—all of whom are searching for ways to improve customer service, increase compliance with federal tax laws and increase productivity. It is not just for upper management decision making anymore (Kmonk, 1999).

Supply Data in a Format Readable by Spreadsheets

Although online analytical tools such as those supported by Cognos and Business Objects are useful for data analysis, the spreadsheet is still the basic tool used by most analysts.

U.S. Army OPTEC wanted users to transfer data and work with information on applications that they are familiar with. In OPTEC, they transfer the data into a format readable by spreadsheets so that analysts can really crunch the data. Specifically, pivot tables found in spreadsheets allows the analysts to manipulate the information to put meaning behind the data (Microsoft, 2000).

Restrict or Encrypt Classified/Sensitive Data

Depending on requirements, a data warehouse can contain confidential information that should not be revealed to unauthorized users. If privacy is breached, the organization may become legally liable for damages and suffer a negative reputation with the ensuing loss of customers' trust and confidence. Financial consequences can result.

DoD Computerized Executive Information System uses an online analytical processing tool from a popular vendor that could be used to restrict access to certain data, such as HIV test results, so that any confidential data would not be disclosed (Hamblen, 1998). Considerations must be made in the architecting of a data warehouse. One alternative is to use a roles-based architecture that allows access to sensitive data by only authorized users and the encryption of data in the event of data interception.

Perform Analysis During the Data Collection Process

Most data analyses involve completing data collection before analysis can begin. With data warehouses, a new approach can be undertaken.

Census 2000 Cost and Progress System was built to consolidate information from several computer systems. The data warehouse allowed users to perform analyses during the data collection process; something was previously not possible. The system allowed executives to take a more proactive management role. With this system, Census directors, regional offices, managers, and congressional oversight committees have the ability to track the 2000 census, which never been done before (SAS, 2000).

Leverage User Familiarity with Browsers to Reduce Training Requirements

The interface of a Web browser is very familiar to most employees. Navigating through a learning management system using a browser may be more user friendly than using the navigation system of a proprietary training software.

U.S. Department of Agriculture (USDA) Rural Development, Office of Community Development, administers funding programs for the Rural Empowerment Zone Initiative. There was a need to tap into legacy databases to provide accurate and timely rural funding information to top policy makers. Through Web accessibility using an intranet system, there were dramatic improvements in financial reporting accuracy and timely access to data. Prior to the intranet, questions such as "What were the Rural Development investments in 1997 for the Mississippi Delta region?" required weeks of laborious data gathering and analysis, yet yielded obsolete answers with only an 80 percent accuracy factor. Now, similar analysis takes only a few minutes to perform, and the accuracy of the data is as

high as 98 percent. More than 7,000 Rural Development employees nationwide can retrieve the information at their desktops, using a standard Web browser. Because employees are familiar with the browser, they did not need training to use the new data mining system (Ferris, 2003).

Use Information Visualization Techniques Such as Geographic Information Systems (GIS)

A GIS combines layers of data about a physical location to give users a better understanding of that location. GIS allows users to view, understand, question, interpret, and visualize data in ways simply not possible in paragraphs of text or in the rows and columns of a spreadsheet or table.

EPA Envirofacts Warehouse includes the capability of displaying its output via the EnviroMapper GIS system. It maps several types of environmental information, including drinking water, toxic and air releases, hazardous waste, water discharge permits, and Superfund sites at the national, state, and county levels (Garvey, 2003). Individuals familiar with Mapquest and other online mapping tools can easily navigate the system and quickly get the information they need.

Leverage a Data Warehouse to Support Disaster Recovery

A warehouse can serve as a centralized repository of key data that can be backed up and secured to ensure business continuity in the event of a disaster.

The *Securities and Exchange Commission* (SEC) tracks daily stock transactions for the entire country. To manage this transactional data, the agency established a disaster recovery architecture that is based on a data warehouse. (Sybase Corporation, 2007)

Provide a Single Access Point to Multiple Sources of Data as part of the War Against Terrorism

A data warehouse can be used in the war against terrorism by bring together a collection of diverse data thereby allowing authorities to "connect the dots," e.g., identify associations, trends and anomalies.

The FBI uses its *Investigative Data Warehouse* to access more than 47 sources of counterterrorism data including file information from the FBI and other agencies as well as public sources. The FBI's warehouse includes a feature called "alert capability" which automatically notifies users when a newly uploaded document meets their search criteria. (Federal Bureau of Investigation, 2007).

Involve the Users when Identifying Warehousing Requirements

Users were asked for their requirements for the health-care-based data warehousing by surveying business users at the Health Care Financing Administration. Specifically, sample queries were identified such as: Of the total number of hip fractures in a given year, how many patients had surgery? Of those who had surgery, how many had infections?

By being more responsive to user needs, this led to the successful launch of HCFA's *Teraplex Integration Center*. (Makulowich, 1999)

Use a Modular Architecture to Respond to Changes

The data warehouse is a dynamic structure that changes due to new requirements. A monolithic architecture often mean changes throughout the data warehousing structure. By using a modular architecture instead, one can isolate where changes are needed.

Lawrence Livermore National Laboratory of the Department of Energy uses a modular architecture for its *Enterprise Reporting Workbench Data Architecture* to maximize flexibility, control and self-sufficiency. (The Data Warehouse Institute, 2007).

FUTURE TRENDS

Data warehousing will continue to grow as long as there are disparate silos of data sources throughout an organization. However, the irony is that there will be a proliferation of data warehouses as well as data marts, which will not interoperate within an organization. Some experts predict the evolution toward a federated architecture for the data warehousing environment. For example, there will be a common staging area for

data integration and, from this source, data will flow among several data warehouses. This will ensure that the "single truth" requirement is maintained throughout the organization (Hackney, 2000).

Another important trend in warehousing is one away from historic nature of data in warehouses and toward real-time distribution of data so that information visibility will be instantaneous (Carter, 2004). This is a key factor for business decision-making in a constantly changing environment. Emerging technologies, namely service-oriented architectures and Web services, are expected to be the catalyst for this to occur.

CONCLUSION

An organization needs to understand how it can leverage data from a warehouse or mart to improve its level of service and the quality of its products and services. Also, the organization needs to recognize that its most valuable resource, the workforce, needs to be adequately trained in accessing and utilizing a data warehouse. The workforce should recognize the value of the knowledge that can be gained from data warehousing and how to apply it to achieve organizational success.

A data warehouse should be part of an enterprise architecture, which is a framework for visualizing the information technology assets of an enterprise and how these assets interrelate. It should reflect the vision and business processes of an organization. It should also include standards for the assets and interoperability requirements among these assets.

KEY TERMS

ASCII: American Standard Code for Information Interchange. Serves a code for representing English characters as numbers with each letter assigned a number from 0 to 127.

Data Warehousing: A compilation of data designed to for decision support by executives, managers, analysts and other key stakeholders in an organization. A data warehouse contains a consistent picture of business conditions at a single point in time.

Database: A collection of facts, figures, and objects that is structured so that it can easily be accessed, organized, managed, and updated.

Enterprise Architecture: A business and performance-based framework to support cross-agency collaboration, transformation, and organization-wide improvement.

Extraction-Transformation-Loading (ETL): A key transitional set of steps in migrating data from the source systems to the database housing the data warehouse. Extraction refers to drawing out the data from the source system, transformation concerns converting the data to the format of the warehouse and loading involves storing the data into the warehouse.

Geographic Information Systems: Map-based tools used to gather, transform, manipulate, analyze, and produce information related to the surface of the Earth.

Hierarchical Data Files: Database systems that are organized in the shape of a pyramid with each row of objects linked to objects directly beneath it. This approach has generally been superceded by relationship database systems.

Knowledge Management: A concept where an organization deliberately and comprehensively gathers, organizes, and analyzes its knowledge, then shares it internally and sometimes externally.

Legacy System: Typically, a database management system in which an organization has invested considerable time and money and resides on a mainframe or minicomputer.

Outsourcing: Acquiring services or products from an outside supplier or manufacturer in order to cut costs and/or procure outside expertise.

Performance Metrics: Key measurements of system attributes that is used to determine the success of the process.

Pivot Tables: An interactive table found in most spreadsheet programs that quickly combines and compares typically large amounts of data. One can rotate its rows and columns to see different arrangements of the source data, and also display the details for areas of interest.

Terabyte: A unit of memory or data storage capacity equal to roughly 1,000 gigabytes.

Total Cost of Ownership: Developed by Gartner Group, an accounting method used by organizations seeking to identify their both direct and indirect systems costs.

Bibliomining for Library Decision-Making

Scott Nicholson
Syracuse University School of Information Studies, USA

Jeffrey Stanton
Syracuse University School of Information Studies, USA

INTRODUCTION

Most people think of a library as the little brick building in the heart of their community or the big brick building in the center of a college campus. However, these notions greatly oversimplify the world of libraries. Most large commercial organizations have dedicated in-house library operations, as do schools; nongovernmental organizations; and local, state, and federal governments. With the increasing use of the World Wide Web, digital libraries have burgeoned, serving a huge variety of different user audiences. With this expanded view of libraries, two key insights arise. First, libraries are typically embedded within larger institutions. Corporate libraries serve their corporations, academic libraries serve their universities, and public libraries serve taxpaying communities who elect overseeing representatives. Second, libraries play a pivotal role within their institutions as repositories and providers of information resources. In the provider role, libraries represent in microcosm the intellectual and learning activities of the people who comprise the institution. This fact provides the basis for the strategic importance of library data mining: By ascertaining what users are seeking, bibliomining can reveal insights that have meaning in the context of the library's host institution.

Use of data mining to examine library data might be aptly termed *bibliomining.* With widespread adoption of computerized catalogs and search facilities over the past quarter century, library and information scientists have often used bibliometric methods (e.g., the discovery of patterns in authorship and citation within a field) to explore patterns in bibliographic information. During the same period, various researchers have developed and tested *data-mining techniques,* which are advanced statistical and visualization methods to locate nontrivial patterns in large datasets. Bibliomining refers to the use of these bibliometric and data-mining techniques to explore the enormous quantities of data generated by the typical automated library.

BACKGROUND

Forward-thinking authors in the field of library science began to explore sophisticated uses of library data some years before the concept of data mining became popularized. Nutter (1987) explored library data sources to support decision making but lamented that "the ability to collect, organize, and manipulate data far outstrips the ability to interpret and to apply them" (p. 143). Johnston and Weckert (1990) developed a data-driven expert system to help select library materials, and Vizine-Goetz, Weibel, and Oskins (1990) developed a system for automated cataloging based on book titles (see also Morris, 1992, and Aluri & Riggs, 1990). A special section of *Library Administration and Management*, "Mining your automated system," included articles on extracting data to support system management decisions (Mancini, 1996), extracting frequencies to assist in collection decision making (Atkins, 1996), and examining transaction logs to support collection management (Peters, 1996).

More recently, Banerjeree (1998) focused on describing how data mining works and how to use it to provide better access to the collection. Guenther (2000) discussed data sources and bibliomining applications but focused on the problems with heterogeneous data formats. Doszkocs (2000) discussed the potential for applying neural networks to library data to uncover possible associations between documents, indexing terms, classification codes, and queries. Liddy (2000) combined natural language processing with text mining to discover information in digital library collections. Lawrence, Giles, and Bollacker (1999) created a system to retrieve and index citations from works in digital libraries. Gutwin, Paynter, Witten, Nevill-Manning, and Frank (1999) used text mining to support resource discovery.

These projects all shared a common focus on improving and automating two of the core functions of a library: acquisitions and collection management. A few

authors have recently begun to address the need to support management by focusing on understanding library users: Schulman (1998) discussed using data mining to examine changing trends in library user behavior; Sallis, Hill, Jancee, Lovette, and Masi (1999) created a neural network that clusters digital library users; and Chau (2000) discussed the application of Web mining to personalize services in electronic reference.

The December 2003 issue of *Information Technology and Libraries* was a special issue dedicated to the bibliomining process. Nicholson presented an overview of the process, including the importance of creating a data warehouse that protects the privacy of users. Zucca discussed the implementation of a data warehouse in an academic library. Wormell; Suárez-Balseiro, Iribarren-Maestro, & Casado; and Geyer-Schultz, Neumann, & Thede used bibliomining in different ways to understand the use of academic library sources and to create appropriate library services.

We extend these efforts by taking a more global view of the data generated in libraries and the variety of decisions that those data can inform. Thus, the focus of this work is on describing ways in which library and information managers can use data mining to understand patterns of behavior among library users and staff and patterns of information resource use throughout the institution.

MAIN THRUST

Integrated Library Systems and Data Warehouses

Most managers who wish to explore bibliomining will need to work with the technical staff of their Integrated Library System (ILS) vendors to gain access to the databases that underlie the system and create a data warehouse. The cleaning, preprocessing, and anonymizing of the data can absorb a significant amount of time and effort. Only by combining and linking different data sources, however, can managers uncover the hidden patterns that can help them understand library operations and users.

Exploration of Data Sources

Available library data sources are divided into three groups for this discussion: data from the *creation of the library,* data from the *use of the collection,* and data *from external sources* not normally included in the ILS.

ILS Data Sources from the Creation of the Library System

Bibliographic Information

One source of data is the collection of bibliographic records and searching interfaces that represents materials in the library, commonly known as the Online Public Access Catalog (OPAC). In a digital library environment, the same type of information collected in a bibliographic library record can be collected as metadata. The concepts parallel those in a traditional library: Take an agreed-upon standard for describing an object, apply it to every object, and make the resulting data searchable. Therefore, digital libraries use conceptually similar bibliographic data sources to traditional libraries.

Acquisitions Information

Another source of data for bibliomining comes from acquisitions, where items are ordered from suppliers and tracked until they are received and processed. Because digital libraries do not order physical goods, somewhat different acquisition methods and vendor relationships exist. Nonetheless, in both traditional and digital library environments, acquisition data have untapped potential for understanding, controlling, and forecasting information resource costs.

ILS Data Sources from Usage of theLibrary System

User Information

In order to verify the identity of users who wish to use library services, libraries maintain user databases. In libraries associated with institutions, the user database is closely aligned with the organizational database. Sophisticated public libraries link user records through zip codes with demographic information in order to learn more about their user population. Digital libraries may or may not have any information about their users, based upon the login procedure required. No matter

what data are captured about the patron, it is important to ensure that the identification information about the patron is separated from the demographic information before this information is stored in a data warehouse; doing so protects the privacy of the individual.

Circulation and Usage Information

The richest sources of information about library user behavior are circulation and usage records. Legal and ethical issues limit the use of circulation data, however. A data warehouse can be useful in this situation, because basic demographic information and details about the circulation could be recorded without infringing upon the privacy of the individual.

Digital library services have a greater difficulty in defining circulation, as viewing a page does not carry the same meaning as checking a book out of the library, although requests to print or save a full text information resource might be similar in meaning. Some electronic full-text services already implement the server-side capture of such requests from their user interfaces.

Searching and Navigation Information

The OPAC serves as the primary means of searching for works owned by the library. Additionally, because most OPACs use a Web browser interface, users may also access bibliographic databases, the World Wide Web, and other online resources during the same session; all this information can be useful in library decision making. Digital libraries typically capture logs from users who are searching their databases and can track, through clickstream analysis, the elements of Web-based services visited by users. In addition, the combination of a login procedure and cookies allows the connection of user demographics to the services and searches they used in a session.

External Data Sources

Reference Desk Interactions

In the typical face-to-face or telephone interaction with a library user, the reference librarian records very little information about the interaction. Digital reference transactions, however, occur through an electronic format, and the transaction text can be captured for later analysis, which provides a much richer record than is available in traditional reference work. The utility of these data can be increased if identifying information about the user can be captured as well, but again, anonymization of these transactions is a significant challenge.

Item Use Information

Fussler and Simon (as cited in Nutter, 1987) estimated that 75 to 80% of the use of materials in academic libraries is in house. Some types of materials never circulate, and therefore, tracking in-house use is also vital in discovering patterns of use. This task becomes much easier in a digital library, as Web logs can be analyzed to discover what sources the users examined.

Interlibrary Loan and Other Outsourcing Services

Many libraries use interlibrary loan and/or other outsourcing methods to get items on a need-by-need basis for users. The data produced by this class of transactions will vary by service but can provide a window to areas of need in a library collection.

Applications of Bibliomining Through a Data Warehouse

Bibliomining can provide an understanding of the individual sources listed previously in this article; however, much more information can be discovered when sources are combined through common fields in a data warehouse.

Bibliomining to Improve Library Services

Most libraries exist to serve the information needs of users, and therefore, understanding the needs of individuals or groups is crucial to a library's success. For many decades, librarians have suggested works; market basket analysis can provide the same function through usage data in order to aid users in locating useful works. Bibliomining can also be used to determine areas of deficiency and to predict future user needs. Common areas of item requests and unsuccessful searches may point to areas of collection weakness. By looking for patterns in high-use items, librarians can better predict the demand for new items.

Virtual reference desk services can build a database of questions and expert-created answers, which can be used in a number of ways. Data mining could be used to discover patterns for tools that will automatically assign questions to experts based upon past assignments. In addition, by mining the question/answer pairs for patterns, an expert system could be created that can provide users an immediate answer and a pointer to an expert for more information.

Bibliomining for Organizational Decision Making Within the Library

Just as the user behavior is captured within the ILS, the behavior of library staff can also be discovered by connecting various databases to supplement existing performance review methods. Although monitoring staff through their performance may be an uncomfortable concept, tighter budgets and demands for justification require thoughtful and careful performance tracking. In addition, research has shown that incorporating clear, objective measures into performance evaluations can actually improve the fairness and effectiveness of those evaluations (Stanton, 2000).

Low-use statistics for a work may indicate a problem in the selection or cataloging process. Looking at the associations between assigned subject headings, call numbers, and keywords, along with the responsible party for the catalog record, may lead to a discovery of system inefficiencies. Vendor selection and price can be examined in a similar fashion to discover if a staff member consistently uses a more expensive vendor when cheaper alternatives are available. Most libraries acquire works both by individual orders and through automated ordering plans that are configured to fit the size and type of that library. Although these automated plans do simplify the selection process, if some or many of the works they recommend go unused, then the plan might not be cost effective. Therefore, merging the acquisitions and circulation databases and seeking patterns that predict low use can aid in appropriate selection of vendors and plans.

Bibliomining for External Reporting and Justification

The library may often be able to offer insights to their parent organization or community about their user base through patterns detected with bibliomining. In addition, library managers are often called upon to justify the funding for their library when budgets are tight. Likewise, managers must sometimes defend their policies, particularly when faced with user complaints. Bibliomining can provide the data-based justification to back up the anecdotal evidence usually used for such arguments.

Bibliomining of circulation data can provide a number of insights about the groups who use the library. By clustering the users by materials circulated and tying demographic information into each cluster, the library can develop conceptual user groups that provide a model of the important constituencies of the institution's user base; this grouping, in turn, can fulfill some common organizational needs for understanding where common interests and expertise reside in the user community. This capability may be particularly valuable within large organizations where research and development efforts are dispersed over multiple locations.

FUTURE TRENDS

Consortial Data Warehouses

One future path of bibliomining is to combine the data from multiple libraries through shared data warehouses. This merger will require standards if the libraries use different systems. One such standard is the COUNTER project (2004), which is a standard for reporting the use of digital library resources. Libraries working together to pool their data will be able to gain a competitive advantage over publishers and have the data needed to make better decisions. This type of data warehouse can power evidence-based librarianship, another growing area of research (Eldredge, 2000).

Combining these data sources will allow library science research to move from making statements about a particular library to making generalizations about librarianship. These generalizations can then be tested on other consortial data warehouses and in different settings and may be the inspiration for theories. Bibliomining and other forms of evidence-based librarianship can therefore encourage the expansion of the conceptual and theoretical frameworks supporting the science of librarianship.

Bibliomining, Web Mining, and Text Mining

Web mining is the exploration of patterns in the use of Web pages. Bibliomining uses Web mining as its base but adds some knowledge about the user. This aids in one of the shortcomings of Web mining — many times, nothing is known about the user. This lack still holds true in some digital library applications; however, when users access password-protected areas, the library has the ability to map some information about the patron onto the usage information. Therefore, bibliomining uses tools from Web usage mining but has more data available for pattern discovery.

Text mining is the exploration of the context of text in order to extract information and understand patterns. It helps to add information to the usage patterns discovered through bibliomining. To use terms from information science, bibliomining focuses on patterns in the data that label and point to the information container, while text mining focuses on the information within that container. In the future, organizations that fund digital libraries can look to text mining to greatly improve access to materials beyond the current cataloging/metadata solutions.

The quality and speed of text mining continues to improve. Liddy (2000) has researched the extraction of information from digital texts; implementing these technologies can allow a digital library to move from suggesting texts that might contain the answer to just providing the answer by extracting it from the appropriate text or texts. The use of such tools risks taking textual material out of context and also provides few hints about the quality of the material, but if these extractions were links directly into the texts, then context could emerge along with an answer. This situation could provide a substantial asset to organizations that maintain large bodies of technical texts, because it would promote rapid, universal access to previously scattered and/or uncataloged materials.

Example of Hybrid Approach

Hwang and Chuang (in press) have recently combined bibliomining, Web mining, and text mining in a recommender system for an academic library. They started by using data mining on Web usage data for articles in a digital library and combining that information with information about the users. They then built a system that looked at patterns between works based on their content by using text mining. By combing these two systems into a hybrid system, they found that the hybrid system provides more accurate recommendations for users than either system taken separately. This example is a perfect representation of the future of bibliomining and how it can be used to enhance the text-mining research projects already in progress.

CONCLUSION

Libraries have gathered data about their collections and users for years but have not always used those data for better decision making. By taking a more active approach based on applications of data mining, data visualization, and statistics, these information organizations can get a clearer picture of their information delivery and management needs. At the same time, libraries must continue to protect their users and employees from the misuse of personally identifiable data records. Information discovered through the application of bibliomining techniques gives the library the potential to save money, provide more appropriate programs, meet more of the users' information needs, become aware of the gaps and strengths of their collection, and serve as a more effective information source for its users. Bibliomining can provide the data-based justifications for the difficult decisions and funding requests library managers must make.

KEY TERMS

Bibliometrics: The study of regularities in citations, authorship, subjects, and other extractable facets from scientific communication by using quantitative and visualization techniques. This study allows researchers to understand patterns in the creation and documented use of scholarly publishing.

Bibliomining: The application of statistical and pattern-recognition tools to large amounts of data associated with library systems in order to aid decision making or to justify services. The term *bibliomining* comes from the combination of bibliometrics and data mining, which are the two main toolsets used for analysis.

Data Warehousing: The gathering and cleaning of data from disparate sources into a single database, which is optimized for exploration and reporting. The data warehouse holds a cleaned version of the data from operational systems, and data mining requires the type of cleaned data that live in a data warehouse.

Evidence-Based Librarianship: The use of the best available evidence, combined with the experiences of working librarians and the knowledge of the local user base, to make the best decisions possible (Eldredge, 2000).

Integrated Library System: The automation system for libraries that combines modules for cataloging, acquisition, circulation, end-user searching, database access, and other library functions through a common set of interfaces and databases.

Online Public Access Catalog (OPAC): The module of the Integrated Library System designed for use by the public to allow discovery of the library's holdings through the searching of bibliographic surrogates. As libraries acquire more digital materials, they are linking those materials to the OPAC entries.

INTRODUCTION

Bioinformatics is a new, rapidly expanding field that uses computational approaches to answer biological questions (Baxevanis, 2005). These questions are answered by means of *analyzing* and *mining biological data*. The field of *bioinformatics* or *computational biology* is a multidisciplinary research and development environment, in which a variety of techniques from computer science, applied mathematics, linguistics, physics, and, statistics are used. The terms *bioinformatics* and *computational biology* are often used interchangeably (Baldi, 1998; Pevzner, 2000). This new area of research is driven by the wealth of data from high throughput genome projects, such as the *human genome sequencing project* (International Human Genome Sequencing Consortium, 2001; Venter, 2001). As of early 2006, 180 organisms have been sequenced, with the capacity to sequence constantly increasing. Three major DNA databases collaborate and mirror over 100 billion base pairs in Europe (EMBL), Japan (DDBJ) and the USA (Genbank.) The advent of high throughput methods for monitoring gene expression, such as microarrays (Schena, 1995) detecting the expression level of thousands of genes simultaneously. Such data can be utilized to establish gene function (*functional genomics*) (DeRisi, 1997). Recent advances in *mass spectrometry* and proteomics have made these fields high-throughput. Bioinformatics is an essential part of *drug discovery*, *pharmacology*, *biotechnology*, *genetic engineering* and a wide variety of other *biological research* areas.

In the context of these proceedings, we emphasize that *machine learning* approaches, such as neural networks, hidden Markov models, or kernel machines, have emerged as good mathematical methods for analyzing (i.e. classifying, ranking, predicting, estimating and finding regularities on) biological datasets (Baldi, 1998). The field of bioinformatics has presented challenging problems to the machine learning community and the algorithms developed have resulted in new biological hypotheses. In summary, with the huge amount of information a mutually beneficial knowledge feedback has developed between theoretical disciplines and the life sciences. As further reading, we recommend the excellent "*Bioinformatics: A Machine Learning Approac*h" (Baldi, 1998), which gives a thorough insight into topics, methods and common problems in Bioinformatics.

The next section introduces the most important subfields of bioinformatics and computational biology. We go on to discuss current issues in bioinformatics and what we see are future trends.

BACKGROUND

Bioinformatics is a wide field covering a broad range of research topics that can broadly be defined as the management and analysis of data from generated by biological research. In order to understand bioinformatics it is essential to be familiar with at least a basic understanding of biology. The *central dogma* of molecular biology: DNA (a string of As, Cs, Gs and Ts) encodes genes which are *transcribed* into RNA (comprising As, Cs, Gs and Us) which are then generally *translated* into proteins (a string of *amino acids* – also denoted by single letter codes). The physical structure of these amino acids determines the proteins structure, which determines its function. A range of textbooks containing exhaustive information is available from the NCBI's website (http://www.ncbi.nlm.nih.gov/).

Major topics within the field of *bioinformatics* and *computational biology* can be structured into a number of categories, among which: prediction of gene expression and protein interactions, genome assembly, sequence alignment, gene finding, protein structure prediction, and evolution modeling are the most active

for the data mining community. Each of these problems requires different tools, computational techniques and machine learning methods. In the following section we briefly describe the main objectives in these areas:

1. *Databases and ontologies*. The overwhelming array of data being produced by experimental projects is continually being added to a collection of databases. The primary databases typically hold raw data and submission is often a requirement for publication. Primary databases include: a) sequence databases such as *Genbank, EMBL* and *DDBJ*, which hold nucleic acid sequence data (DNA, RNA), b) microarray databases such as *ArrayExpress* (Parkinson *et. al.* 2005), c) literature databases containing links to published articles such as *PubMed* (http://www.pubmed.com), and d) *PDB* containing protein structure data. Derived databases, created by analyzing the contents of primary databases creating higher order information such as a) protein domains, families and functional sites (*InterPro*, http://www.ebi.ac.uk/interpro/, Mulder *et. al.* 2003), and b) gene catalogs providing data from many different sources (*GeneLynx*, http://www.genelynx.org, Lenhard *et. al.* 2001, *GeneCards*, http://www.genecards.org, Safran *et. al.* 2003). An essential addition is the *Gene Ontology* project (http://www.geneontology.org). The Gene Ontology Consortium (2000), which provides a controlled vocabulary to describe genes and gene product attributes.
2. *Sequence analysis*. The most fundamental aspect of bioinformatics is sequence analysis. This broad term can be thought of as the identification of biologically significant regions in DNA, RNA or protein sequences. Genomic sequence data is analyzed to identify genes that code for RNAs or proteins, as well as regulatory sequences involved in turning on and off of genes. Protein sequence data is analyzed to identify signaling and structural information such as the location of biological active site(s). A comparison of genes within or between different species can reveal *relationships* between the genes (i.e. functional constraints). However, manual analysis of DNA sequences is impossible given the huge amount of data present. Database searching tools such as *BLAST* (http://www.ncbi.nlm.nih.gov/BLAST, Altschul *et. al.* 1990) are used to *search* the databases for similar sequences, using knowledge about *protein evolution*. In the context of genomics, *genome annotation* is the process biological features in a sequence. A popular system is the *ensembl* system which produces and maintains automatic annotation on selected eukaryotic genomes (http://www.ensembl.org).
3. *Expression analysis*. The expression of genes can be determined by measuring mRNA levels with techniques including microarrays, expressed cDNA sequence tag (EST) sequencing, sequence tag reading (e.g., SAGE and CAGE), massively parallel signature sequencing (MPSS), or various applications of multiplexed in-situ hybridization. Recently the development of protein microarrays and high throughput *mass spectrometry* can provide a snapshot of the proteins present in a biological sample. All of these techniques, while powerful, are noise-prone and/or subject to bias in the biological measurement. Thus, a major research area in computational biology involves developing *statistical tools to separate signal from noise* in high-throughput gene expression (HT) studies. Expression studies are often used as a first step in the process of identifying genes involved in pathologies by comparing the expression levels of genes between different tissue types (e.g. breast cancer cells vs. normal cells.) It is then possible to apply *clustering* algorithms to the data to determine the properties of cancerous vs. normal cells, leading to classifiers to diagnose novel samples. For a review of the microarray approaches in cancer, see Wang (2005).
4. *Genetics and population analysis*. The genetic variation in the population holds the key to identifying disease associated genes. Common polymorphisms such as single nucleotide polymorphisms (SNPs), insertions and deletions (*indels*) have been identified and ~3 million records are in the HGVBase polymorphism database (Fredman et. al. 2004). The international HapMap project is a key resource for finding genes affecting health, disease, and drug response (The International HapMap Consortium, 2005).
5. *Structural bioinformatics*. A proteins amino acid sequence (*primary structure*), is determined from the sequence of the gene that encodes it. This structure uniquely determines its physical structure. Knowledge of structure is vital to

understand protein function. Techniques available to predict the structure depend on the level of similarity to previously determined protein structures. In *homology modeling*, for instance, structural information from a homologous protein is used as a template to predict the structure of a protein once the structure of a homologous protein is known. State of the art in protein prediction is regularly gauged at the CASP (Critical Assessment of Techniques for Protein Structure Prediction, http://predictioncenter.org/) meeting, where leading protein structure prediction groups predict the structure of proteins that are experimentally verified.

6. *Comparative genomics and phylogenetic analysis.* In this field, the main goal is to identify similarities and differences between sequences in different organisms, to trace the evolutionary processes that have occurred in the divergence of the genomes. In bacteria, the study of many different species can be used to identify virulence genes (Raskin *et. al*. 2006). *Sequence analysis* commonly relies on evolutionary information about a gene or gene family (e.g. sites within a gene that are highly conserved over time imply a functional importance of that site). The complexity of genome evolution poses many exciting challenges to developers of mathematical models and algorithms, who have developed novel algorithmic, *statistical* and mathematical techniques, ranging from exact, heuristics, fixed parameter and approximation algorithms. In particular, the use of probabilistic-based models, such as *Markov Chain Monte Carlo* algorithms and *Bayesian analysis,* has demonstrated good results.
7. *Text mining.* The number of published scientific articles is rapidly increasing, making it difficult to keep up without using automated approaches based on text-mining (Scherf *et. al*. 2005). The extraction of biological knowledge from unstructured free text is a highly complex task requiring knowledge from *linguistics*, *machine learning* and the use of experts in the subject field.
8. *Systems biology*. The integration of large amounts of data from complementary methods is a major issue in bioinformatics. Combining datasets from many different sources makes it possible to construct networks of genes and interactions between genes. Systems biology incorporates disciplines such as statistics, graph theory and network analysis. An applied approach to the methods of systems biology is presented in detail by Winzeler (2006).

Biological systems are complex and constantly in a state of flux, making the measurement of these systems difficult. Data used in bioinformatics today is inherently noisy and incomplete. The increasing integration of data from different experiments adds to this noise. Such datasets require the application of sophisticated machine learning tools with the ability to work with such data.

Machine Learning Tools

A complete suite of machine learning tools is freely available to the researcher. In particular, it is worth noting the extended use of classification and regression trees (Breiman, 1984), Bayesian learning, neural networks (Baldi, 1998), Profile Markov models (Durbin *et. al.* 1998), rule-based strategies (Witten, 2005), or kernel methods (Schölkopf, 2004) in bioinformatics applications. For the interested reader, the software *Weka* (http://www.cs.waikato.ac.nz/ml/weka/, Witten, 2005), provides an extensive collection of machine learning algorithms for data mining tasks in general, and in particular bioinformatics. Specifically, implementations of well-known algorithms such as trees, Bayes learners, supervised and unsupervised classifiers, statistical and advanced regression, splines and visualization tools.

Bioinformatics Resources

The explosion of bioinformatics in recent years has lead to a wealth of databases, prediction tools and utilities and *Nucleic Acids Research* dedicates an issue to databases and web servers annually. Online resources are clustered around the large genome centers such as the National Center for Biotechnology Information (NCBI, http://www.ncbi.nlm.nih.gov/) and European Molecular Biology Laboratory (EMBL, http://www.embl.org/), which provide a multitude of public databases and services. For a useful overview of available links see "The Bioinformatics Links Directory" (http://bioinformatics.ubc.ca/resources/links_directory/, Fox *et. al.* 2005) or http://www.cbs.dtu.dk/biolinks/.

In addition to the use of online tools for analysis, it is common practice for research groups to access these databases and utilities locally. Different communities of bioinformatics programmers have set up free and open source projects such as EMBOSS (http://emboss.sourceforge.net/, Rice et al., 2000), Bioconductor (http://www.bioconductor.org), BioPerl, (http://www.bioperl.org, Stajich *et al.*, 2002), BioPython (http://www.biopython.org), and BioJava (http://www.biojava.org), which develop and distribute shared programming tools and objects. Several integrated software tools are also available, such as Taverna for bioinformatics workflow and distributed systems (http://taverna.sourceforge.net/), or Quantum 3.1 for drug discovery (http://www.q-pharm.com/home/contents/drug_d/soft).

FUTURE TRENDS

We have identified a broad set of problems and tools used within bioinformatics. In this section we focus specifically on the future of machine learning within bioinformatics. While a large set of data mining or machine learning tools have captured attention in the field of bioinformatics, it is worth noting that in application fields where a *similarity* measure has to be built, either to classify, cluster, predict or estimate, the use of *support vector machines* (SVM) and *kernel methods* (KM) are increasingly popular. This has been especially significant in computational biology, due to performance in real-world applications, strong modularity, mathematical elegance and convenience. Applications are encountered in a wide range of problems, from the classification of tumors to the automatic annotation of proteins. Their ability to work with high dimensional data, to process and efficiently integrate non-vectorial data (strings and images), along with a natural and consistent mathematical framework, make them very suitable to solve various problems arising in computational biology.

Since the early papers using SVM in bioinformatics (Mukherjee *et. al.*, 1998; Jaakkola *et. al.*, 1999), the application of these methods has grown exponentially. More than a mere application of well-established methods to new datasets, the use of kernel methods in computational biology has been accompanied by new developments to match the specificities and the needs of bioinformatics, such as methods for *feature selection* in combination with the classification of high-dimensional data, the introduction of *string kernels* to process biological sequences, or the development of methods to *learn from several kernels simultaneously* ('composite kernels'). The reader can find references in the book by Schölkopf et al. (2004), and a comprehensive introduction in (Vert, 2006). Several kernels for structured data, such as *sequences*, *trees* or *graphs*, widely developed and used in computational biology, are also presented in detail by Shawe-Taylor and Cristianini (2004).

In the near future, developments in *transductive* learning (improving learning through exploiting unlabeled samples), refinements in *feature selection* and *string-based* algorithms, and design of *biological-based kernels* will take place. Certainly, many computational biology tasks are transductive and/or can be specified through optimizing *similarity* criteria on strings. In addition, exploiting the nature of these learning tasks through engineered and problem-dependent kernels may lead to improved performance in many biological domains. In conclusion, the development of new methods for specific problems under the paradigm of kernel methods is gaining popularity and how far these methods can be extended is an unanswered question.

CONCLUSION

In this chapter, we have given an overview of the field of bioinformatics and computational biology, with its needs and demands. We have exposed the main research topics and pointed out common tools and software to tackle existing problems. We noted that the paradigm of kernel methods can be useful to develop a consistent formalism for a number of these problems. The application of advanced machine learning techniques to solve problems based on biological data will surely bring greater insight into the functionality of the human body. What the future will bring is unknown, but the challenging questions answered so far and the set of new and powerful methods developed ensure exciting results in the near future.

KEY TERMS

Alignment: A sequence alignment is a way of arranging DNA, RNA, or protein sequences so that similar regions are aligned. This may indicate functional or evolutionary relationships between the genes.

Functional Genomics: The use of the vast quantity of data produced by genome sequencing projects to describe genome function. Functional genomics utilizes high-throughput techniques such as microarrays to describe the function and interactions of genes.

Gene Expression: The process by which a gene's DNA sequence is converted into the structures and functions of a cell. Non-protein coding genes (e.g. rRNA genes) are not translated into protein.

Gene Ontology: A controlled vocabulary of terms to describe the function, role in biological processes and the location in the cell of a gene.

Homology: Similarity in sequence that is based on descent from a common ancestor.

Phylogenetics: The study of evolutionary relatedness among various groups of organisms usually carried out using alignments of a gene that is contained in every organism.

Protein Structure Prediction: The aim of determining the three-dimensional structure of proteins from their amino acid sequences.

Proteomics: The large-scale study of proteins, particularly their structures and functions.

Sequence Analysis: Analyzing a DNA or peptide sequence by sequence alignment, sequence searches against databases, or other bioinformatics methods.

Sequencing: To determine the primary structure (sequence) of a DNA, RNA or protein.

Similarity: How related one nucleotide or protein sequence is to another. The extent of similarity between two sequences is based on the percent of sequence identity and/or conservation.

Systems Biology: Integrating different levels of information to understand how biological systems function. The relationships and interactions between various parts of a biological system are modeled so that eventually model of the whole system can be developed. Computer simulation is often used.

Tertiary Structure: The three-dimensional structure of a polypeptide chain (protein) that results from the way that the alpha helices and beta sheets are folded and arranged.

Transcription: The process by which the information contained in a section of DNA is transferred to a newly assembled piece of messenger RNA (mRNA).

ENDNOTE

[1] Two genes are homologous if they originated from a gene in a common ancestral organism. Homology does not imply that the genes have the same function.

INTRODUCTION

Understanding the roles of genes and their interactions is one of the central challenges in genome research. One popular approach is based on the analysis of microarray gene expression data (Golub *et al*., 1999; White, *et al*., 1999; Oshlack *et al*., 2007). By their very nature, these data often do not capture spatial patterns of individual gene expressions, which is accomplished by direct visualization of the presence or absence of gene products (mRNA or protein) (e.g., Tomancak *et al.*, 2002; Christiansen *et al.*, 2006). For instance, the gene expression pattern images of a *Drosophila melanogaster* embryo capture the spatial and temporal distribution of gene expression patterns at a given developmental stage (Bownes, 1975; Tsai *et al.*, 1998; Myasnikova *et al*., 2002; Harmon *et al.*, 2007). The identification of genes showing spatial overlaps in their expression patterns is fundamentally important to formulating and testing gene interaction hypotheses (Kumar *et al*., 2002; Tomancak *et al.*, 2002; Gurunathan *et al.*, 2004; Peng & Myers, 2004; Pan *et al.*, 2006).

Recent high-throughput experiments of *Drosophila* have produced over fifty thousand images (http://www.fruitfly.org/cgi-bin/ex/insitu.pl). It is thus desirable to design efficient computational approaches that can automatically retrieve images with overlapping expression patterns. There are two primary ways of accomplishing this task. In one approach, gene expression patterns are described using a controlled vocabulary, and images containing overlapping patterns are found based on the similarity of textual annotations. In the second approach, the most similar expression patterns are identified by a direct comparison of image content, emulating the visual inspection carried out by biologists [(Kumar *et al*., 2002); see also www.flyexpress.net]. The direct comparison of image content is expected to be complementary to, and more powerful than, the controlled vocabulary approach, because it is unlikely that all attributes of an expression pattern can be completely captured via textual descriptions. Hence, to facilitate the efficient and widespread use of such datasets, there is a significant need for sophisticated, high-performance, informatics-based solutions for the analysis of large collections of biological images.

BACKGROUND

The identification of overlapping expression patterns is critically dependent on a pre-defined pattern similarity between the standardized images. Quantifying pattern similarity requires deriving a vector of features that describes the image content (gene expression and localization patterns). We have previously derived a binary feature vector (BFV) in which a threshold value of intensity is used to decide the presence or absence of expression at each pixel coordinate, because our primary focus is to find image pairs with the highest spatial similarities (Kumar *et al.*, 2002; Gurunathan *et al*., 2004). This feature vector approach performs quite well for detecting overlapping expression patterns from early stage images. However, the BFV representation does not utilize the gradations in the intensity of gene expression because it gives the same weight to all pixels with greater intensity than the cut-off value. As a result, small regions without expression or with faint expression may be ignored, and areas containing mere noise may influence image similarity estimates. Pattern similarity based on the vector of pixel intensities

(of expression) has been examined by Peng & Myers (2004), and their early experimental results appeared to be promising. Peng & Myers (2004) model each image using the Gaussian Mixture Model (GMM) (McLachlan& Peel, 2000), and they evaluate the similarity between images based on patterns captured by GMMs. However, this approach is computationally expensive.

In general, the number of features in the BFV representation is equal to the number of pixels in the image. This number is over 40,000 because the FlyExpress database currently scales all embryos to fit in a standardized size of 320×128 pixels (www.flyexpress.net). Analysis of such high-dimensional data typically takes the form of extracting correlations between data objects and discovering meaningful information and patterns in data. Analysis of data with continuous attributes (e.g., features based on pixel intensities) and with discrete attributes (e.g., binary feature vectors) pose different challenges.

Principal Component Analysis (PCA) is a popular approach for extracting low-dimensional patterns from high-dimensional, continuous-attribute data (Jolliffe, 1986; Pittelkow & Wilson, 2005). It has been successfully used in applications such as computer vision, image processing, and bioinformatics. However, PCA involves the expensive eigen-decomposition of matrices, which does not scale well to large databases. Furthermore, PCA works only on data in vector form, while the native form of an image is a matrix. We have recently developed an approach called "Generalized Low Rank Approximation of Matrices" (GLRAM) to overcome the limitations of PCA by working directly on data in matrix form; this has been shown to be effective for natural image data (Ye *et al.*, 2004; Ye, 2005).

Here, we propose expression similarity measures that are derived from the correlation information among all images in the database, which is an advancement over the previous efforts wherein image pairs were exclusively used for deriving such measures (Kumar *et al.*, 2002; Gurunathan *et al.*, 2004; Peng & Myers, 2004). In other words, in contrast to previous approaches, we attempt to derive data-dependent similarity measures in detecting expression pattern overlap. It is expected that data-dependent similarity measures will be more flexible in dealing with more complex expression patterns, such as those from the later developmental stages of embryogenesis.

MAIN FOCUS

We are given a collection of n gene expression pattern images $\{A_1, A_2, \cdots, A_n\} \in \Re^{r \times c}$, with r rows and c columns. GLRAM (Ye, 2005, Ye *et al.*, 2004) aims to extract low-dimensional patterns from the image dataset by applying two transformations $L \in \Re^{r \times u}$ and $R \in \Re^{c \times v}$ with orthonormal columns, that is, $L^T L = I_u$ and $R^T R = I_v$, where I_u and I_v are identity matrices of size u and v, respectively. Each image A_i is transformed to a low-dimensional matrix $M_i = L^T A_i R \in \Re^{u \times v}$, for $i = 1, ..., n$. Here, $u < r$ and $v < c$ are two pre-specified parameters.

In GLRAM, the optimal transformations L^* and R^* are determined by solving the following optimization problem:

$$(L^*, R^*) = \arg\max_{L,R:L^T L=I_u, R^T R=I_v} \sum_{i=1}^{n} \left\| L^T A_i R \right\|_F^2 .$$

Here, $\|\cdot\|_F$ denotes the Frobenius norm of a matrix (Golub & Van Loan, 1996). To the best of our knowledge, there is no closed-form solution to the above maximization problem. However, if one of the two matrices L and R is given, the other one can be readily computed. More specifically, if L is given, the optimal R is given by the top eigenvectors of the matrix

$$\sum_{i=1}^{n} A_i^T L L^T A_i ,$$

while for a given R, the optimal L is given by the top eigenvectors of the matrix

$$\sum_{i=1}^{n} A_i R R^T A_i^T .$$

This results in an iterative procedure for computing L and R in GLRAM. For the given L and R, the low-dimensional matrix is given by $M_i = L^T A_i R$.

The dissimilarity between two expression patterns A_i and A_j is defined to be $\left\| M_i - M_j \right\|_F = \left\| L^T (A_i - A_j) R \right\|_F$. That is, GLRAM extracts the similarity between images through the transformations L and R. A key difference between the similarity computation based on the M_i's and the direct similarity computation based on the A_i's lies in the pattern extraction step involved in GLRAM. The columns of L and R form the basis

for expression pattern images, while M_i keeps the coefficients for the i-th image. Let L_j and R_k denote the j-th and k-th columns of L and R, respectively. Then, $L_j \cdot R_j \in \Re^{r \times c}$, for $j = 1, ..., u$ and $k = 1, ..., v$, forms the basis images. Note that the principal components in Principal Component Analysis (PCA) form the basis images, also called eigenfaces (Turk & Pentland, 1991) in face recognition.

We have conducted preliminary investigations on the use of GLRAM for expression pattern images from early developmental stages, and we have found that it performs quite well. Before GLRAM is applied, the mean is subtracted from all images. Using $u = 20$ and $v = 20$ on a set of *301* images from stage range *7--8*, the relative reconstruction error defined as

$$\sum_{i=1}^{n} \left\| A_i - LM_i R^T \right\|_F^2 \Big/ \sum_{i=1}^{n} \left\| A_i \right\|_F^2$$

is about *5.34%*. That is, even with a compression ratio as high as $320 \times 128/(20 \times 20) \approx 100$, the majority of the information (*94.66%*) in the original data is preserved. This implies that the intrinsic dimensionality of these embryo images from stage range *7-8* is small, even though their original dimensionality is large (about *40000*). Applying PCA with a similar compression ratio, we get a relative reconstruction error of about *30%*. Thus, by keeping the 2D structure of images, GLRAM is more effective in compression than PCA. The computational complexity of GLRAM is linear in terms of both the sample size and the data dimensionality, which is much lower than that of PCA. Thus, GLRAM scales to large-scale data sets. Wavelet transform (Averbuch *et al.*, 1996) is a commonly used scheme for image compression. Similar to the GLRAM algorithm, wavelets can be applied to images in matrix representation. A subtle but important difference is that wavelets mainly aim to compress and reconstruct a single image with a small cost of basis representations, which is extremely important for image transmission in computer networks. Conversely, GLRAM aims to compress a set of images by making use of the correlation information between images, which is important for pattern extraction and similarity-based pattern comparison.

FUTURE TRENDS

We have applied GLRAM for gene expression pattern image retrieval. Our preliminary experimental results show that GLRAM is able to extract biologically meaningful features and is competitive with previous approaches based on BFV, PCA, and GMM. However, the entries in the factorized matrices in GLRAM are allowed to have arbitrary signs, and there may be complex cancellations between positive and negative numbers, resulting in weak interpretability of the model. Non-negative Matrix Factorization (NMF) (Lee & Seung, 1999) imposes the non-negativity constraint for each entry in the factorized matrices, and it extracts bases that correspond to intuitive notions of the parts of objects. A useful direction for further work is to develop non-negative GLRAM, which restricts the entries in the factorized matrices to be non-negative while keeping the matrix representation for the data as in GLRAM.

One common drawback of all methods discussed in this chapter is that, for a new query image, the pairwise similarities between the query image and all the images in the database need to be computed. This pairwise comparison is computationally prohibitive, especially for large image databases, and some ad hoc techniques, like pre-computing all pairwise similarities, are usually employed. Recall that in BFV (Kumar *et al.*, 2002; Gurunathan *et al.*, 2004), we derive a binary feature vector for each image, which indicates the presence or absence of expression at each pixel coordinate. This results in a binary data matrix where each row corresponds to a BFV representation of an image. Rank-one approximation of binary matrices has been previously applied for compression, clustering, and pattern extraction in high-dimensional binary data (Koyuturk *et al.*, 2005). It can also be applied to organize the data into a binary tree where all data are contained collectively in the leaves and each internal node represents a pattern that is shared by all data at this node (Koyuturk *et al.*, 2005). Another direction for future work is to apply binary matrix approximations to construct such a tree-structured representation for efficient image retrieval.

CONCLUSION

Identification of genes with overlapping patterns gives important clues about gene function and interaction. Recent high-throughput experiments have produced a large number of images. It is thus desirable to design computational approaches that can automatically retrieve images with overlapping expression patterns. The approach presented here (GLRAM) approximates a set of data matrices with matrices of low rank, thus avoiding the conversion of images into vectors. Experimental results on gene expression pattern images demonstrate its effectiveness in image compression and retrieval.

KEY TERMS

Compression Ratio: The ratio between the space needed to store the original data, and the space needed to store the compressed data.

Drosophila Melanogaster: A two-winged insect that belongs to the Order Diptera, the order of the flies. The species is commonly known as the fruit fly, and is one of the most widely used model organisms in biology, including studies in genetics, physiology and life history evolution.

Developmental Stage: A distinct phase in Embryogenesis, which is traditionally divided into a series of consecutive stages distinguished by morphological markers. In a high throughput experimental study, embryonic images have been grouped into six stage ranges, 1-3, 4-6, 7-8, 9-10, 11-12, and 13-16.

Dimensionality Reduction: The process of reducing the number of random variables under consideration, which can be divided into feature selection and feature extraction.

Embryogenesis: A process by which the embryo is formed and develops. It starts with the fertilization of the ovum, egg, which, after fertilization, is then called a zygote. The zygote undergoes rapid mitotic divisions, the formation of two exact genetic replicates of the original cell, with no significant growth (a process known as cleavage) and cellular differentiation, leading to development of an embryo.

Gene: A set of segments of nucleic acid that contains the information necessary to produce a functional RNA product in a controlled manner.

Gene Expression: A process by which a gene's DNA sequence is converted into functional proteins.

Bitmap Join Indexes vs. Data Partitioning

Ladjel Bellatreche
Poitiers University, France

INTRODUCTION

Scientific databases and data warehouses store large amounts of data ith several tables and attributes. For instance, the Sloan Digital Sky Survey (SDSS) astronomical database contains a large number of tables with hundreds of attributes, which can be queried in various combinations (Papadomanolakis & Ailamaki, 2004). These queries involve many tables using binary operations, such as joins. To speed up these queries, many optimization structures were proposed that can be divided into two main categories: *redundant structures* like materialized views, advanced indexing schemes (bitmap, bitmap join indexes, etc.) (Sanjay, Chaudhuri & Narasayya, 2000) and vertical partitioning (Sanjay, Narasayya & Yang 2004) and *non redundant structures* like horizontal partitioning (Sanjay, Narasayya & Yang 2004; Bellatreche, Boukhalfa & Mohania, 2007) and parallel processing (Datta, Moon, & Thomas, 2000; Stöhr, Märtens & Rahm, 2000). These optimization techniques are used either in a sequential manner ou combined. These combinations are done intra-structures: materialized views and indexes for redundant and partitioning and data parallel processing for no redundant. Materialized views and indexes *compete for the same resource representing storage*, and *incur maintenance overhead in the presence of updates* (Sanjay, Chaudhuri & Narasayya, 2000). None work addresses the problem of selecting combined optimization structures. In this paper, we propose two approaches; one for combining a non redundant structures horizontal partitioning and a redundant structure bitmap indexes in order to reduce the query processing and reduce the maintenance overhead, and another to exploit algorithms for vertical partitioning to generate bitmap join indexes. To facilitate the understanding of our approaches, for review these techniques in details.

Data partitioning is an important aspect of physical database design. In the context of relational data warehouses, it allows tables, indexes and materialised views to be partitioned into disjoint sets of rows and columns that are physically stored and accessed separately (Sanjay, Narasayya & Yang 2004). It has a significant impact on performance of queries and manageability of data warehouses. Two types of data partitioning are available: vertical and horizontal partitionings.

The vertical partitioning of a table T splits it into two or more tables, called, sub-tables or vertical fragment, each of which contains a subset of the columns in T. Since many queries access only a small subset of the columns in a table, vertical partitioning can reduce the amount of data that needs to be scanned to answer the query. Note that the key columns are *duplicated* in each vertical fragment, to allow "reconstruction" of an original row in T. Unlike horizontal partitioning, indexes or materialized views, in most of today's commercial database systems there is no native Database Definition Language (DDL) support for defining vertical partitions of a table (Sanjay, Narasayya & Yang 2004). The horizontal partitioning of an object (a table, a vertical fragment, a materialized view, and an index) is specified using a partitioning method (range, hash, list), which maps a given row in an object to a key partition. All rows of the object with the same partition number are stored in the same partition.

Bitmap index is probably the most important result obtained in the data warehouse physical optimization field (Golfarelli, Rizzi & Saltarelli, 2002). The bitmap index is more suitable for low cardinality attributes since its size strictly depends on the number of distinct values of the column on which it is built. Bitmap join indexes (BJIs) are proposed to speed up join operations (Golfarelli, Rizzi & Saltarelli, 2002). In its simplest form, it can be defined as a bitmap index on a table R based on a single column of another table S, where S commonly joins with R in a specific way.

Many studies have recommended the combination of redundant and non redundant structures to get a better performance for a given workload (Sanjay, Narasayya & Yang 2004; Bellatreche, Schneider, Lorinquer & Mohania, 2004). Most of previous work in physical database design did not consider the interdependence between redundant and no redundant optimization structures. Logically, BJIs and horizontal partitioning

are two similar optimization techniques - both speed up query execution, pre-compute join operations and concern selection attributes of dimension tables[1]. Furthermore, BJIs and HP can interact with one another, i.e., the presence of an index can make a partitioned schema more efficient and vice versa (since fragments have the same schema of the global table, they can be indexed using BJIs and BJIs can also be partitioned (Sanjay, Narasayya & Yang 2004)).

BACKGROUND

Note that each BJI can be defined on one or several non key dimension's attributes with a low cardinality (that we call indexed columns) by joining dimension tables owned these attributes and the fact table[2].

Definition: An indexed attribute A_j candidate for defining a BJI is a column A_j of a dimension table D_i with a low cardinality (like gender attribute) such that there is a selection predicate of the form: $D_i.A_j$ θ value, θ is one of six comparison operators {=,<,>,<=,>=}, and value is the predicate constant.

For a large number of indexed attributes candidates, selecting optimal BJIs is an NP-hard problem (Bellatreche, Boukhalfa & Mohania, 2007).

On the other hand, the best way to partition a relational data warehouse is to decompose the fact table based on the fragmentation schemas of dimension tables (Bellatreche & Boukhalfa, 2005). Concretely, (1) partition some/all dimension tables using their simple selection predicates ($D_i.A_j$ θ value), and then (2) partition the facts table using the fragmentation schemas of the fragmented dimension tables (this fragmentation is called derived horizontal fragmentation (Özsu a Valduriez, 1999)). This fragmentation procedure takes into consideration the star join queries requirements. The number of horizontal fragments (denoted by N) of the fact table generated by this partitioning procedure is given by:

$$N = \prod_{i=1}^{g} m_i,$$

where m_i and g are the number of fragments of the dimension table D_i and the number of dimension tables participating in the fragmentation process, respectively. This number may be very large (Bellatreche & Boukhalfa & Abdalla, 2006). Based on this definition, there is a strong similarity between BJIs and horizontal partitioning as show the next section.

Similarity between HP and BJIs

To show the similarity between HP and BJIs, the following scenario is considered[3]. Suppose a data warehouse represented by three dimension tables (TIME, CUSTOMER and PRODUCT) and one fact table (SALES). The population of this schema is given in Figure 1. On the top of this the following query is executed:

```
SELECT Count(*)
FROM CUSTOMER C, PRODUCT P, TIME T, SALES S
WHEERE C.City='LA'
AND P.Range='Beauty'
AND T.Month='June'
AND P.PID=S.PID
AND C.CID=S.CID
AND T.TID=S.TID
```

This query has three selection predicates defined on dimension table attributes City (City='LA'), Range (Range='Beauty') and Month (Month = 'June') and

25	313	105	66	19
26	313	105	22	17
27	313	106	11	15

three join operations. It can be executed using either horizontal partitioning (this strategy is called HPFIRST) or BJI (called BJIFIRST).

HPFIRST: The Database Administrator (DBA) partition the fact table using the derived horizontal fragmentation based on partitioning schemas of dimension tables: CUSTOMER, TIME and PRODUCT based on City (thee fragments), Month (six fragments), Range (five fragments), respectively (see Figure 2). Consequently, the fact table is fragmented in 90 fragments (3 * 6 * 5), where each fact fragment is defined as follows:

$Sales_i$ = SALES $\lceil$ $CUSTOMER_j$ $\lceil$ $TIME_k$ $\lceil$ $PRODUCT_m$

where $\lceil$ represents semi join operation, $(1 \le i \le 90)$, $(1 \le j \le 3)$, $(1 \le k \le 6)$, $(1 \le m \le 5)$.

Figure 2c shows the fact fragment SALES_BPJ corresponding to sales of beauty products realized by customers living at LA City during month of June.

To execute the aforementioned query, the optimizer shall rewrite it according to the fragments. The result of the rewriting process is:

```
SELECT Count(*) FROM SALES_BPJ
```

Instead of loading all tables (fact table and the three dimension tables) of the warehouse, the query optimizer loads only the fact fragment SALES_BPJ.

BJIFIRST: The DBA may define a BJI on three dimension attributes: City, Month and Range as follows:

```
CREATE BITMAP INDEX Sales_CPT_bjix
ON SALES(CUSTOMER.City, PRODUCT.Range,
TIME.Month)
FROM SALES S, CUSTOMER C, TIME T, PROD-
UCT P
WHERE S.CID= C.CID AND S.PID=P.PID AND
S.TID=T.TID
```

Figure 2a shows the population of the BJI Sales_CPT_bjix. Note that the three attributes: City, Month and Range are indexed attributes and fragmentation attributes. To execute the aforementioned query, the optimizer just accesses the bitmaps corresponding to the columns of Sales_CPT_bjx representing June, Beauty and LA and performs AND operation. This

example shows a strong similarity between horizontal partitioning and BJIs – both save three join operations and optimize selection operations defined on dimension tables.

Another similarity between BJI and horizontal partitioning resides on their selection problem formalisations.

The HP selection problem may be formulated as follows: (Bellatreche & Boukhalfa, 2005): Given a data warehouse with a set of dimension tables $D = \{D_1, D_2, ..., D_d\}$ and a fact table F, a workload Q of queries $Q = \{Q_1, Q_2, ..., Q_m\}$, where each query Q_i $(1 \leq i \leq m)$ has an access frequency f_i. The HP selection problem consists in fragmenting the fact table into a set of N fact fragments $\{F_1, F_2, ..., F_N\}$ such that: (1) the sum of the query processing cost when executed on top of the partitioned star schema is minimized and (2) $N \leq W$, where W is a threshold, fixed by the database administrator (DBA), representing the maximal number of fact fragments that she can maintain.

The BJI selection problem has the same formulation as HP, except the definition of its constraint (Bellatreche, Missaoui, Necir & Drias, 2007). The aim of BJI selection problem is to find a set of BJIs minimizing the query processing cost and storage requirements of BJIs do not exceed S (representing storage bound).

Differences

The main difference between the data partitioning and BJI concerns the storage cost and the maintenance overhead required for storing and maintaining (after INSERT, DELETE, or UPDATE operations) BJIs. To reduce the cost of storing BJIs, several works has been done on compression techniques (Johnson, 1999).

MAIN FOCUS

Horizontal Partitioning and BJIs

Actually, many commercial database systems support horizontal partitioning and BJIs. The use of these optimization structures is done in a sequential manner by DBA: (1) HPFIRST or (2) BJIFIRST. It will interesting to combine these two structures to optimize queries processing cost and to reduce the maintenance and storage cost. This combination, called HP→BJI is feasible since horizontal partitioning preserves the schema of base tables, therefore, the obtained fragments can further be indexed. Note that HP and BJIs are defined on selection attributes ($A = \{A1, \ldots, Ao\}$) of dimension tables defined on the queries. The main issue to combine these optimization techniques is to identify selection attributes (from A) for HP and for BJI. We propose a technique to combine them: Given a data warehouse schema with a fact table F and set of dimension tables $\{D_1, \ldots, D_l\}$. Let $Q = \{Q_1, Q_2, \cdots, Q_m\}$ be a set of most frequently queries.

1. Partition the database schema using any fragmentation algorithm (for example the genetic algorithm developed in (Bellatreche & Boukhalfa, 2005)) according a set of queries Q and the threshold W fixed by the DBA. Our genetic algorithm generates a set of N fragments of fact tables. Let FASET be the set of fragmentation attributes of dimension tables used in definition of fragments ($FASET \subseteq A$). In the motivating example (see Background), Month, City and Range represent fragmentation attributes. Among m queries, an identification of those that get benefit from HP, denoted by $Q' = \{Q'_1, Q'_2, \cdots, Q'_l\}$ is done. This identification thanks to a rate defined for each query Q_j of Q as follows:

$$rate(Q_j) = \frac{C[Q_j, FS]}{C[Q_j, \varphi]} \text{ where } C[Q_j, FS] \text{ and } C[Q_j, \phi]$$

represent the cost of executing the query Q_j on un-partitioned data warehouse and partitioned schema FS, respectively. The DBA has the right to set up this rate using a threshold λ: if rate $(Q_j) \leq \lambda$ then Q_j is a profitable query, otherwise no profitable query.

2. Among (A - FASET), pick up attribute(s) with a low cardinality in order to built BJIs. The set of these attributes is denoted by BJISET.
3. The selection of BJIs is then done using BJISET and no profitable queries $Q' = \{Q'_1, Q'_2, \cdots, Q'_l\}$ using a greedy algorithm (Bellatreche, Boukhalfa, Mohania, 2007). Note that the selected BJIs shall reduce the cost of executing no profitable queries generated by HPFIRST. This combination reduces the storage cost and especially the maintenance overhead. This approach shows the complementarity between horizontal partitioning and BJIs.

Vertical Partitioning and BJIs

Let A= $\{A_1, A_2, \ldots, A_K\}$ be the set of indexed attributes candidate for BJIs. For selecting **only one** BJI, the number of possible BJIs grows exponentially, and is given by:

$$\binom{K}{1} + \binom{K}{2} + \ldots + \binom{K}{K} = 2^K - 1$$

For (K=4), this number is 15. The total number of generating any combination of BJIs is given by:

$$\binom{2^K-1}{1} + \binom{2^K-1}{2} + \ldots + \binom{2^K-1}{2^K-1} = 2^{2^K-1} - 1$$

For K=4, **all possible BJIs** is $(2^{15} - 1)$. Therefore, the problem of efficiently finding the set of BJIs that minimize the total query processing cost while satisfying a storage constraint is very challenging to solve.

To vertically partition a table with m non primary keys, the number of possible fragments is equal to B(m), which is the m^{th} Bell number (Özsu & Valduriez, 1999). For a large values of m, $B(m) \cong m^m$. For example, for m = 10; B(10) ≅ 115 975. These values indicate that it is futile to attempt to obtain optimal solutions to the vertical partitioning problem. Many algorithms were proposed (Özsu & Valduriez, 1999) classified into two categories: (1) **Grouping:** starts by assigning each attribute to one fragment, and at each step, joins some of the fragments until some criteria is satisfied, (2) **Splitting:** starts with a table and decides on beneficial partitionings based on the frequency accesses of queries. The problem of generating BJIs is similar to the vertical partitioning problem. Since it tries to generate a group of attributes, where each group generates a BJI. Therefore, existing vertical partitioning algorithms could be adapted to BJIs selection.

Example

Let A= {Gender, City, Range} be three selection attributes candidate for indexing process. Suppose we use a vertical partitioning algorithm that generates two fragments {Gender} and {City, Range}. Based on these fragments, two BJIs (B1 and B2) can be generated as follows: (see Box 1).

FUTURE TRENDS

The selection of different optimization techniques is very challenging problem in designing and auto administrating very large databases. To get a better performance of queries, different optimization techniques should be combined, since each technique has its own advantages and drawbacks. For example, horizontal partitioning is an optimization structure that reduces query processing cost and storage and maintenance overhead. But it may generate a large number of fragments. BJIs may be used with horizontal partitioning to ovoid the explosion of fragments. Actually, only few algorithms are available for selecting bitmap join indexes. These algorithms are based on data mining techniques. It will be interested to adapt vertical partitioning algorithms for selecting bitmap join indexes and compare their performances with the existing ones. Another issue concerns the choice of threshold λ that identifies queries that get benefit from horizontal partitioning. This choice can be done using queries, selectivity factors of selection and join predicates, etc. This parameter may also play a role of tuning of the data warehouse.

CONCLUSION

Due to the complexity of queries on scientific and data warehouse applications, there is a need to develop query optimization techniques. We classify the existing techniques into two main categories: redundant and no redundant structures. We show a strong interdependency and complementarity between redundant structures and no redundant structures. For performance issue, we show how bitmap join indexes and data partitioning

Box 1.

CREATE BITMAP INDEX B1 ON SALES(CUSTOMER.Gender) FROM SALES S, CUSTOMER C WHERE S.CID= C.CID	CREATE BITMAP INDEX B2 ON SALES(CUSTOMER.City, Product. Range) FROM SALES S, CUSTOMER C, PRODUCT P WHERE S.CID= C.CID AND S.PID=P.PID

can interact each other. For selection issue, vertical partitioning can be easily dapted for selecting BJIs to speed up frequently asked queries. By exploiting the similarities between these two structures, an approach for combining them has been presented.

KEY TERMS

Bitmap Join Index: It is an index, where the indexed values come from one table, but the bitmaps point to another table.

Database Tuning: Is the activity of making a database application run quicker.

Fragmentation Attribute: Is an attribute of a dimension table participating in the fragmentation process of that table.

Horizontal Partitioning: Of a table R produces fragments R1, …, Rr, each of which contains a subset of tuples of the relation.

Indexed Attribute: Is an attribute of a dimension table participating in the definition of a BJI.

Maintenance Overhead: The cost required for maintaining any redundant structure.

Query Optimization: Is the process of reducing the query processing cost.

Selection Predicate: Selection predicate is the parameter of the selection operator of the relational algebra. It has the following form: Attribute θ Value; where Attribute is a column of a given table, $\theta \in \{=, <, >, \geq, \leq\}$, and Value $\in$ Domain(A_i)).

Vertical Partitioning: Of a table R produces fragments R1, …, Rr, each of which contains a subset of R's attributes as well as the primary key.

ENDNOTES

1. A dimension table is table containing the data for one dimension within a star schema. The primary key is used to link to the fact table, and each level in the dimension has a corresponding field in the dimension table.
2. A fact table is a central table in a star schema, containing the basic facts or measures of interest. Dimension fields are also included (as foreign keys) to link to each dimension table
3. This example serves as a running example along this paper.

Bridging Taxonomic Semantics to Accurate Hierarchical Classification

Lei Tang
Arizona State University, USA

Huan Liu
Arizona State University, USA

Jiangping Zhang
The MITRE Corporation, USA

INTRODUCTION

The unregulated and open nature of the Internet and the explosive growth of the Web create a pressing need to provide various services for content categorization. The hierarchical classification attempts to achieve both accurate classification and increased comprehensibility. It has also been shown in literature that hierarchical models outperform flat models in training efficiency, classification efficiency, and classification accuracy (Koller & Sahami, 1997; McCallum, Rosenfeld, Mitchell & Ng, 1998; Ruiz & Srinivasan ,1999; Dumais & Chen, 2000; Yang, Zhang & Kisiel, 2003; Cai & Hofmann, 2004; Liu, Yang, Wan, Zeng, Cheng & Ma, 2005). However, the quality of the taxonomy attracted little attention in past works. Actually, different taxonomies can result in differences in classification. So the quality of the taxonomy should be considered for real-world classifications. Even a semantically sound taxonomy does not necessarily lead to the intended classification performance (Tang, Zhang & Liu 2006). Therefore, it is desirable to construct or modify a hierarchy to better suit the hierarchical content classification task.

BACKGROUND

Hierarchical models rely on certain predefined content taxonomies. Content taxonomies are usually created for ease of content management or access, so semantically similar categories are grouped into a parent category. Usually, a subject expert or librarian is employed to organize the category labels into a hierarchy using some ontology information. However, such a taxonomy is often generated independent of data (e.g., documents). Hence, there may exist some inconsistency between the given taxonomy and data, leading to poor classification performance.

First, semantically similar categories may not be similar in lexical terms. Most content categorization algorithms are statistical algorithms based on the occurrences of lexical terms in content. Hence, a semantically sound hierarchy does not necessarily lead to the intended categorization result.

Second, even for the same set of categories, there could be different semantically sound taxonomies. Semantics does not guarantee a unique taxonomy. Different applications may need different category taxonomies. For example, sports teams may be grouped according to their locations such as Arizona, California, Oregon, etc and then the sports types such as football, basketball, etc.. Depending upon the application, they may also be grouped according to the sports types first and then locations. Both taxonomies are reasonable in terms of semantics. With a hierarchical classification model, however, the two taxonomies would likely result in different performances. Hence, we need to investigate the impact of different hierarchies (taxonomies) on classification.

In addition, semantics may change over time. For example, when the semantic taxonomy was first generated, people would not expect the category *Hurricane* related to *Politics*, and likely put it under *Geography*. However, after investigating the data recently collected, it is noticed that a good number of documents in category *Hurricane* are actually talking about the disasters Hurricane Katrina and Rita in the United States and the responsibility and the faults of FEMA during the crises. Based on the content, it is more reasonable to put

Hurricane under *Politics* for better classification. This example demonstrates the stagnant nature of taxonomy and the dynamic change of semantics reflected in data. It also motivates the data-driven adaptation of a given taxonomy in hierarchical classification.

MAIN FOCUS

In practice, semantics based taxonomies are always exploited for hierarchical classification. As the taxonomic semantics might not be compatible with specific data and applications and can be ambiguous in certain cases, the semantic taxonomy might lead hierarchical classifications astray. There are mainly two directions to obtain a taxonomy from which a good hierarchical model can be derived: *taxonomy generation via clustering* or *taxonomy adaptation via classification learning*.

Taxonomy Generation via Clustering

Some researchers propose to generate taxonomies from data for document management or classification. Note that the taxonomy generated here focus more on comprehensibility and accurate classification, rather than efficient storage and retrieval. Therefore, we omit the tree-type based index structures for high-dimensional data like R*-tree (Beckmann, Kriegel, Schneider & Seeger 1990), TV-tree (Lin, Jagadish & Faloutsos 1994), etc. Some researchers try to build a taxonomy with the aid of human experts (Zhang, Liu, Pan & Yang 2004, Gates, Teiken & Cheng 2005) whereas other works exploit some hierarchical clustering algorithms to automatically fulfill this task. Basically, there are two approaches for hierarchical clustering: *agglomerative* and *divisive*.

In Aggarwal, Gates & Yu (1999), Chuang & Chien (2004) and Li & Zhu (2005), all employ a hierarchical *agglomerative* clustering (HAC) approach. In Aggarwal, Gates & Yu (1999), the centroids of each class are used as the initial seeds and then projected clustering method is applied to build the hierarchy. During the process, a cluster with few documents is discarded. Thus, the taxonomy generated by this method may have different categories than predefined. The authors evaluated their generated taxonomies by some user study and found its perfomrance is comparable to the Yahoo directory. In Li & Zhu (2005), a linear discriminant projection is applied to the data first and then a hierarchical clustering method UPGMA (Jain & Dubes 1988) is exploited to generate a dendrogram which is a binary tree. For classification, the authors change the dendrogram to a two-level tree according to the cluster coherence, and hierarchical models yield classification improvement over flat models. But it is not sufficiently justified why a two-level tree should be adopted. Meanwhile, a similar approach, HAC+P was proposed by Chuang & Chien (2004). This approach adds one post-processing step to automatically change the binary tree obtained from HAC, to a wide tree with multiple children. However, in this process, some parameters have to be specified as the maximum depth of the tree, the minimum size of a cluster, and the cluster number preference at each level. These parameters make this approach rather ad hoc.

Comparatively, the work in Punera, Rajan & Ghosh (2005) falls into the category of *divisive* hierarchical clustering. The authors generate a taxonomy in which each node is associated with a list of categories. Each leaf node has only one category. This algorithm basically uses the centroids of the two most distant categories as the initial seeds and then applies Spherical K-Means (Dhillon, Mallela & Kumar, 2001) with k=2 to divide the cluster into 2 sub-clusters. Each category is assigned to one sub-cluster if majority of its documents belong to the sub-cluster (its ratio exceeds a predefined parameter). Otherwise, this category is associated to both sub-clusters. Another difference of this method from other HAC methods is that it generates a taxonomy with one category possibly occurring in multiple leaf nodes.

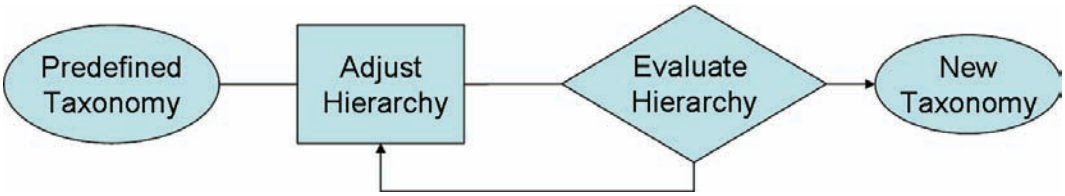
Taxonomy Adaptation via Classification Learning

Taxonomy clustering approach is appropriate if no taxonomy is provided at the initial stage. However, in reality, a human-provided semantic taxonomy is almost always available. Rather than "start from scratch", Tang, Zhang & Liu (2006) proposes to adapt the predefined taxonomy according the classification result on the data.

Three elementary hierarchy adjusting operations are defined:

- **Promote:** Roll up one node to upper level;
- **Demote:** Push down one node to its sibling;

Figure 1.



- **Merge:** Merge two sibling nodes to form a super node; Then a wrapper approach is exploited as in seen Figure 1.

The basic idea is, given a predefined taxonomy and training data, a different hierarchy can be obtained by performing the three elementary operations. Then, the newly generated hierarchy is evaluated on some validation data. If the change results in a performance improvement, we keep the change; otherwise, new change to the original taxonomy is explored. Finally, if no more change can lead to performance improvement, we output the new taxonomy which acclimatizes the taxonomic semantics according to the data.

In (Tang, Zhang & Liu 2006), the hierarchy adjustment follows a top-down traversal of the hierarchy. In the first iteration, only promoting is exploited to adjust the hierarchy whereas in the next iteration, demoting and merging are employed. This pair-wise iteration keeps running until no performance improvement is observed on the training data. As shown in their experiment, two iterations are often sufficient to achieve a robust taxonomy for classification which outperforms the predefined taxonomy and the taxonomy generated via clustering.

FUTURE TRENDS

Taxonomy can be considered as a form of prior knowledge. Adapting the prior knowledge to better suit the data is promising and desirable. Current works either abandon the hierarchy information or start taxonomy adaptation using a wrapper model. This short article provides some starting points that can hopefully lead to more effective and efficient methods to explore the prior knowledge in the future. When we better understand the problem of hierarchical classification and hierarchy consistency with data, we will investigate how to provide a filter approach which is more efficient to accomplish taxonomy adaptation.

This problem is naturally connected to Bayesian inference as well. The predefined hierarchy is the prior and the newly generated taxonomy is a "posterior" hierarchy. Integrating these two different fields—data mining and Bayesian inference, to reinforce the theory of taxonomy adaptation and to provide effective solution is a big challenge for data mining practitioners.

It is noticed that the number of features selected at each node can affect the performance and the structure of a hierarchy. When the class distribution is imbalanced, which is common in real-world applications, we should also pay attention to the problem of feature selection in order to avoid the bias associated with skewed class distribution (Forman, 2003; Tang & Liu, 2005). An effective criterion to select features can be explored in combination with the hierarchy information in this regard. Some general discussions and research issues of feature selection can be found in Liu & Motoda (1998) and Liu & Yu (2005).

CONCLUSION

Hierarchical models are effective for classification when we have a predefined semantically sound taxonomy. Since a given taxonomy may not necessarily lead to the best classification performance. Our task is how to obtain a data-driven hierarchy so that a reasonably good classifier can be inducted. In this article, we present an initial attempt to review and categorize the existing approaches: *taxonomy generation via clustering* and *taxonomy adaptation via classification learning*. It is anticipated that this active area of research will produce more effective and efficient approaches that are likely to emerge in a vast range of applications of web mining and text categorization.

KEY TERMS

Classification: A process of predicting the classes of unseen instances based on patterns learned from available instances with predefined classes.

Clustering: A process of grouping instances into clusters so that instances are similar to one another within a cluster but dissimilar to instances in other clusters.

Filter Model: A process that selects the best hierarchy without building hierarchical models.

Flat Model: A classifier outputs a classification from the input without any intermediate steps.

Hierarchical Model: A classifier outputs a classification using the taxonomy information in intermediate steps.

Hierarchy/Taxonomy: A tree with each node representing a category. Each leaf node represents a class label we are interested.

Taxonomy Adaptation: A process which adapts the predefined taxonomy based on the some data with class labels. All the class labels appear in the leaf node of the newly generated taxonomy.

Taxonomy Generation: A process which generates taxonomy based on some data with class labels so that all the labels appear in the leaf node of the taxonomy.

Wrapper Model: A process which builds a hierarchical model on training data and evaluates the model on validation data to select the best hierarchy. Usually, this process involves multiple constructions and evaluations of hierarchical models.

A Case Study of a Data Warehouse in the Finnish Police

Arla Juntunen
Department of Marketing and Management Helsinki School of Economics, Finland
Finland's Government Ministry of the Interior, Police Department, Finland

INTRODUCTION

The high level objectives of public authorities are to create value at minimal cost, and achieve ongoing support and commitment from its funding authority. Similar to the private sector, today's government agencies face a rapidly changing operating environment and many challenges. Where public organizations differ is that they need to manage this environment while answering to demands for increased service, reduced costs, fewer resources and at the same time increased efficiency and accountability. Public organization must cope with changing expectations of multiple contact groups, emerging regulation, changes in politics, decentralization of organization, and centralization of certain functions providing similar services, and growing demand for better accountability. The aim of public management is to create public value.

Public sector managers create value through their organization's performance and demonstrated accomplishments. The public value is difficult to define: it is something that exists within each community. It is created and affected by the citizens, businesses and organizations of that community (cf. also Moore, 1995). This increased interest to questions of value is partly due to the adoption of values and value-related concepts taken from business, like value creation and added value. It is argued that the public sector adopts business-like techniques to increase efficiency (Khademian, 1995; cf. Turban et al. 2007; Chen et al. 2005). In addition, there is a growing concern to the non-tangible, political, and ethical aspects of the public sector governance and actions (See Berg, 2001) Decision making that turns the resources in to public value is a daily challenge in the government (Khademian, 1999; Flynn, 2007) and not only because of the social or political factors. Most of decision problems are no longer well-structured problems that are easy to be solved by experience. Even problems that used to be fairly simple to define and solve are now much more complex because of the globalization of the economy, and rapid pace of changes in the technology and political and social environment. Therefore, modern decision makers often need to integrate quickly and reliably knowledge from different areas of data sources to use it in their decision making process. Moreover, the tools and applications developed for knowledge representations in key application areas are extremely diversified, therefore knowledge and data modeling and integration is important (See also the decision support systems (DSS) modeling methods and paradigms: Ruan et al., 2001; Carlsson & Fuller, 2002; Fink, 2002; Makowski & Wierzbicki, 2003). The application s of real-world problems and the abundance of different software tools allow to integrate several methods, specifications and analysis and to apply them to new, arising, complex problems.

In addition, business like methods and measurements to assist in managing and evaluating performance are hot topics in the government, and therefore, many government bodies are currently developing or have an existing data warehouse and a reporting solution. Recently, there has been a growing interest in measuring performance and productivity as a consequence of the convergence of two issues: (1) increased demand for accountability on the part of governing bodies, the media, and the public in general, and (2) a commitment of managers and government bodies to focus on results and to work more intentionally towards efficiency and improved performance (Poister, 2003).

This chapter discusses the issues and challenges of the adoption, implementation, effects and outcomes of the data warehouse and its use in analyzing the different operations of the police work, and the increased efficiency and productivity in the Finnish police organization due to the implementation and utilization of the data warehouse and reporting solution called PolStat (Police Statistics). Furthermore, the design of a data warehouse and analyzing system is not an easy task. It requires considering all phases from the requirements

specification to the final implementation including the ETL process. It should also take into account that the inclusion of different data items depends on both, users' needs and data availability in source systems. (Malinowski & Zimányi, 2007). The efficiency and productivity of the organization is measured with the key indicators defined and described by the police organization itself. The indicator data is stored in the data warehouse. The different organizational units are allowed to add their own static or dynamic reports into PolStat. The suggestions of how to further develop the content and measures are gathered from all over the organization as well as from external partners, like the customs and the boarder control.

The Data Warehouse and business intelligence are seen as a strategic management tool in the Finnish Police; a tool for better and comprehensive assessment of the police performance; a tool for balancing the most important perspectives of the police performance; and finally, a tool to communicate the current status of the police organization versus the development compared to previous years. Effectively, the Data Warehouse is also the means by which the police work as a whole will be made open and accountable to all interested parties. The system developed identifies what is to be achieved (target i.e. commonly agreed views of the police work and organization based on relevant measures), how to achieve the target, and by who, and the monthly estimates based on current data versus the previous years since 1997.

This chapter offers an overview of the development process of the data warehouse in the Finnish police, its critical success factors and challenges. The writer had an opportunity to make a follow-up study from the beginning of the process, and this contribution is an outline of the project initiated in the Police Department in 2002 and of main findings.

BACKGROUND

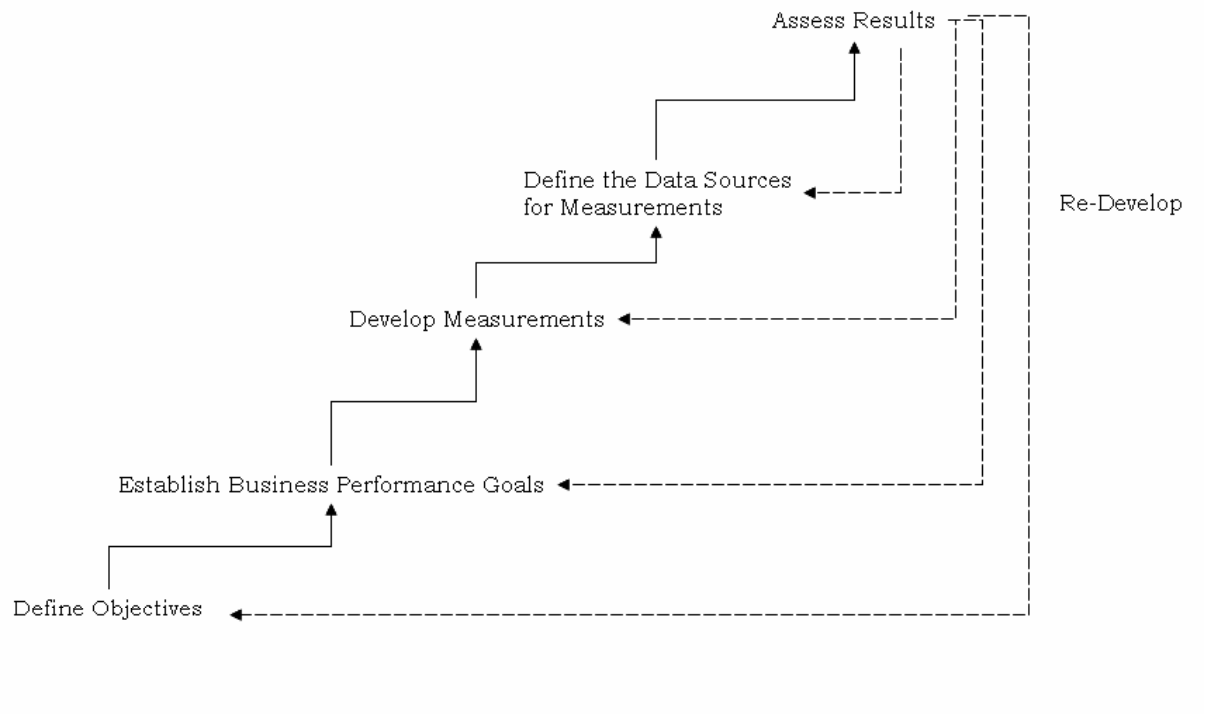
Storing (1981) stated that the separation of powers includes the assumption that certain kinds of functions are best performed in unique ways by distinctive organizational units: "With each branch distinct from the others, each can perform its function in its appropriate way." (Storing,1981, 59 - 60). The Finnish Police operates under the direction of the Ministry of the Interior. The Police Department of the Ministry of the Interior acts as the Supreme Police Command of Finland. The Supreme Police Command, which heads all police operations, decides on national strategies and ensures that the basic preconditions for effective operations exist. Within its command are five Provincial Police Commands; three national units, namely the National Bureau of Investigation, the Security Police and the National Traffic Police, the Police IT Management Agency, the Police Technical Center and the Helsinki Police Department and the police training establishments.

Inside the police organization, the challenge to improve the management by results–steering and –reporting has been among the main drivers why the development of the data warehouse started. The most important drivers to built a new data warehouse based on Oracle database, Informatica (ETL -extract, transform and load -tool), and Cognos Reporting and Analyzing tools in 2002 was the need to improve the strategic management and planning of the Finnish Police, and to develop a more suitable and comprehensive management reporting system (Management Information System, MIS) and to be able to collect and combine data from internal and external data sources.

The data warehouse content development is based on organizational needs and current governmental strategies and 'hot topics'. The strategy and vision drives the development. The assessment model (see Figure 1) supports the strategy and strategic goals and it assists the organization to understand the cyclic process of the data warehouse development. The performance planning consists of defining the organizational strategy including its vision and strategic objectives, defining and developing specific measurable goals. The current data collection and analysis processes are developed after the initial planning phase.

The measures developed are used to assess the organizational effectiveness, productivity, accountability and public value. Performance measures can be divided to direct and indirect, hard and soft measures (Bayley 1996, 47-48). Direct and hard performance measures are for example crime rates and criminal victimizations. Direct and soft measures are for example public confidence in police work, and satisfaction with police actions or feeling insecure in public places like streets at night time. Indirect and hard performance measures are for example number of police and police response times, arrests and a number of follow-up contacts with crime victims. Indirect soft measures are for example the awareness of the public reputation of the police, and

Figure 1. Strategy and vision drives the assessment model. The model supports the strategy and strategic goals



how well police knows its operational environment in different areas of the country. Also, Bailey states that only direct measures show police effectiveness. Soft indicators are significant complement to hard measurements. They contribute to the public value and quality of work. They also affect the police behavior.

MAIN FOCUS

The creation of a corporate-wide data warehouse, particularly on a public sector, is a major undertaking. It involves several issues, like for example the public acquisition procedures, project management, development or acquisition of tools for user access, database maintenance, data transfer and quality issues (Radding, 1995).

The Finnish Police started its first reporting systems back in 1992 (Törmänen, 2003) with SAS Institute's reporting tools. The first data warehouse was ready in 1996, and the first data was gathered to a SAS database in 1997. The long initial development period from 1992 to 1996 was due to the lack of skilled resources and unclear goals. However, even in 1992 there was an explicit opinion within the management of the Finnish Police that an executive information system was needed with static monthly and yearly reports (Pike, 1992). Though, it was not realized then that the development of a reporting system would eventually lead to a data warehouse with multidimensional cubes and different data analyzing and mining possibilities.

The rapid changes in the operating environment, organization and new technologies led to the redefinition of the technology architecture and the creation of PolStat data warehouse in 2002-2004. The development process consisted of the conversion of the old SAS-database to an Oracle 7 database, and after that started the new content development process of each of the topic areas (see figure 2).The end-users and managers were actively involved in the conversion and the development process of the new data warehouse, OLAP-cubes and the static and dynamic reports.

The Figure 2 shows the general configuration of the PolStat data warehouse and reporting solution. It enables the organization to consolidate its data from multiple internal and external data sources. The internal data bases include information, for example of the following topics: citizens (customers), licenses (passports, driver's

licenses, gun permits), different types of crimes, traffic information, book keeping and finance information, employee information. The consolidated data is used to monitor, plan, analyze and estimate the different operations of the police work. The data warehouse is built to be scalable and robust: there are currently about 12,000 users. The data warehouse model is based on a star schema. The data base itself is scalable up to terabytes. The data warehouse's metadata management allows to search, capture, use and publish metadata objects as dimensions, hierarchies, measures, and performance metrics and report layout objects.

The old legacy systems are based on various different technology architectures due to the long development history. The oldest systems are from 1983 and the newest from 2007, therefore, there is not only one technological solution for interfaces but several based on the various technologies used during the last 25 years. The data mining tool used is SPSS. Cognos 7 is used for reporting and analyzing the data in the data warehouse. Currently, there is an ongoing project to upgrade into the Cognos 8 version.

The Cognos analysis solution enables the users to search through large, complex data sets using drag-and-drop techniques on their own computer. It allows the drill down through increasing levels of detail, and view by different dimensions such as crime types per region or by the police department. It allows viewing and analyzing data relationships graphically. The end-users can easily drill down, slice and dice, rank, sort, forecast, and nest information to gain greater insight into the crime trends, causes to sudden changes compared to previous years, and effects on resource planning (see Figure 3).

The OLAP offers multidimensional views to the data and the analysts can analyze the data from different viewpoints. The different users are allowed to view the data and create new reports. There are only a few users with admin-rights. Most users only view the basic reports that are made ready monthly or every three months. The Cognos has also a common XML-based report format. The technical information of the data warehouse solution is as follows: The server operating system is HP-UX; The Web-Server is Microsoft IIS;

Figure 2. POLSTAT- Data warehouse stores data from different operational databases and external data sources. The information is used to monitor, plan, analyze and estimate. The management can use the data gathered to steer the organization towards its goals timely, efficiently and productively. (Figure mod. from BI-consultant Mika Naatula/Platon Finland's presentation)

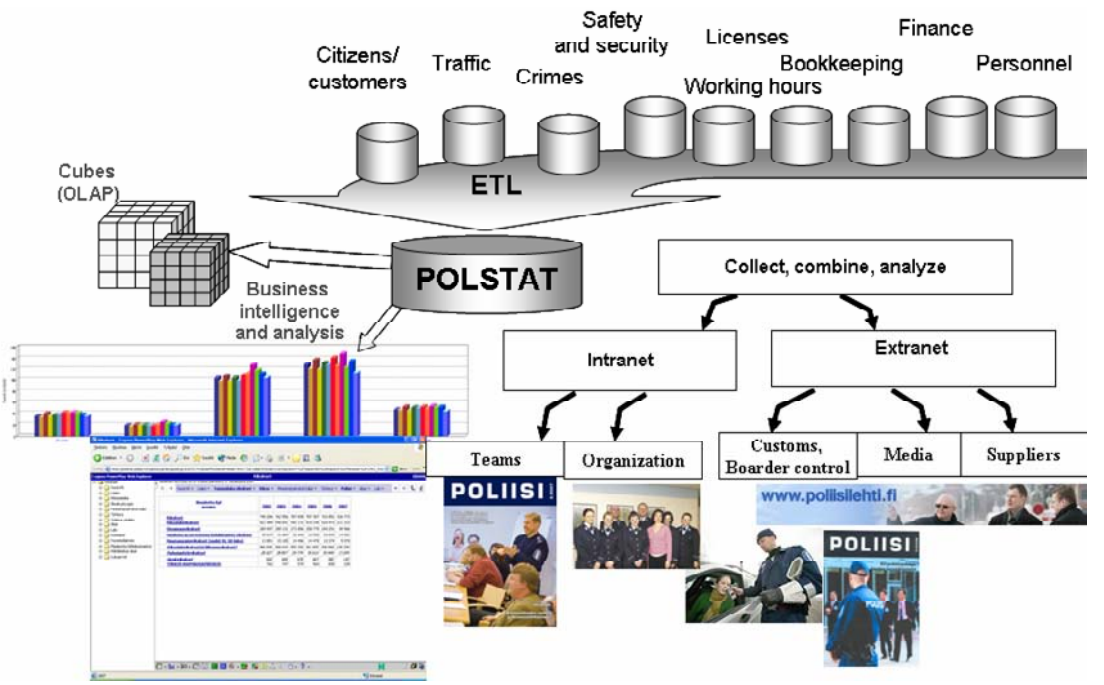


Figure 3. The percentage of solved crimes in jnauary-August 2003-2007 (source: Polstat)

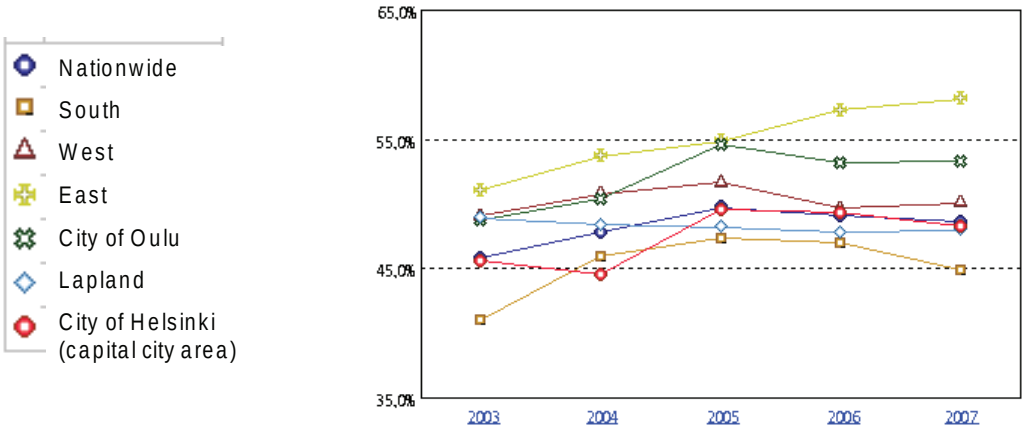

Solved Crimes, % year	2003	2004	2005	2006	2007
Nationwide	45,8%	47,9%	49,8%	49,1%	48,6%
South	41,1%	46,0%	47,4%	47,0%	44,9%
West	49,1%	50,8%	51,7%	49,7%	50,1%
East	51,1%	53,8%	54,9%	57,3%	58,2%
City of Oulu	48,8%	50,4%	54,6%	53,2%	53,3%
Lapland	49,0%	48,4%	48,2%	47,9%	48,0%
City of Helsinki (capital city area)	45,6%	44,5%	49,6%	49,3%	48,3%

and the authentication providers used is Cognos Series 7 Namespace, however, that is changing with the new Cognos version 8 installation.

Enablers/Critical Success Factors

1. **Top-level commitment:** Commitment of the Ministry of the Interior and of the Supreme Command of the Police has been the most critical enabler to guarantee the success of the data warehouse development. This commitment has come not merely in terms of statements, but also in the commitment of development and maintenance resources.
2. **Use of technology:** The Government uses secure and standardized solutions and platforms in the development of Information Technology architecture and solutions. They try to foresee the future trends in technology and find out the most suitable solutions that would be cost-effective, secure and easy to use for the whole organization.
3. **Communication:** Communication performance is an essential part of the success of the data warehouse. However, it can also be the most difficult one to accomplish well. The successful communication needs: (i) the clarity of the goals; (ii) the flexibility—not rigidity—in decision process; and (iii) organizational culture that supports open discussion and communication between teams and different levels of organization (See also Pandey and Garnett, 2006)
4. **Supportive human resources:** The most valuable suppliers in this development have been TietoEnator Plc as a business intelligence consultant partner and Cognos as reporting and analyzing tool provider. However, the most important human resources are the organization's own resources. The end-users, like managers and analysts, make the data in the warehouse alive with their own knowledge and interpretations of the existing data.
5. **"Small is good":** Considering the high cost of data warehousing technology and the inherent risks of failure, the Finnish Police conclude that

the success is better when implementation begins with the creation of small data marts (OLAPs) for end-users (analysts) with considerable end-user computing and data analyzing experience.

The challenges of the data warehouse development process have caused time-related delays, re-prioritizing tasks and activities in the content development and maintenance.

Constraints/Challenges

1. **Resource instability:** Governmental and organizational changes as well as the current and time-related "hot topics" have an effect on the resource allocations. They can either reduce or increase the resource allocations. Lack of skilled staff to maintain and develop the data warehouse and reporting system has caused some delays in the content development.
2. **Data Security:** Data security can impact data warehousing projects and especially at the police even when there is no intent to make the data available outside the organization. This includes data transfer from an external data source and to the organization from external sources. Sometimes the data is protected by law and it is strictly defined who can access the data; sometimes data is protected by intra-departmental rules and by different user profiles with different data access.
3. **Technology Architecture Issues:** Like many public and private organizations, the police organization faces the problem of legacy systems that are several decades old and made with old and different technologies. These databases contain critically important data for daily operational management. Even more challenging are the constant maintenance of these old legacy systems due to changing operational environment, new crimes and laws. Also, old legacy systems are being renewed piece by piece. This creates more challenges in keeping the content of the data warehouse up to date.
4. **Changing organizational structures:** Changing organizational and reporting structures are challenging when the data sometimes needs to be seen both with the structure of the old organization and with the structure of the new organization.

FUTURE TRENDS

During the 1990s, a concept of Knowledge Management(See e.g. Davenport, 2001; Möller and Svahn, 2006; Nonaka et al., 2001) emerged, and both the public and private sector researchers accepted it in the information technology and management literature. Sharing, transferring and storing organizational knowledge has stressed the idea of further developing a data warehouse to support organizational learning and knowledge management within the organization (cf. Malinowski & Zimányi, 2007). The requirement specification and gathering can depend on the users, operational data sources or both. Therefore, the future challenges lies on designing and modeling the spatial and temporal data warehouses for various data requirements. Other challenges are to integrate data from diverse source systems in the face of organizational or economic constraints that require those systems to remain autonomous. Important future research challenges therefore include schema integration and evolution, and the query processing in such a heterogeneous environment (See March et al., 2000; March & Hevner, 2007; Phuboon-ob & Auepanwiriyakul, 2007).

The Finnish Police's plans include developing the data warehouse to support organizational learning because sharing new ideas, information and knowledge with the colleagues working in the same field are important in developing organizational resources and to be more effective and productive. Moreover, a substantial portion of the Finnish Police workforce will become eligible to retire within ten years. Workforce planning, organizational learning and knowledge management are integrated together because they are critical in ensuring that the different organizational units have sufficient and skilled staff to account for these retirements. Besides, high staff turnover, and lack of knowledge based on experience can hinder organizational effectiveness and productivity. In addition, to survive in the fast-changing environment the police as "an adaptive organization" (Radjou, et al., 2006) would have to be more like a shifting "constellation" (Mintzberg, 1998; Toffler, 1985) that has linkages (Pinfield et al., 1974) with its decentralized and semi-autonomous organizational units. These linkages can be for example linked organizational groups like functional teams, cross-functional teams, special task forces or project teams (Edgelow, 2006). The adaptive organization is a networked organization with internal

and external networks and flexible decision processes (Larraine, 2002; Möller et al. 2005, 2006).

CONCLUSION

This increased interest in questions of value creation and the never-ending struggle to develop passable result indicators and performance measures are probably due to the complexity of public service provision, and also because the different values and rationalities of public sector services are indeed incompatible with the private sector (See Berg, 2001). Still, this continuing discussion of public value and accountability of public sector actors, and how to measure and evaluate the performance and effectiveness means also increasing efforts to maintain the content of the data warehouse to support the new and growing demands.

KEY TERMS

Accountability: It is a social relationship in which an actor feels an obligation to explain and to justify his or her conduct to some significant other. It presupposes that an organization has a clear policy on who is accountable to whom and for what. It involves the expectation that the accountable group will face consequences of its actions and be willing to accept advice

or criticism and to modify its practices in the light of that advice or criticism.

Data Warehouse: A data warehouse is a relational database that is designed for query and analysis rather than for transaction processing. It usually contains historical data derived from transaction data, but it can include data from both internal and external sources. It separates analysis workload from transaction workload and enables an organization to consolidate its data from multiple sources. In addition to a relational database, a data warehouse environment includes an extraction, transportation, transformation, and loading (ETL) solution, an online analytical processing (OLAP) engine, client analysis tools, and other applications that manage the process of gathering data and delivering it to business users.

Effectiveness and Efficiency: In this chapter, **effectiveness** in the public sector means that the organization is able to achieve its goals and be competitive. **Efficiency** means that the resources are not wasted.

ETL: ETL-tool is an extract, transform and load -tool. ETL is also a process in data warehousing that involves extracting data from different sources, transforming it to fit organizational needs, and finally loading it into the data warehouse.

Knowledge Management: (KM) deals with concept of how organizations, groups, and individuals handle their knowledge in all forms, in order to improve organizational performance.

Online Analytical Processing (OLAP): OLAP is a category of software tools providing analysis of data stored in a database. OLAP tools enable users to analyze different dimensions of multidimensional data. For example, it provides time series and trend analysis views. [http://en.wikipedia.org/wiki/OLAP_cube]

Organizational Learning (OL): It is the way organizations "build, supplement, and organize knowledge and routines around their activities and within their cultures and adapt and develop organizational efficiency by improving the use of the broad skills of their workforces" (Dodgson 1993: 377)

Productivity: Public sector productivity involves efficiency and outputs, it also involves effectiveness and outcomes.

Classification and Regression Trees

Johannes Gehrke
Cornell University, USA

INTRODUCTION

It is the goal of classification and regression to build a data mining model that can be used for prediction. To construct such a model, we are given a set of training records, each having several attributes. These attributes can either be numerical (for example, age or salary) or categorical (for example, profession or gender). There is one distinguished attribute, the dependent attribute; the other attributes are called predictor attributes. If the dependent attribute is categorical, the problem is a classification problem. If the dependent attribute is numerical, the problem is a regression problem. It is the goal of classification and regression to construct a data mining model that predicts the (unknown) value for a record where the value of the dependent attribute is unknown. (We call such a record an unlabeled record.) Classification and regression have a wide range of applications, including scientific experiments, medical diagnosis, fraud detection, credit approval, and target marketing (Hand, 1997).

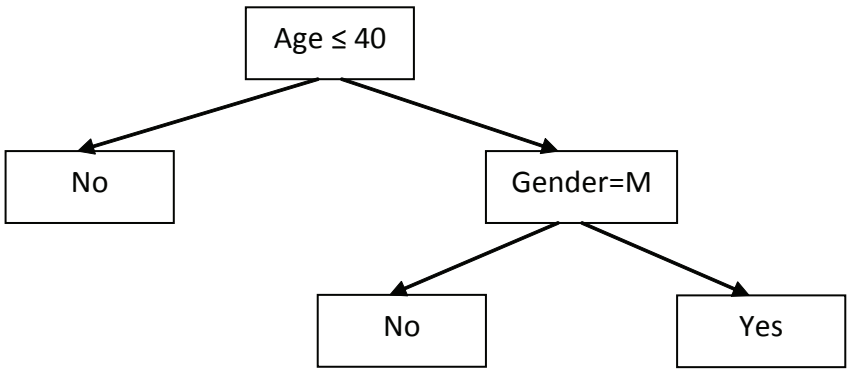
Many classification and regression models have been proposed in the literature, among the more popular models are neural networks, genetic algorithms, Bayesian methods, linear and log-linear models and other statistical methods, decision tables, and tree-structured models, the focus of this chapter (Breiman, Friedman, Olshen, & Stone, 1984). Tree-structured models, so-called decision trees, are easy to understand, they are non-parametric and thus do not rely on assumptions about the data distribution, and they have fast construction methods even for large training datasets (Lim, Loh, & Shih, 2000). Most data mining suites include tools for classification and regression tree construction (Goebel & Gruenwald, 1999).

BACKGROUND

Let us start by introducing decision trees. For the ease of explanation, we are going to focus on binary decision trees. In binary decision trees, each internal node has two children nodes. Each internal node is associated with a predicate, called the splitting predicate, which involves only the predictor attributes. Each leaf node is associated with a unique value for the dependent attribute. A decision encodes a data mining model as follows: For an unlabeled record, we start at the root node. If the record satisfies the predicate associated with the root node, we follow the tree to the left child of the root, and we go to the right child otherwise. We continue this pattern through a unique path from the root of the tree to a leaf node, where we predict the value of the dependent attribute associated with this leaf node. An example decision tree for a classification problem, a classification tree, is shown in Figure 1. Note that a decision tree automatically captures interactions between variables, but it only includes interactions that help in the prediction of the dependent attribute. For example, the rightmost leaf node in the example shown in Figure 1 is associated with the classification rule: "If (Age >= 40) and (Salary > 80k), then YES", as classification rule that involves an interaction between the two predictor attributes age and salary.

Decision trees can be mined automatically from a training database of records where the value of the dependent attribute is known: A decision tree construction algorithm selects which attribute(s) to involve in the splitting predicates and the algorithm decides also on the shape and depth of the tree (Murthy, 1998).

Figure 1. An example classification tree



MAIN THRUST

Let us discuss how decision trees are mined from a training database. A decision tree is usually constructed in two phases. In the first phase, the growth phase, an overly large and deep tree is constructed from the training data. In the second phase, the pruning phase, the final size of the tree is determined with the goal to minimize the expected mis-prediction error (Quinlan, 1993).

There are two problems that make decision tree construction a hard problem. First, construction of the "optimal" tree for several measure of optimality is an NP-hard problem. Thus all decision tree construction algorithms grow the tree top-down according to the following greedy heuristic: At the root node, the training database is examined and a splitting predicate is selected. Then the training database is partitioned according to the splitting predicate, and the same method is applied recursively at each child node. The second problem is that the training database is only a sample from a much larger population of records. The decision tree has to perform well on records drawn from the population, not on the training database. (For the records in the training database we already know the value of the dependent attribute.)

Three different algorithmic issues need to be addressed during the tree construction phase. The first issue is to devise a split selection algorithm such that the resulting tree models the underlying dependency relationship between the predictor attributes and the dependent attribute well. During split selection, we have to make two decisions. First, we need to decide which attribute we will select as splitting attribute. Second, given the splitting attribute, we have to decide on the actual splitting predicate. For a numerical attribute X, splitting predicates are usually of the form $X \leq c$, where c is a constant. For example, in the tree shown in Figure 1, the splitting predicate of the root node is of this form. For a categorical attribute X, splits are usually of the form X in C, where C is a set of values in the domain of X. For example, in the tree shown in Figure 1, the splitting predicate of the right child node of the root is of this form. There exist decision trees that have a larger class of possible splitting predicates, for example, there exist decision trees with linear combinations of numerical attribute values as splitting predicates for example $\Sigma a_i X_i + c \geq 0$, where i ranges over all attributes (Loh & Shih, 1997). Such splits, also called oblique splits, result in shorter trees, however, the resulting trees are no longer easy to interpret.

The second issue is to devise a pruning algorithm that selects the tree of the right size. If the tree is too large, then the tree models the training database too closely instead of modeling the underlying population. One possible choice of pruning a tree is to hold out part of the training set as a test set and to use the test set to estimate the misprediction error of trees of different size. We then simply select the tree that minimizes the misprediction error.

The third issue is to devise an algorithm for intelligent management of the training database in case the training database is very large (Ramakrishnan & Gehrke, 2002). This issue has only received attention in the last decade, but there exist now many algorithms that can construct decision trees over extremely large, disk-

resident training databases (Gehrke, Ramakrishnan, & Ganti, 2000; Shafer, Agrawal, & Mehta, 1996).

In most classification and regression scenarios, we also have costs associated with misclassifying a record, or with being far off in our prediction of a numerical dependent value. Existing decision tree algorithms can take costs into account, and they will bias the model towards minimizing the expected misprediction cost instead of the expected misclassification rate, or the expected difference between the predicted and true value of the dependent attribute.

FUTURE TRENDS

Recent developments have expanded the types of model that a decision tree can have in its leaf nodes. So far, we assumed that each leaf node just predicts a constant value for the dependent attribute. Recent work however, has shown how to construct decision trees with linear models in the leaf nodes (Dobra & Gehrke, 2002). Another recent development in the general area of data mining is the use of ensembles of models, and decision trees are a popular model for use as a base model in ensemble learning (Caruana, Niculescu-Mizil, Crew, & Ksikes, 2004). Another recent trend is the construction of data mining models of high-speed data streams, and there have been adaptations of decision tree construction algorithms to such environments (Domingos & Hulten, 2002). A last recent trend is to take adversarial behavior into account, for example in classifying spam. In this case, an adversary who produces the records to be classified actively changes her behavior over time to outsmart a static classifier (Dalvi, Domingos, Mausam, Sanghai, & Verma, 2004).

CONCLUSION

Decision trees are one of the most popular data mining models. Decision trees are important since they can result in powerful predictive models while at the same time they allow users to get insight into the phenomenon that is being modeled.

KEY TERMS

Attribute: Column of a dataset

Categorical Attribute: Attribute that takes values from a discrete domain.

Numerical Attribute: Attribute that takes values from a continuous domain.

Decision Tree: Tree-structured data mining model used for prediction, where internal nodes are labeled with predicates ("decisions") and leaf nodes are labeled with data mining models.

Classification Tree: A decision tree where the dependent attribute is categorical.

Regression Tree: A decision tree where the dependent attribute is numerical.

Splitting Predicate: Predicate at an internal node of the tree; it decides which branch a record traverses on its way from the root to a leaf node.

Classification Methods

Aijun An
York University, Canada

INTRODUCTION

Generally speaking, classification is the action of assigning an object to a category according to the characteristics of the object. In data mining, classification refers to the task of analyzing a set of pre-classified data objects to learn a model (or a function) that can be used to classify an unseen data object into one of several predefined classes. A data object, referred to as an example, is described by a set of attributes or variables. One of the attributes describes the class that an example belongs to and is thus called the class attribute or class variable. Other attributes are often called independent or predictor attributes (or variables). The set of examples used to learn the classification model is called the training data set. Tasks related to classification include regression, which builds a model from training data to predict numerical values, and clustering, which groups examples to form categories. Classification belongs to the category of supervised learning, distinguished from unsupervised learning. In supervised learning, the training data consists of pairs of input data (typically vectors), and desired outputs, while in unsupervised learning there is no a priori output.

Classification has various applications, such as learning from a patient database to diagnose a disease based on the symptoms of a patient, analyzing credit card transactions to identify fraudulent transactions, automatic recognition of letters or digits based on handwriting samples, and distinguishing highly active compounds from inactive ones based on the structures of compounds for drug discovery.

BACKGROUND

Classification has been studied in statistics and machine learning. In statistics, classification is also referred to as discrimination. Early work on classification focused on discriminant analysis, which constructs a set of discriminant functions, such as linear functions of the predictor variables, based on a set of training examples to discriminate among the groups defined by the class variable. Modern studies explore more flexible classes of models, such as providing an estimate of the join distribution of the features within each class (e.g. Bayesian classification), classifying an example based on distances in the feature space (e.g. the k-nearest neighbor method), and constructing a classification tree that classifies examples based on tests on one or more predictor variables (i.e., classification tree analysis).

In the field of machine learning, attention has more focused on generating classification expressions that are easily understood by humans. The most popular machine learning technique is decision tree learning, which learns the same tree structure as classification trees but uses different criteria during the learning process. The technique was developed in parallel with the classification tree analysis in statistics. Other machine learning techniques include classification rule learning, neural networks, Bayesian classification, instance-based learning, genetic algorithms, the rough set approach and support vector machines. These techniques mimic human reasoning in different aspects to provide insight into the learning process.

The data mining community inherits the classification techniques developed in statistics and machine learning, and applies them to various real world problems. Most statistical and machine learning algorithms are memory-based, in which the whole training data set is loaded into the main memory before learning starts. In data mining, much effort has been spent on scaling up the classification algorithms to deal with large data sets. There is also a new classification technique, called association-based classification, which is based on association rule learning.

MAIN THRUST

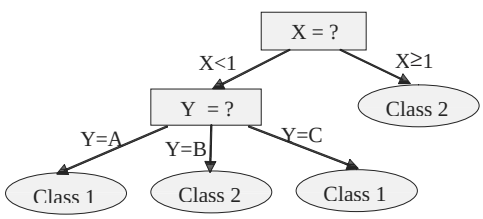
Major classification techniques are described below. The techniques differ in the learning mechanism and in the representation of the learned model.

Decision Tree Learning

Decision tree learning is one of the most popular classification algorithms. It induces a decision tree from data. A decision tree is a tree structured prediction model where each internal node denotes a test on an attribute, each outgoing branch represents an outcome of the test, and each leaf node is labeled with a class or class distribution. A simple decision tree is shown in Figure 1. With a decision tree, an object is classified by following a path from the root to a leaf, taking the edges corresponding to the values of the attributes in the object.

A typical decision tree learning algorithm adopts a top-down recursive divide-and-conquer strategy to construct a decision tree. Starting from a root node representing the whole training data, the data is split into two or more subsets based on the values of an attribute chosen according to a splitting criterion. For each subset a child node is created and the subset is associated with the child. The process is then separately repeated on the data in each of the child nodes, and so on, until a termination criterion is satisfied. Many decision tree learning algorithms exist. They differ mainly in attribute-selection criteria, such as information gain, gain ratio (Quinlan, 1993), gini index (Breiman, Friedman, Olshen, & Stone, 1984), etc., termination criteria and post-pruning strategies. Post-pruning is a technique that removes some branches of the tree after the tree is constructed to prevent the tree from over-fitting the training data. Representative decision tree algorithms include CART (Breiman et al., 1984) and C4.5 (Quinlan, 1993). There are also studies on fast and scalable construction of decision trees. Representative algorithms of such kind include RainForest (Gehrke, Ramakrishnan, & Ganti, 1998) and SPRINT (Shafer, Agrawal, & Mehta, 1996).

Figure 1. A decision tree with tests on attributes X and Y



Decision Rule Learning

Decision rules are a set of if-then rules. They are the most expressive and human readable representation of classification models (Mitchell, 1997). An example of decision rules is "if X<1 and Y=B, then the example belongs to Class 2". This type of rules is referred to as propositional rules. Rules can be generated by translating a decision tree into a set of rules – one rule for each leaf node in the tree. A second way to generate rules is to learn rules directly from the training data. There is a variety of rule induction algorithms. The algorithms induce rules by searching in a hypothesis space for a hypothesis that best matches the training data. The algorithms differ in the search method (e.g. general-to-specific, specific-to-general, or two-way search), the search heuristics that control the search, and the pruning method used. The most widespread approach to rule induction is *sequential covering*, in which a greedy general-to-specific search is conducted to learn a disjunctive set of conjunctive rules. It is called sequential covering because it sequentially learns a set of rules that together cover the set of positive examples for a class. Algorithms belonging to this category include CN2 (Clark & Boswell, 1991), RIPPER (Cohen, 1995) and ELEM2 (An & Cercone, 1998).

Naive Bayesian Classifier

The naive Bayesian classifier is based on Bayes' theorem. Suppose that there are m classes, $C_1, C_2, \ldots, C_m$. The classifier predicts an unseen example X as belonging to the class having the highest posterior probability conditioned on X. In other words, X is assigned to class C_i if and only if:

$$P(C_i|X) > P(C_j|X) \text{ for } 1 \le j \le m,\ j \ne i.$$

By Bayes' theorem, we have

$$P(C_i \mid X) = \frac{P(X \mid C_i)P(C_i)}{P(X)}.$$

As $P(X)$ is constant for all classes, only $P(X \mid C_i)P(C_i)$ needs to be maximized. Given a set of training data, $P(C_i)$ can be estimated by counting how often each class occurs in the training data. To reduce the computational expense in estimating $P(X|C_i)$ for all possible Xs, the classifier makes a naïve assumption that the attributes

used in describing X are conditionally independent of each other given the class of X. Thus, given the attribute values (x_1, x_2, ... x_n) that describe X, we have:

$$P(X \mid C_i) = \prod_{j=1}^{n} P(x_j \mid C_i).$$

The probabilities $P(x_1|C_i), P(x_2|C_i), \ldots, P(x_n|C_i)$ can be estimated from the training data.

The naïve Bayesian classifier is simple to use and efficient to learn. It requires only one scan of the training data. Despite the fact that the independence assumption is often violated in practice, naïve Bayes often competes well with more sophisticated classifiers. Recent theoretical analysis has shown why the naive Bayesian classifier is so robust (Domingos & Pazzani, 1997; Rish, 2001).

Bayesian Belief Networks

A Bayesian belief network, also known as Bayesian network and belief network, is a directed acyclic graph whose nodes represent variables and whose arcs represent dependence relations among the variables. If there is an arc from node *A* to another node *B*, then we say that *A* is a parent of *B* and *B* is a descendent of *A*. Each variable is conditionally independent of its nondescendents in the graph, given its parents. The variables may correspond to actual attributes given in the data or to "hidden variables" believed to form a relationship. A variable in the network can be selected as the class attribute. The classification process can return a probability distribution for the class attribute based on the network structure and some conditional probabilities estimated from the training data, which predicts the probability of each class.

The Bayesian network provides an intermediate approach between the naïve Bayesian classification and the Bayesian classification without any independence assumptions. It describes dependencies among attributes, but allows conditional independence among subsets of attributes.

The training of a belief network depends on the senario. If the network structure is known and the variables are observable, training the network only consists of estimating some conditional probabilities from the training data, which is straightforward. If the network structure is given and some of the variables are hidden, a method of gradient decent can be used to train the network (Russell, Binder, Koller, & Kanazawa, 1995). Algorithms also exist for learning the netword structure from training data given observable variables (Buntime, 1994; Cooper & Herskovits, 1992; Heckerman, Geiger, & Chickering, 1995).

The *k*-Nearest Neighbour Classifier

The *k*-nearest neighbour classifier classifies an unknown example to the most common class among its *k* nearest neighbors in the training data. It assumes all the examples correspond to points in a *n*-dimensional space. A neighbour is deemed nearest if it has the smallest distance, in the Euclidian sense, in the *n*-dimensional feature space. When $k = 1$, the unknown example is classified into the class of its closest neighbour in the training set. The *k*-nearest neighbour method stores all the training examples and postpones learning until a new example needs to be classified. This type of learning is called instance-based or lazy learning.

The *k*-nearest neighbour classifier is intuitive, easy to implement and effective in practice. It can construct a different approximation to the target function for each new example to be classified, which is advantageous when the target function is very complex, but can be discribed by a collection of less complex local approximations (Mitchell, 1997). However, its cost of classifying new examples can be high due to the fact that almost all the computation is done at the classification time. Some refinements to the k-nearest neighbor method include weighting the attributes in the distance computation and weighting the contribution of each of the *k* neighbors during classification according to their distance to the example to be classified.

Neural Networks

Neural networks, also referred to as *artificial neural networks*, are studied to simulate the human brain although brains are much more complex than any artificial neural network developed so far. A neural network is composed of a few layers of interconnected computing units (neurons or nodes). Each unit computes a simple function. The input of the units in one layer are the outputs of the units in the previous layer. Each connection between units is associated with a weight. Parallel computing can be performed among the units in each layer. The units in the first layer take input and are called the input units. The units in the last layer produces the output of the networks and are called

the output units. When the network is in operation, a value is applied to each input unit, which then passes its given value to the connections leading out from it, and on each connection the value is multiplied by the weight associated with that connection. Each unit in the next layer then receives a value which is the sum of the values produced by the connections leading into it, and in each unit a simple computation is performed on the value - a sigmoid function is typical. This process is then repeated, with the results being passed through subsequent layers of nodes until the output nodes are reached. Neural networks can be used for both regression and classification. To model a classification function, we can use one output unit per class. An example can be classified into the class corresponding to the output unit with the largest output value.

Neural networks differ in the way in which the neurons are connected, in the way the neurons process their input, and in the propogation and learning methods used (Nurnberger, Pedrycz, & Kruse, 2002). Learning a neural network is usually restricted to modifying the weights based on the training data; the structure of the initial network is usually left unchanged during the learning process. A typical network structure is the *multilayer feed-forward neural network*, in which none of the connections cycles back to a unit of a previous layer. The most widely used method for training a feed-forward neural network is backpropagation (Rumelhart, Hinton, & Williams, 1986).

Support Vector Machines

The support vector machine (SVM) is a recently developed technique for multidimensional function approximation. The objective of support vector machines is to determine a classifier or regression function which minimizes the empirical risk (that is, the training set error) and the confidence interval (which corresponds to the generalization or test set error) (Vapnik, 1998).

Given a set of N linearly separable training examples $S = \{\mathbf{x}_i \in R^n \mid i = 1,2,...,N\}$, where each example belongs to one of the two classes, represented by $y_i \in \{+1,-1\}$, the SVM learning method seeks the optimal hyperplane $\mathbf{w} \cdot \mathbf{x} + b = 0$, as the decision surface, which separates the positive and negative examples with the largest margin. The decision function for classifying linearly separable data is:

$$f(\mathbf{x}) = sign(\mathbf{w} \cdot \mathbf{x} + b),$$

where $\mathbf{w}$ and b are found from the training set by solving a constrained quadratic optimization problem. The final decision function is

$$f(\mathbf{x}) = sign\left(\sum_{i=1}^{N} \alpha_i y_i (\mathbf{x}_i \cdot \mathbf{x}) + b\right).$$

The function depends on the training examples or which α_i is non-zero. These examples are called support vectors. Often the number of support vectors is only a small fraction of the original dataset. The basic SVM formulation can be extended to the nonlinear case by using nonlinear kernels that map the input space to a high dimensional feature space. In this high dimensional feature space, linear classification can be performed. The SVM classifier has become very popular due to its high performances in practical applications such as text classification and pattern recognition.

FUTURE TRENDS

Classification is a major data mining task. As data mining becomes more popular, classification techniques are increasingly applied to provide decision support in business, biomedicine, financial analysis, telecommunications and so on. For example, there are recent applications of classification techniques to identify fraudulent usage of credit cards based on credit card transaction databases; and various classification techniques have been explored to identify highly active compounds for drug discovery. To better solve application-specific problems, there has been a trend toward the development of more application-specific data mining systems (Han & Kamber, 2001).

Traditional classification algorithms assume that the whole training data can fit into the main memory. As automatic data collection becomes a daily practice in many businesses, large volumes of data that exceed the memory capacity become available to the learning systems. Scalable classification algorithms become essential. Although some scalable algorithms for decision tree learning have been proposed, there is still a need to develop scalable and efficient algorithms for other types of classification techniques, such as decision rule learning.

Previously, the study of classification techniques focused on exploring various learning mechanisms to improve the classification accuracy on unseen examples. However, recent study on imbalanced data sets has shown that classification accuracy is not an appropriate measure to evaluate the classification performance when the data set is extremely unbalanced, in which almost all the examples belong to one or more, larger classes and far fewer examples belong to a smaller, usually more interesting class. Since many real world data sets are unbalanced, there has been a trend toward adjusting existing classification algorithms to better identify examples in the rare class.

Another issue that has become more and more important in data mining is privacy protection. As data mining tools are applied to large databases of personal records, privacy concerns are rising. Privacy-preserving data mining is currently one of the hottest research topics in data mining and will remain so in the near future.

CONCLUSION

Classification is a form of data analysis that extracts a model from data to classify future data. It has been studied in parallel in statistics and machine learning, and is currently a major technique in data mining with a broad application spectrum. Since many application problems can be formulated as a classification problem and the volume of the available data has become overwhelming, developing scalable, efficient, domain-specific, and privacy-preserving classification algorithms is essential.

KEY TERMS

Backpropagation: A neural network training algorithm for feedforward networks where the errors at the output layer are propagated back to the previous layer to update connection weights in learning. If the previous layer is not the input layer, then the errors at this hidden layer are propagated back to the layer before.

Disjunctive Set of Conjunctive Rules: A conjunctive rule is a propositional rule whose antecedent consists of a conjunction of attribute-value pairs. A disjunctive set of conjunctive rules consists of a set of conjunctive rules with the same consequent. It is called disjunctive because the rules in the set can be combined into a single disjunctive rule whose antecedent consists of a disjunction of conjunctions.

Generic Algorithm: An algorithm for optimizing a binary string based on an evolutionary mechanism that uses replication, deletion, and mutation operators carried out over many generations.

Information Gain: Given a set E of classified examples and a partition $P = \{E_1, ..., E_n\}$ of E, the information gain is defined as:

$$entropy(E) - \sum_{i=1}^{n} entropy(E_i) * \frac{|E_i|}{|E|},$$

where $|X|$ is the number of examples in X, and $entropy(X) = -\sum_{j=1}^{m} p_j \log_2(p_j)$ (assuming there are m classes in X and p_j denotes the probability of the jth class in X). Intuitively, the information gain measures the decrease of the weighted average impurity of the partitions E_1, ..., E_n, compared with the impurity of the complete set of examples E.

Machine Learning: The study of computer algorithms that develop new knowledge and improve its performance automatically through past experience.

Rough Set Data Analysis: A method for modeling uncertain information in data by forming lower and upper approximations of a class. It can be used to reduce the feature set and to generate decision rules.

Sigmod Function: A mathematical function defined by the formula

$$P(t) = \frac{1}{1 + e^{-t}}$$

Its name is due to the sigmoid shape of its graph. This function is also called the standard logistic function.

Classification of Graph Structures

Andrzej Dominik
Warsaw University of Technology, Poland

Zbigniew Walczak
Warsaw University of Technology, Poland

Jacek Wojciechowski
Warsaw University of Technology, Poland

INTRODUCTION

Classification is a classical and fundamental data mining (machine learning) task in which individual items (objects) are divided into groups (classes) based on their features (attributes). Classification problems have been deeply researched as they have a large variety of applications. They appear in different fields of science and industry and may be solved using different algorithms and techniques: e.g. neural networks, rough sets, fuzzy sets, decision trees, etc. These methods operate on various data representations. The most popular one is information system/decision table (e.g. Dominik, & Walczak, 2006) denoted by a table where rows represent objects, columns represent attributes and every cell holds a value of the given attribute for a particular object. Sometimes it is either very difficult and/or impractical to model a real life object (e.g. road map) or phenomenon (e.g. protein interactions) by a row in decision table (vector of features). In such a cases more complex data representations are required e.g. graphs, networks. A graph is basically a set of nodes (vertices) connected by either directed or undirected edges (links). Graphs are used to model and solve a wide variety of problems including classification. Recently a huge interest in the area of graph mining can be observed (e.g. Cook, & Holder, 2006). This field of science concentrates on investigating and discovering relevant information from data represented by graphs.

In this chapter, we present basic concepts, problems and methods connected with graph structures classification. We evaluate performance of the most popular and effective classifiers on two kinds of classification problems from different fields of science: computational chemistry, chemical informatics (chemical compounds classification) and information science (web documents classification).

BACKGROUND

There are numerous types of pattern that can be used to build classifiers. Three of these are frequent, common and contrast patterns.

Mining patterns in graph dataset which fulfill given conditions is a much more challenging task than mining patterns in decision tables (relational databases). The most computationally complex tasks are subgraph isomorphism (determining if one smaller graph is included in other larger graph) and isomorphism (testing whether any two graphs are isomorphic (really the same). The former is proved to be NP-complete while the complexity of the latter one is still not known. All the algorithms for solving the isomorphism problem present in the literature have an exponential time complexity in the worst case, but the existence of a polynomial solution has not yet been disproved. A universal exhaustive algorithm for both of these problems was proposed by Ullman (1976). It operates on the matrix representation of graphs and tries to find a proper permutation of nodes. The search space can be greatly reduced by using nodes invariants and iterative partitioning. Moreover multiple graph isomorphism problem (for a set of graphs determine which of them are isomorphic) can be efficiently solved with canonical labelling (Fortin, 1996). Canonical label is a unique representation (code) of a graph such that two isomorphic graphs have the same canonical label.

Another important issue is generating all non-isomorphic subgraphs of a given graph. The algorithm for generating DFS (Depth First Search) code can used to enumerate all subgraphs and reduce the number of required isomorphism checking. What is more it can be improved by introducing canonical labelling.

Contrast patterns are substructures that appear in one class of objects and do not appear in other classes

whereas common patterns appear in more than one class of objects. In data mining, patterns which uniquely identify certain class of objects are called jumping emerging patterns (JEP). Patterns common for different classes are called emerging patterns (EP). Concepts of jumping emerging patterns and emerging patterns have been deeply researched as a tool for classification purposes in databases (Kotagiri, & Bailey, 2003). They are reported to provide high classification accuracy results. Frequent pattern is a pattern which appears in samples of a given dataset more frequently than specified threshold. Agarwal and Srikant proposed an efficient algorithm for mining frequent itemsets in the transaction database called Apriori.

In graph mining contrast graph is a graph that is subgraph isomorphic to at least one graph from particular class of graphs and is not subgraph isomorphic to any graph from any other class of graphs. The concept of contrast graphs was studied by Ting and Bailey (2006). They proposed an algorithm (containing backtracking tree and hypergraph traversal algorithm) for mining all disconnected contrast graphs from dataset. Common graph is subgraph isomorphic to at least one graph in at least two different classes of graphs while frequent graph is subgraph isomorphic to at least as many graphs in a particular class of graphs as specified threshold (minimal support of a graph). Kuramochi and Karypis (2001) proposed an efficient (using canonical labelling and iterative partitioning) Apriori based algorithm for mining frequent graphs.

MAIN FOCUS

One of the most popular approaches for graph classification is based on SVM (Support Vector Machines). SVMs have good generalization properties (both theoretically and experimentally) and they operate well in high-dimensional datasets. Numerous different kernels were designed for this method (Swamidass, Chen, Bruand, Phung, Ralaivola & Baldi, 2005).

Another approach is based on k-NN (k-Nearest Neighbors) method. The most popular similarity measures for this method use concept of MCS (maximum common subgraph) (Markov, Last, & Kandel, 2006).

Deshpande, Kuramochi and Karypis (2003) proposed classification algorithms that decouples graph discovery process from the classification model construction. These methods use frequent topological and geometric graphs.

Recently a new algorithm called the CCPC (Contrast Common Patterns Classifier) was proposed by Dominik, Walczak, & Wojciechowski (2007). This algorithm uses concepts that were originally developed and introduced for data mining (jumping emerging patterns - JEP and emerging patterns - EP). The CCPC approach uses minimal (with respect to size and inclusion (non-isomorphic)) contrast and common connected graphs. Classification process is performed by aggregating supports (or other measure based on support) of contrast graphs. Common graphs play marginal role in classification and are only used for breaking ties.

Applications: Chemical Compounds Classification

Chemical molecules have various representations depending on their dimensions and features. Basic representations are: 1-dimensional strings expressed in SMILES language (language that unambiguously describe the structure of chemical molecules using short ASCII strings), 2-dimensional topological graphs and 3-dimensional geometrical structures containing coordinates of atoms. We are particularly interested in 2-dimensional graph representation in which atoms correspond to vertices and bonds to edges. Nodes are labelled with molecule symbols and links with bond multiplicities. These graphs are typically quite small (in terms of number of vertices and edges) and the average number of edges per vertex is usually slightly above 2.

Sample classification problems in the area of chemical informatics and computational chemistry include: detection/prediction of mutagenicity, toxicity and anti-cancer activity of chemical compounds for a given organism. There are two major approaches to classifying chemical compounds: quantitative structure-activity relationships (QSAR) and structural approach. The former one (King, Muggleton, Srinivasan, Sternberg, 1996) requires genuine chemical knowledge and concentrates on physico-chemical properties derived from compounds while the latter one (Deshpande, Kuramochi, & Karypis, 2003; Kozak, Kozak, & Stapor, 2007; Dominik, Walczak, & Wojciechowski, 2007) searches directly structure of the compound and discover significant substructures (e.g. contrast, common, frequent

pattern) which discriminate between different classes of structures.

We evaluated performance of most popular and effective classification methods on three publicly available datasets: Mutag, PTC and NCI (Datasets: Mutag, PTC, NCI, 2007). The Mutag dataset consists of 188 chemical compounds (aromatic and heteroaromatic nitro-compounds) along with the information indicating whether they have mutagenicity in *Salmonella typhimurium*. The Predictive Toxicology Challenge (PTC) dataset reports carcinogenicity of 417 compounds for female mice (FM), female rats (FR), male mice (MM) and male rats (MR). There are four independent problems (for each sex-animal pair) in this dataset. The National Cancer Institute (NCI) dataset provides screening results for about 70 000 compounds that suppress or inhibit the growth of a panel of 73 human tumor cell lines corresponding to the concentration parameter GI50 (the concentration that causes 50% growth inhibition). Each cell line contains approximately 3500 compounds and information on their cancer-inhibiting action. For our research we choose 60 out of 73 cell lines. There are two decision classes in all of these three problems: positive and negative.

Table 1 reports classification accuracy for different datasets and algorithms (Dominik, Walczak, & Wojciechowski, 2007). We made a selection of best available (in case of algorithms parameters) results for the following methods: PD (Pattern Discovery (De Readt, & Kramer, 2001)), SVM (Support Vector Machine with different kernels (Swamidass, Chen, Bruand, Phung, Ralaivola & Baldi, 2005)) and the CCPC. For the Mutag and PTC datasets, classification accuracy was estimated through leave-one-out cross-validation. In case of NCI dataset cross-validation using 20 random 80/20 training/test splits was used. For this dataset reported values are average values from all 60 cell lines. Best results for each dataset are in bold face and second best are in italic face. NA indicates that the given value was not available. For all datasets the CCPC classifier outperformed other approaches in case of accuracy.

Applications: Web Documents Classification

There are three basic document representations: vector, graph and hybrid which is a combination of two previous ones. In vector model each term in a document becomes a feature (dimension). The value of each dimension in a vector is some measure based on frequency of appropriate term in a given document. In graph model terms refer to nodes. Nodes are connected by edges which provides both text structure (e.g. the order in which the words appear or the location of a word within the document) and document structure (e.g. markup elements (tags) inside HTML web document) information.

HTML web documents are often represented using standard model. According to this model web document is represented as a graph containing N labelled nodes corresponding to N unique most frequently appearing words in a document. Nodes are labelled with words they represent. Two nodes are connected by undirected labelled edge if they are adjacent in a document. An edge's label depends on the section in which two particular words are adjacent. There are three major sections: title, which contains the text related to the document's title and any provided keywords; link, which is text appearing in clickable hyperlinks on the document; and text, which comprises any of the readable text in the document (this includes link text but not title and keyword text).

One of the most popular approaches for document classification is based on k-NN (k-Nearest Neighbors) method. Different similarity measures were proposed

Table 1. Comparison of classification accuracy for chemical compounds

Algorithm	Mutag	PTC-FM	PTC-FR	PTC-MM	PTC-MR	NCI
PD	89.9	61.0	66.7	61.0	62.8	NA
SVM, 1D SMILES	85.6	63.0	*67.0*	*66.4*	57.6	NA
SVM, 2D Tanimoto	*90.4*	64.2	66.7	*66.4*	63.7	71.5
SVM, 2D MinMax	**91.5**	*64.5*	66.4	64.0	*64.5*	*72.3*
CCPC	**91.5**	**81.4**	**82.3**	**77.7**	**77.0**	**86.2**

for different document representations. For vector representation the most popular is cosine measure while for graph representation distance based on maximum common subgraph (MCS) is widely used (Markov, Last, & Kandel, 2006). Recently methods based on hybrid document representations have become very popular. They are reported to provide better results than methods using simple representations. Markov and Last (2005) proposed an algorithm that uses hybrid representation. It extracts subgraphs from a graph that represents document, then creates vector with Boolean values indicating relevant subgraphs.

In order to evaluate the performance of the CCPC classifier we performed several experiments on three publicly available, benchmark collections of web documents, called F-series, J-series and K-series (Datasets: PDDPdata, 2007). Each collection contains HTML documents which were originally news pages hosted at Yahoo (www.yahoo.com). Each document in every collection has a category (class) associated to the content of the document. The F-series collection contains 98 documents divided into 4 major categories, the J-series collection contains 185 documents assigned to 10 categories while the K-series consists of 2340 documents belonging to 20 categories. In all of those datasets document is assigned to exactly one category.

Table 2 reports classification accuracy for different datasets, document representations and algorithms (Dominik, Walczak, & Wojciechowski, 2007). We made a selection of best available (in case of algorithms parameters) results for following methods: k-NN (k-Nearest Neighbor) (Markov, Last, & Kandel, 2006; Markov, & Last, 2006) and the CCPC. For all document collections classification accuracy was estimated through leave-one-out cross-validation. Best results for each dataset are in bold face and second best are in italic face. The results show that our algorithm is competitive to existing schemes in terms of accuracy and data complexity (number of terms in document model used for classification).

FUTURE TRENDS

Future research may concentrate on developing different graph classifiers based on structural patterns. These patterns can be used in combination with popular algorithms solving classification problems e.g. k-Nearest Neighbors (similarity measure based on contrast graphs). Currently, the CCPC is the only classifier that uses contrast graphs. Experiments show that this kind of patterns provide high classification accuracy results for both data representations: decision table and graphs.

CONCLUSION

The most popular methods for solving graph classification problems are based on SVM, k-NN and structural patterns (contrast, common, and frequent graphs). All of these methods are domain independent so they can be used in different areas (where data is represented by a graph).

The recently proposed CCPC algorithm that uses minimal contrast and common graphs outperformed

Table 2.Comparison of classification accuracy for web documents

Document series	Document model, algorithm, parameters	Number of features (dimensions)	Classification accuracy
F	vector, k-NN, cosine graph, k-NN, MCS hybrid, k-NN graph, CCPC	332 30 100 30 / 50 / 100	94.6 *96.8* 95.7 91.4 / **98.9** / **98.9**
J	vector, k-NN, cosine graph, k-NN, MCS hybrid, k-NN graph, CCPC	474 30 / 60 30 / 40 30 / 45	74.6 85.4 / 86.5 87.6 / **94.6** 86.5 / *91.4*

KEY TERMS

Contrast Graph: Graph that is subgraph isomorphic to at least one graph from particular class of graphs and is not subgraph isomorphic to any graph from any other class of graphs.

Contrast Pattern: Pattern (substructure) that appears in one class of objects and does not appear in other classes.

Common Graph: Graph that is subgraph isomorphic to at least one graph in at least two different classes of graphs.

Common Pattern: Pattern (substructure) that appears in at least two different classes of objects.

Frequent Graph: Graph which support is greater than specified threshold.

Graph Isomorphism: The procedure of testing whether any two graphs are isomorphic (really the same) i.e. finding a mapping from one set of vertices to another set. The complexity of this problem is yet not known to be either P or NP-complete.

Graph Mining: Mining (discovering relevant information) data that is represented as a graph.

Subgraph Isomorphism: The procedure of determining if one smaller graph is included in other larger graph. This problem is proved to be NP-complete.

Subgraph of a Graph G: Graph whose vertex and edge sets are subsets of those of G.

Support of a Graph: The number of graphs to which a particular graph is subgraph isomorphic.

Classifying Two-Class Chinese Texts in Two Steps

Xinghua Fan
Chongqing University of Posts and Telecommunications, China

INTRODUCTION

Text categorization (TC) is a task of assigning one or multiple predefined category labels to natural language texts. To deal with this sophisticated task, a variety of statistical classification methods and machine learning techniques have been exploited intensively (Sebastiani, 2002), including the Naïve Bayesian (NB) classifier (Lewis, 1998), the Vector Space Model (VSM)-based classifier (Salton, 1989), the example-based classifier (Mitchell, 1996), and the Support Vector Machine (Yang & Liu, 1999).

Text filtering is a basic type of text categorization (two-class TC). There are many real-life applications (Fan, 2004), a typical one of which is the ill information filtering, such as erotic information and garbage information filtering on the web, in e-mails and in short messages of mobile phones. It is obvious that this sort of information should be carefully controlled. On the other hand, the filtering performance using the existing methodologies is still not satisfactory in general. The reason lies in that there exist a number of documents with high degree of ambiguity, from the TC point of view, in a document collection, that is, there is a fuzzy area across the border of two classes (for the sake of expression, we call the class consisting of the ill information-related texts, or, the negative samples, the category of TARGET, and, the class consisting of the ill information-not-related texts, or, the positive samples, the category of Non-TARGET). Some documents in one category may have great similarities with some other documents in the other category, for example, a lot of words concerning love story and sex are likely appear in both negative samples and positive samples if the filtering target is erotic information.

BACKGROUND

Fan et al observed a valuable phenomenon, that is, most of the classification errors result from the documents of falling into the fuzzy area between two categories, and presented a two-step TC method based on Naive Bayesian classifier (Fan, 2004; Fan, Sun, Choi & Zhang, 2005; Fan & Sun, 2006), in which the idea is inspired by the fuzzy area between categories. In the first step, the words with parts of speech verb, noun, adjective and adverb are regarded as candidate feature, a Naive Bayesian classifier is used to classify texts and fix the fuzzy area between categories. In the second step, bi-gram of words with parts of speech verb and noun as feature, a Naive Bayesian classifier same as that in the previous step is used to classify documents in the fuzzy area.

The two-step TC method described above has a shortcoming: its classification efficiency is not well. The reason lies in that it needs word segmentation to extract the features, and at currently, the speed of segmenting Chinese words is not high. To overcome the shortcoming, Fan et al presented an improved TC method that uses the bi-gram of character as feature at the first step in the two-step framework (Fan, Wan & Wang, 2006).

Fan presented a high performance prototype system for Chinese text categorization including a general two-step TC framework, in which the two-step TC method described above is regarded as an instance of the general framework, and then presents the experiments that are used to validate the assumption as the foundation of two-step TC method (Fan, 2006). Chen et al. has extended the two-step TC method to multi-class multi-label English (Chen et al., 2007).

MAIN FOCUS

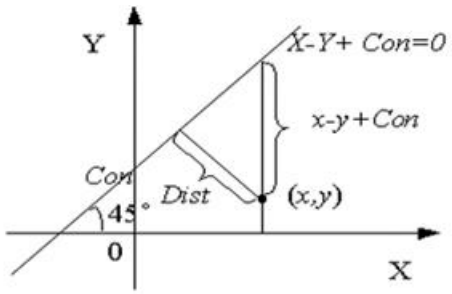
Fix the Fuzzy Area between Categories Using a Naïve Bayesian Classifier

(Fan, 2004; Fan, Sun, Choi & Zhang, 2005; Fan & Sun 2006)

A Naïve Bayesian Classifier is used to fix the fuzzy area in the first step. For a document represented by a binary-valued vector $d=(W_1, W_2, \ldots, W_{|D|})$, the two-class Naïve Bayesian Classifier is given as follows:

$$f(d)=\log\frac{\Pr\{c_1\mid d\}}{\Pr\{c_2\mid d\}} = \log\frac{\Pr\{c_1\}}{\Pr\{c_2\}}+\sum_{k=1}^{|D|}\log\frac{1-p_{k1}}{1-p_{k2}}+\sum_{k=1}^{|D|}W_k\log\frac{p_{k1}}{1-p_{k1}}-\sum_{k=1}^{|D|}W_k\log\frac{p_{k2}}{1-p_{k2}} \quad (1)$$

Figure 1. Distance from point (x,y) to the separate line



where $\Pr\{\cdot\}$ is the probability that event $\{\cdot\}$ occurs, c_i is category i, and $p_{ki}=\Pr\{W_k=1|c_i\}$ (i=1,2). If $f(d)\geq 0$, the document d will be assigned the category label c_1, otherwise, c_2.

Let:

$$Con=\log\frac{\Pr\{c_1\}}{\Pr\{c_2\}}+\sum_{k=1}^{|D|}\log\frac{1-p_{k1}}{1-p_{k2}} \quad (2)$$

$$X=\sum_{k=1}^{|D|}W_k\log\frac{p_{k1}}{1-p_{k1}} \quad (3)$$

$$Y=\sum_{k=1}^{|D|}W_k\log\frac{p_{k2}}{1-p_{k2}} \quad (4)$$

Where *Con* is a constant relevant only to the training set, X and Y are the measures that the document d belongs to categories c_1 and c_2 respectively. (1) is rewritten as:

$$f(d)+X-Y+Con \quad (5)$$

Apparently, $f(d)=0$ is the separate line in a two-dimensional space with X and Y being X-coordinate and Y-coordinate respectively. In this space, a given document d can be viewed as a point (x, y), in which the values of x and y are calculated according to (3) and (4). As shown in Figure1, the distance from the point (x, y) to the separate line will be:

$$Dist=\frac{1}{\sqrt{2}}(x-y+Con) \quad (6)$$

Figure 2. Distribution of the training set in the two-dimensional space

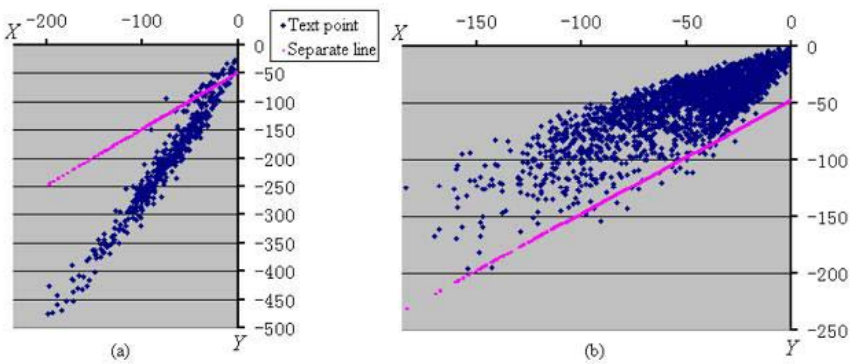


Figure 2 illustrates the distribution of a training set (refer to the next section) regarding *Dist* in the two-dimensional space, with the curve on the left for the negative samples, and the curve on the right for the positive samples. As can be seen in the figure, most of the misclassified documents are near the separate line.

Assumption: the performance of a classifier is relevant to the distance *Dist* in (6), most of the classifying error gathers in an area near the separate line, and the documents falling into this area only are a small portion of the dataset.

Thus, the space can be partitioned into reliable area and unreliable area:

$$\begin{array}{ll} Dist_2 \le Dist \le Dist_1, & \text{Decision for } d \text{ is unreliable} \\ Dist > Dist_1, & \text{Assigning the lable } c_1 \text{ to } d \text{ is reliable} \\ Dist < Dist_2, & \text{Assigning the label } c_2 \text{ to } d \text{ is reliable} \end{array} \quad (7)$$

Where $Dist_1$ and $Dist_2$ are constants determined by experiments, $Dist_1$ is positive real number and $Dist_2$ is negative real number.

Experiments

The experiments include two parts, one is to validate the assumption that is published in Fan (2006), and the other is to valuate the two-step text categorization method that is published in Fan et al. (2005), Fan and Sun (2006), and Fan et al. (2006). In this section, only a part in the latter is given.

Dataset. The dataset used is composed of 12,600 documents with 1,800 negative samples of **TARGET** and 10,800 positive samples of **Non-TARGET**. It is split into 4 parts randomly, with three parts as training set and one part as test set. All experiments are performed in 4-fold cross validation.

Method. Using the naïve as the classifier, reducing features with (8), using five types of features as following: Chinese word, bi-gram of Chinese character, bi-gram of Chinese word, the mixture of Chinese word and bi-gram of Chinese character, and the mixture of Chinese word and bi-gram of Chinese word, doing the seven experiments in table 1, in which every experiment represents a method, the former five methods are one step text categorization and the latter two methods are two step text categorization.

$$MI_1(t_k, c) = \sum_{i=1}^{n} \Pr\{t_k, c_i\} \log \frac{\Pr\{t_k, c_i\}}{\Pr\{t_k\}\Pr\{c_i\}} \quad (8)$$

Table 1. The performance of seven kinds of methods

Exp.	One Step	Two Step	F1 %	Feature Number
1	word	no	91.00	500
2	Bi-gram of Chinese character	no	91.56	800
3	Bi-gram of Chinese word	no	93.65	15000
4	word + Bi-gram of Chinese character	no	96.71	2000
5	word + Bi-gram of Chinese word	no	93.42	800
6	Word	Bi-gram of Chinese word	95.54	500+3000
7	Bi-gram of Chinese character	Bi-gram of Chinese word	97.31	800+8500

Where t_k stands for the kth feature, which may be a Chinese word or a bi-gram of Chinese word, and c_i is the ith-predefined category.

To extract the feature in the second step, CSeg&Tag3.0, a Chinese word segmentation and POS tagging system developed by Tsinghua University, is used to perform the morphological analysis for Chinese texts.

Experimental Results. Only the experimental results for negative samples are considered in evaluation, and the results are showed in Table 1.

Comparing Example 1 and Example 2, it can be seen that Chinese character bi-gram as feature has higher efficiency than Chinese word as feature because it does not need Chinese word segmentation.

Comparing Example 1, Example 3 and Example 5, it can be seen that the bi-gram of Chinese word as feature has better discriminating capability (because the performance of Example 3 and Example 5 is higher than that of Example 1), meanwhile with more serious data sparseness (because the number of features used in Example 3 is more than that used in Example 1 and Example 5)

Comparing Example 5 and Example 3, it can be seen that the mixture of Chinese word and bi-gram of Chinese word as feature is superior to bi-gram of Chinese word as feature because the used feature number in Example 5 is smaller than that in Example 3, and the former has a higher computational efficiency.

Comparing Example 4 and Example 5, it can be seen that the combination of character and word bi-gram is superior to the combination of word and word bi-gram, because the former has better performances.

Comparing Example 6 and Example 7, it can be seen that the method 7 has the best performance and efficiency. Note that Example 7 uses more features, but it does not need Chinese word segmentation in the first step.

Based on experiments and analysis described in above, it shows that bi-gram of Chinese character as feature has better statistic capability than word as feature, so the former has better classification ability in general. But for those documents that have high degree ambiguity between categories, bi-gram of Chinese word as feature has better discriminating capability. So, it obtains high performance if the two types of features are combined to classify Chinese texts in two steps.

Related Works

Combining multiple methodologies or representations has been studied in several areas of information retrieval so far, for example, retrieval effectiveness can be improved by using multiple representations (Rajashekar & Croft, 1995). In the area of text categorization in particular, many methods of combining different classifiers have been developed. For example, Yang et al. (2000) used simple equal weights for normalized score of each classifier output so as to integrate multiple classifiers linearly in the domain of Topic Detection and Tracking; Hull et al. (1996) used linear combination for probabilities or log odds scores of multiple classifier output in the context of document filtering. Larkey and Croft (1996) used weighted linear combination for system ranks and scores of multiple classifier output in the medical document domain; Li and Jain (1998) used voting and classifier selection technique including dynamic classifier selection and adaptive classifier. Lam and Lai (2001) automatically selected a classifier for each category based on the category-specific statistical characteristics. Bennett et al. (2002) used voting, classifier-selection techniques and a hierarchical combination method with reliability indicators.

Comparing with other combination strategy, the two-step method of classifying texts in this chapter has a characteristic: the fuzzy area between categories is fixed directly according to the outputs of the classifier.

FUTURE TRENDS

Our unpublished preliminary experiments show that the two-step TC method is superior to the Support Vector Machine, which is thought as the best TC method in general, not only on the efficiency but also on performance. It is obvious that it needs theory analysis and sufficient experimental validation. At the same time, the possible method of father improving the efficiency is to look for the new feature used in the second step that does not need Chinese word segmentation. I believe that the two-step method can be extended into other language such as English text. A possible solution is to use different type of classifier in the second step. Comparing other classifier combination, this solution will has higher efficiency because only a small part texts in the second step need to process by multiple classifiers.

CONCLUSION

The issue of how to classify Chinese documents with high degree ambiguity is a challenge. A two-step TC approach based on the Naïve Bayesian classifier is developed, which exploits the distributional characteristics of misclassified documents, i.e., most of the misclassified documents are near to the separate line in a constructed two dimensions space. The method has two kinds of implementing editions, one of which exploits the words with parts of speech verb, noun, adjective and adverb as candidate feature at the first step, and the other edition exploits bi-gram of character as candidate feature at the first step. The latter has the best performance and efficiency. The experiments validated the soundness of the two-step method.

It is worth to point out that we believe the two-step method is in principle language independent, though all the experiments are performed on Chinese datasets.

KEY TERMS

Information Retrieval (IR): Information retrieval is the art and science of searching for information in documents, searching for documents themselves, searching for metadata which describes documents, or searching within databases, whether relational stand alone databases or hypertext networked databases such as the Internet or intranets, for text, sound, images or data.

High Degree of Ambiguity Text: A document collection, in which there is a fuzzy area across the border of several classes, and some documents in one category may have great similarities with some other documents in the other categories.

Text Categorization (TC): Text categorization is a task of assigning one or multiple predefined category labels to natural language texts.

Text Filtering: It is an information seeking process in which documents are selected from a dynamic text stream to satisfy a relatively stable and specific information need.

Two-Step Classifying Strategy: Two-step classifying strategy exploits two steps to classify text, firstly, a classifier is used to fix the fuzzy area between categories and classify the documents that are not falling into the fuzzy area, and then another classifier that has subtle and powerful features is used to classify the documents that are in the fuzzy area.

Cluster Analysis for Outlier Detection

Frank Klawonn
University of Applied Sciences Braunschweig/Wolfenbuettel, Germany

Frank Rehm
German Aerospace Center, Germany

INTRODUCTION

For many applications in knowledge discovery in databases finding outliers, rare events, is of importance. Outliers are observations, which deviate significantly from the rest of the data, so that it seems they are generated by another process (Hawkins, 1980). Such outlier objects often contain information about an untypical behavior of the system.

However, outliers bias the results of many data mining methods like the mean value, the standard deviation or the positions of the prototypes of *k-means* clustering (Estivill-Castro, 2004; Keller, 2000). Therefore, before further analysis or processing of data is carried out with more sophisticated data mining techniques, identifying outliers is a crucial step. Usually, data objects are considered as outliers, when they occur in a region of extremely low data density.

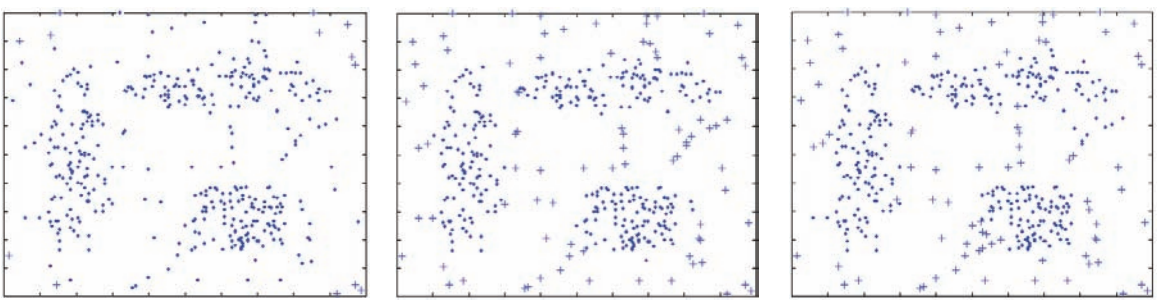
Many clustering techniques like possibilistic clustering (PCM) (Krishnapuram & Keller, 1993; Krishnapuram & Keller, 1996) or noise clustering (NC) (Dave, 1991; Dave & Krishnapuram, 1997) that deal with noisy data and can identify outliers, need good initializations or suffer from lack of adaptability to different cluster sizes (Rehm, Klawonn & Kruse, 2007). Distance-based approaches (Knorr, 1998; Knorr, Ng & Tucakov, 2000) have a global view on the data set. These algorithms can hardly treat data sets containing regions with different data density (Breuning, Kriegel, Ng & Sander, 2000).

In this work we present an approach that combines a fuzzy clustering algorithm (Höppner, Klawonn, Kruse & Runkler, 1999) (or any other prototype-based clustering algorithm) with statistical distribution-based outlier detection.

BACKGROUND

Prototype-based clustering algorithms approximate a feature space by means of an appropriate number of prototype vectors where each prototype vector is located in the center of the group of data *(the cluster)* that belongs to the respective prototype. Clustering usually aims at partitioning a data set into groups or clusters of data where data assigned to the same cluster are similar and data from different clusters are dissimilar. With this partitioning concept in mind, in typical applications of cluster analysis an important aspect is the identification of the number of clusters in a data set. However, when we are interested in identifying outliers, the exact number of clusters is irrelevant (Georgieva & Klawonn, 2006). If one prototype covers two or more data clusters or if two or more prototypes

Figure 1. Outlier detection with different number of prototypes



(a) 1 prototype (b) 3 prototypes (c) 10 prototypes

compete for the same data cluster, this is not important as long as the actual outliers are identified and note assigned to a proper cluster. The number of prototypes used for clustering depends of course on the number of expected clusters but also on the distance measure respectively the shape of the expected clusters. Since this information is usually not available, it is often recommended to use the Euclidean distance measure with rather copious prototypes.

One of the most referred statistical tests for outlier detection is the Grubbs' test (Grubbs, 1969). This test is used to detect outliers in a univariate data set. Grubbs' test detects one outlier at a time. This outlier is removed from the data set and the test is iterated until no outliers are detected.

The detection of outliers as we propose in this work is a modified version of the one proposed in (Santos-Pereira & Pires, 2002) and is composed of two different techniques. In the first step we partition the data set with the fuzzy c-means clustering algorithm so that the feature space is approximated with an adequate number of prototypes. The prototypes will be placed in the center of regions with a high density of feature vectors. Since outliers are far away from the typical data they influence the placing of the prototypes.

After partitioning the data, only the feature vectors belonging to each single cluster are considered for the detection of outliers. For each attribute of the feature vectors of the considered cluster, the mean value and the standard deviation has to be calculated. For the vector with the largest distance[a] to the mean vector, which is assumed to be an outlier, the value of the z-transformation for each of its components is compared to a critical value. If one of these values is higher than the respective critical value, than this vector is declared as an outlier. One can use the Mahalanobis distance as in (Santos-Pereira & Pires, 2002), however since simple clustering techniques like the (fuzzy) c-means algorithm tend to spherical clusters, we apply a modified version of Grubbs' test, not assuming correlated attributes within a cluster.

The critical value is a parameter that must be set for each attribute depending on the specific definition of an outlier. One typical criterion can be the maximum number of outliers with respect to the amount of data (Klawonn, 2004). Eventually, large critical values lead to smaller numbers of outliers and small critical values lead to very compact clusters. Note that the critical value is set for each attribute separately. This leads to an axes-parallel view of the data, which in cases of axes-parallel clusters leads to a better outlier detection than the (hyper)-spherical view on the data.

If an outlier was found, the feature vector has to be removed from the data set. With the new data set, the mean value and the standard deviation have to be calculated again for each attribute. With the vector that has the largest distance to the new center vector, the outlier test will be repeated by checking the critical values. This procedure will be repeated until no outlier will be found anymore. The other clusters are treated in the same way.

Results

Figure 1 shows the results of the proposed algorithm on an illustrative example. The crosses in this figure are feature vectors, which are recognized as outliers. As expected, only few points are declared as outliers, when approximating the feature space with only one prototype. The prototype will be placed in the center

Table 1. Estimated flight duration before and after outlier treatment

Cluster	mean flight duration (s) (before outlier test)	RMSE	mean flight duration (s) (after outlier test)	RMSE
1	2021.18	266.17	2021.18	266.17
2	2497.13	407.90	2465.71	358.68
3	2136.85	268.93	2136.85	268.93
4	2303.41	409.35	2303.41	409.35
5	2186.22	292.04	2186.22	292.04
6	1872.23	180.45	1872.23	180.45
7	2033.31	395.33	2033.31	395.33
8	1879.28	187.12	1879.28	187.12
9	1839.65	90.95	1839.65	90.95
10	2566.15	517.01	2523.28	492.60

of all feature vectors. Hence, only points on the edges are defined as outliers. Comparing the solutions with three and ten prototypes one can determine that both solutions are almost identical. Even in the border regions, were two prototypes compete for some data points, the algorithm rarely identifies these points as outliers, which intuitively are not.

We applied the above method on a weather data set describing the weather situation at a major European airport. Partitioning the weather data is done using fuzzy c-means with 10 prototypes. Since the weather data set is high-dimensional in the feature space we prescind here from showing a visualization of the clustering results. Though, table 1 shows some numerical results for the flight duration before the outlier treatment and afterwards. The proposed outlier procedure removes a total of four outliers in two clusters. The according

clusters are highlighted in the table by means of light grey background. Indeed, both clusters benefit from removing the outliers insofar that the estimation of the flight duration, using a simple measure like the mean, can be improved to a considerable extent. The lower RMSE for the flight duration estimation in both clusters confirms this.

FUTURE TRENDS

The above examples show, that the algorithm can identify outliers in multivariate data in a stable way. With only few parameters the solution can be adapted to different requirements concerning the specific definition of an outlier. With the choice of the number of prototypes, it is possible to influence the result in that way that with lots of prototypes even smaller data groups can be found. To avoid an overfitting to the data it makes sense in certain cases, to eliminate very small clusters. However, finding out the proper number of prototypes should be of interest of further investigations.

In case of using a fuzzy clustering algorithm like FCM (Bezdek, 1981) to partition the data, it is possible to assign a feature vector to different prototype vectors. In that way one can consolidate that a certain feature vector is an outlier or not, if the algorithm decides for each single cluster that the corresponding feature vector is an outlier.

FCM provides membership degrees for each feature vector to every cluster. One approach could be, to assign a feature vector to the corresponding clusters with the two highest membership degrees. The feature vector is considered as an outlier if the algorithm makes the same decision in both clusters. In cases where the algorithm gives no definite answers, the feature vector can be labeled and processed by further analysis.

CONCLUSION

In this work, we have described a method to detect outliers in multivariate data. Since information about the number and shape of clusters is often not known in advance, it is necessary to have a method which is relatively robust with respect to these parameters. To obtain a stable algorithm, we combined approved clustering techniques like the FCM or k-means with a statistical method to detect outliers. Since the complexity of the presented algorithm is linear in the number of points, it can be applied to large data sets.

KEY TERMS

Cluster Analysis: Partition a given data set into clusters where data assigned to the same cluster should be similar, whereas data from different clusters should be dissimilar.

Cluster Prototypes (Centers): Clusters in objective function-based clustering are represented by prototypes that define how the distance of a data object to the corresponding cluster is computed. In the simplest case a single vector represents the cluster, and the distance to the cluster is the Euclidean distance between cluster center and data object.

Fuzzy Clustering: Cluster analysis where a data object can have membership degrees to different clusters. Usually it is assumed that the membership degrees of a data object to all clusters sum up to one, so that a membership degree can also be interpreted as the probability the data object belongs to the corresponding cluster.

Noise Clustering: An additional noise cluster is induced in objective function-based clustering to collect the noise data or outliers. All data objects are assumed to have a fixed (large) distance to the noise cluster, so that only data far away from all other clusters will be assigned to the cluster.

Outliers: are defined as observations in a sample, so far separated in value from the remainder as to suggest that they are generated by another process, or the result of an error in measurement.

Overfitting: is the phenomenon that a learning algorithm adapts so well to a training set, that the random disturbances in the training set are included in the model as being meaningful. Consequently, as these disturbances do not reflect the underlying distribution, the performance on the test set, with its own, but definitively other disturbances, will suffer from techniques that tend to fit to well to the training set.

Possibilistic Clustering: The Possibilistic C-Means (PCM) family of clustering algorithms is designed to alleviate the noise problem by relaxing the constraint on memberships used in probabilistic fuzzy clustering.

Z-Transformation: With the z-transformation one can transform the values of any variable into values of the standard normal distribution.

ENDNOTES

1 To determine the vector with the largest distance to the center vector different distance measures can

be used. For elliptical non axes-parallel clusters, the Mahalanobis distance leads to good results. If no information about the shape of the clusters is available, the Euclidean distance is commonly used.

Cluster Analysis in Fitting Mixtures of Curves

Tom Burr
Los Alamos National Laboratory, USA

INTRODUCTION

One data mining activity is cluster analysis, which consists of segregating study units into relatively homogeneous groups. There are several types of cluster analysis; one type deserving special attention is clustering that arises due to a mixture of curves. A mixture distribution is a combination of two or more distributions. For example, a bimodal distribution could be a mix with 30% of the values generated from one unimodal distribution and 70% of the values generated from a second unimodal distribution.

The special type of mixture we consider here is a mixture of curves in a two-dimensional scatter plot. Imagine a collection of hundreds or thousands of scatter plots, each containing a few hundred points including background noise but also containing from zero to four or five bands of points, each having a curved shape. In one application (Burr et al. 2001), each curved band of points was a potential thunderstorm event (see Figure 1) as observed from a distant satellite and the goal was to cluster the points into groups associated with thunderstorm events. Each curve has its own shape, length, and location, with varying degrees of curve overlap, point density, and noise magnitude. The scatter plots of points from curves having small noise resemble a smooth curve with very little vertical variation from the curve, but there can be a wide range in noise magnitude so that some events have large vertical variation from the center of the band. In this context, each curve is a cluster and the challenge is to use only the observations to estimate how many curves comprise the mixture, plus their shapes and locations. To achieve that goal, the human eye could train a classifier by providing cluster labels to all points in example scatter plots. Each point would either belong to a curved-region or to a catch-all noise category and a specialized cluster analysis would be used to develop an approach for labeling (clustering) the points generated according to the same mechanism in future scatter plots.

BACKGROUND

Two key features that distinguish various types of clustering approaches are the assumed mechanism for how the data is generated and the dimension of the data. The data-generation mechanism includes deterministic and stochastic components and often involves deterministic mean shifts between clusters in high dimensions. But there are other settings for cluster analysis. The particular one discussed here involves identifying thunderstorm events from satellite data as described in the Introduction. From the four examples in Figure 1, note that the data can be described as a mixture of curves where any notion of a cluster mean would be quite different from that in more typical clustering applications. Furthermore, although finding clusters in a two-dimensional scatter plot seems less challenging than in higher-dimensions (the trained human eye is likely to perform as well as any machine-automated method, although the eye would be slower), complications include: overlapping clusters, varying noise magnitude, varying feature and noise and density, varying feature shape, locations, and length, and varying types of noise (scene-wide and event-specific). Any one of these complications would justify treating the fitting of curve mixtures as an important special case of cluster analysis.

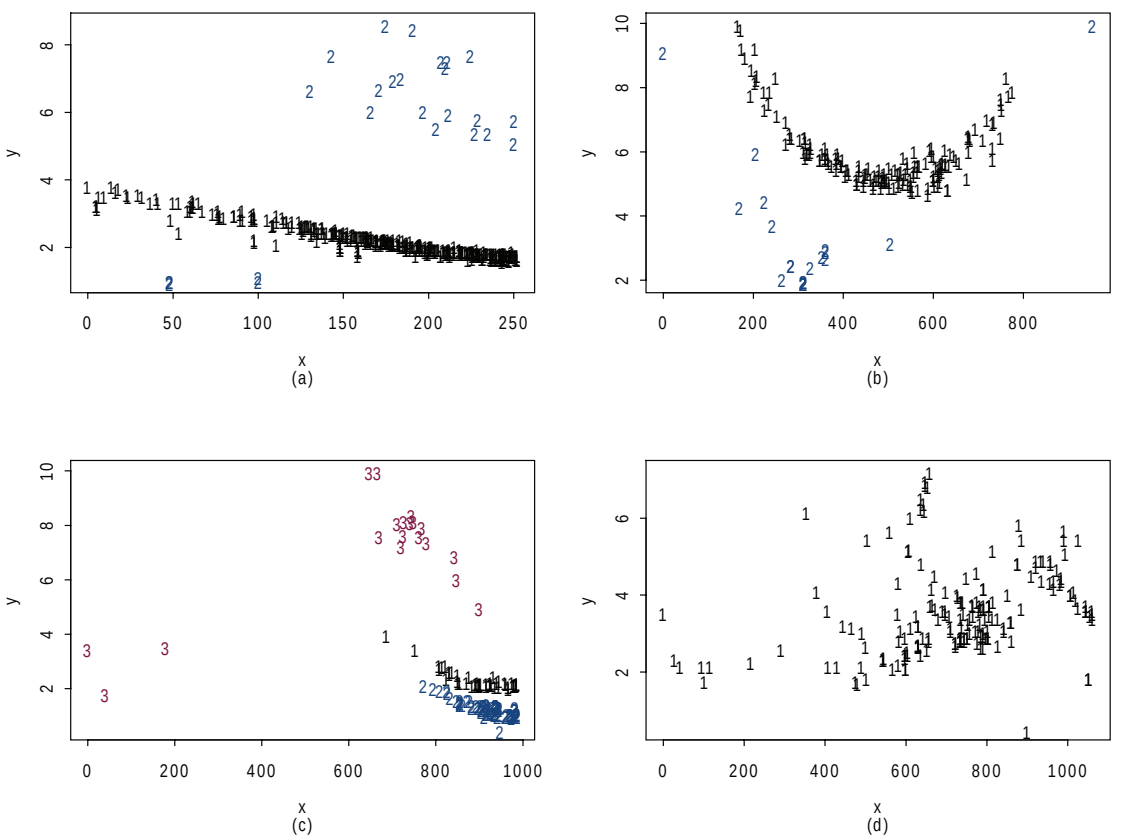
Although as in pattern recognition, the methods discussed below require training scatter plots with points labeled according to their cluster memberships, we regard this as cluster analysis rather than pattern recognition because all scatter plots have from zero to four or five clusters whose shape, length, location, and extent of overlap with other clusters varies among scatter plots. The training data can be used to both train clustering methods, and then judge their quality. Fitting mixtures of curves is an important special case that has received relatively little attention to date. Fitting mixtures of probability distributions dates to Titterington et al. (1985), and several model-based clustering schemes have been developed (Banfield and

Raftery, 1993, Bensmail et al., 1997 and Dasgupta and Raftery, 1998) along with associated theory (Leroux, 1992). However, these models assume that the mixture is a mixture of probability distributions (often Gaussian, which can be long and thin, ellipsoidal, or more circular) rather than curves. More recently, methods for mixtures of curves have been introduced, including a mixture of principal curves model (Stanford and Raftery, 2000), a mixture of regressions model (Turner, 2000; Gaffney and Smyth 2003, and Hurn, Justel, and Robert, 2003), and mixtures of local regression models (smooth curves obtained using splines or nonparametric kernel smoothers for example)

MAIN THRUST OF THE CHAPTER

We describe four methods have been proposed for fitting mixtures of curves. In method 1 (Burr et al., 2001), density estimation is used to reject the background noise points such as those labeled as 2 in Figure 1a. For example, each point has a distance to its *k*th nearest neighbor, which can be used as a local density estimate (Silverman, 1986) to reject noise points. Next, use a distance measure that favors long thin clusters (for example, let the distance between clusters be the minimum distance between a point in the first cluster and a point in the second cluster) together with standard hierarchical clustering to identify at least the central portion of each cluster. Alternatively, model-based clustering favoring long, thin Gaussian shapes (Banfield and Raftery, 1993) or the "fitting straight lines" method in Campbell et al. (1997) are effective for finding the central portion of each cluster. A curve fitted to this central portion can be extrapolated and then used to accept other points as members of the cluster. Because hierarchical clustering cannot accommodate overlapping clusters, this method assumes that the central

Figure 1. Four mixture examples containing (a) one, (b) one, (c) two, and (d) zero thunderstorm events plus background noise. The label "1" is for the first thunderstorm in the scene, "2" for the second, etc., and the highest integer label is reserved for the catch-all "noise" class. Therefore, in (d), because the highest integer is 1, there is no thunderstorm present (the "mixture" is all noise)



portions of each cluster are non-overlapping. Points away from the central portion from one cluster that lie close to the curve fitted to the central portion of the cluster can overlap with points from another cluster. The noise points are initially identified as those having low local density (away from the central portion of any cluster), but during the extrapolation, can be judged to be a cluster member if they lie near the extrapolated curve. To increase robustness, method 1 can be applied twice, each time using slightly different inputs (such as the decision threshold for the initial noise rejection and the criteria for accepting points into a cluster than are close to the extrapolated region of the cluster's curve). Then, only clusters that are identified both times are accepted.

Method 2 uses the minimized integrated squared error (ISE, or L_2 distance) (Scott, 2002, and Scott & Szewczyk, 2002) and appears to be a good approach for fitting mixture models, including mixtures of regression models as is our focus here. Qualitatively, the minimum L_2 distance method tries to find the largest portion of the data that matches the model. In our context, at each stage, the model is all the points belonging to a single curve plus everything else. Therefore, we first seek cluster 1 having the most points, regard the remaining points as noise, remove the cluster and then repeat the procedure in search of feature 2, and so on until a stop criterion is reached. It should also be possible to estimate the number of components in the mixture in the first evaluation of the data but we that approach has not yet been attempted. Scott (2002) has shown that in the parametric setting with model $f(x|\theta)$, we estimate θ using $\hat{\theta} = \arg\min_\theta \int [f(x|\theta) - f(x|\theta_0)]^2 dx$ where the true parameter θ_O is unknown. It follows that a reasonable estimator minimizing the parametric ISE criterion is $\hat{\theta}_{L_2E} = \arg\min_\theta [\int f(x|\theta)^2 dx - \frac{2}{n}\sum_{i=1}^{n} f(x_i|\theta)]$. This assumes that the correct parametric family is used; the concept can be extended to include the case in which the assumed parametric form is incorrect in order to achieve robustness.

Method 3 (Principal curve clustering with noise) was developed by Stanford and Raftery (2000) to locate principal curves in noisy spatial point process data. Principal curves were introduced by Hastie and Stuetzle (1989). A principal curve is a smooth curvilinear summary of *p*-dimensional data. It is a nonlinear generalization of the first principal component line that uses a local averaging method. Stanford and Raftery (2000) developed an algorithm that first uses hierarchical principal curve clustering (HPCC, which is a hierarchical and agglomerative clustering method) and next uses iterative relocation (reassign points to new clusters) based on the classification estimation-maximization (CEM) algorithm. A probability model included the principal curve probability model for the feature clusters and a homogeneous Poisson process model for the noise cluster. More specifically, let X denote the set of observations, $x_1, x_2, \ldots, x_n$ and C be a partition considering of clusters $C_0, C_1, \ldots, C_K$, where the cluster C_j contains n_j points. The noise cluster is C_0 and assume feature points are distributed uniformly along the true underlying feature so there projections onto the feature's principal curve a randomly drawn from a uniform $U(0,\nu_j)$ distribution, where ν_j is the length of the *j*th curve. An approximation to the probability for 0, 1, …, 5 clusters is available from the Bayesian Information Criterion (BIC), which is defined as BIC= $2\log(L(X|\theta) - M\log(n)$, where L is the likelihood of the data X, and M is the number of fitted parameters, so $M = K(DF + 2) + K + 1$. For each of K features we fit 2 parameters (ν_j and σ_j defined below) and a curve having DF degrees of freedom; there are K mixing proportions (π_j defined below) and the estimate of scene area is used to estimate the noise density. The likelihood L satisfies $L(X|\theta) = L(X|\theta) = \prod_{i=1}^{n} L(x_i|\theta)$ where $L(x_i|\theta) = \sum_{j=0}^{K} \pi_j L(x_i|\theta, x_i \in C_j)$ is the mixture likelihood (π_j is the probability that point *i* belongs to feature *j*) $L(x_i|\theta, x_i \in C_j) = (1/\nu_j)(1/\sqrt{2\pi}\sigma_j)\exp(\frac{-\|x_i - f(\lambda_{ij})\|^2}{2\sigma_j^2})$ and for the feature clusters ($\|x_i - f(\lambda_{ij})\|$ is the Euclidean distance from x_i to its projection point $f(\lambda_{ij})$ on curve j) and $L(x_i|\theta, x_i \in C_j) = 1/Area$ for the noise cluster. Space will not permit a complete description of the HPCC-CEM method, but briefly, the HPCC steps are: (1) Make an initial estimate of noise points and remove then; (2) Form an initial clustering with at least seven points in each cluster; (3) Fit a principal curve to each cluster; (4) Calculate a clustering criterion $V = V_{About} + \alpha V_{Along}$, where V_{About} measures the orthogonal distances to the curve ("residual error sum of squares") and V_{Along} measures the variance in arc length distances between projection points on the curve. Minimizing V (the sum is over all clusters) will lead to clusters with regularly spaced points along the curve, and tightly grouped around it. Large values of α will cause the method to avoid clusters with gaps and small values of α favor thinner clusters. Clustering

(merging clusters) continues until V stops decreasing. The flexibility provided by such a clustering criterion (avoid or allow gaps and avoid or favor thin clusters) is useful and Method 3 is currently the only published method to include it.

Method 4 (Turner, 2000) uses the well-known EM (estimation – maximization) algorithm (Dempster, Laird, and Rubin, 1977) to handle a mixture of regression models. Therefore, it is similar to method 3 in that a mixture model is specified, but differs in that the curve is fit using parametric regression rather than principal curves, so

$$L(x_i \mid \theta, x_i \in C_j) = f_{ij} = (1/\sigma_j)\,\phi\left(\frac{y_i - x_i\beta_j}{\sigma_j}\right)$$

where ϕ is the standard Gaussian distribution. Also, Turner's implementation did not introduce a clustering criterion, but it did attempt to estimate the number of clusters as follows. Introduce indicator variable z_i of which component of the mixture generated observation y_i and iteratively maximize

$$Q = \sum_{i=1}^{n}\sum_{k=1}^{K}\gamma_{ik}\ln(f_{ik})$$

with respect to θ where θ is the complete parameter set π_j for each class. The γ_{ik} satisfy

$$\gamma_{ik} = \pi_k f_{ik} / \sum_{i=1}^{K}\pi_k f_{ik}.$$

Then Q is maximized with respect to t by weighted regression of y_i on $x_1, \ldots, x_n$ with weights γ_{ik} and each s_k^2 is given by

$$\sigma_k^2 = \sum_{i=1}^{n}\lambda_{ik}(y_i - x_i\beta_k)^2 / \sum_{i=1}^{n}\gamma_{ik}.$$

In practice the components of θ come from the value of θ in the previous iteration and

$$\pi_k = (1/n)\sum_{i=1}^{n}\gamma_{ik}.$$

A difficulty in choosing the number of components in the mixture, each with unknown mixing probability, is that the likelihood ratio statistic has an unknown distribution. Therefore Turner (2000) implemented a bootstrap strategy to choose between 1 and 2 components, between 2 and 3, etc. The strategy to choose between K and $K + 1$ components is: (a) calculate the log-likelihood ratio statistic Q for a model having K and for a model having $K + 1$ components; (b) simulate data from the fitted K -component model; (c) fit the K and $K + 1$ component Q*; (d) compute the p-value for Q as

$$p = 1/n\sum_{i=1}^{n} I(Q \geq Q^*),$$

where the indicator $I(Q \geq Q^*) = 1$ if $Q \geq Q^*$ and 0 otherwise.

To summarize, method 1 avoids the mathematics of mixture fitting and seeks high-density regions to use as a basis for extrapolation. It also checks the robustness of its solution by repeating the fitting using different input parameters and comparing results. Method 2 uses a likelihood for one cluster and "everything else," then removes the highest-density cluster, and repeats the procedure. Methods 3 and 4 both include formal mixture fitting (known to be difficult), with method 3 assuming the curve is well modeled as a principal curve and method 4 assuming the curve is well fit using parametric regression. Only method 3 allows the user to favor or penalize clusters with gaps. All methods can be tuned to accept only thin (small residual variance) clusters.

FUTURE TRENDS

Although we focus here on curves in the two dimensions, clearly there are analogous features in higher dimensions, such as principal curves in higher dimensions. Fitting mixtures in two dimensions is fairly straightforward, but performance is rarely as good as desired. More choices for probability distributions are needed; for example, the noise in Burr et al. (2001) was a non-homogeneous Poisson process, which might be better handled with adaptively chosen regions of the scene. Also, regarding noise removal in the context of mixtures of curves, Maitra and Ramler (2006) introduce some options to identify and remove "scatter" as a preliminary step to traditional cluster analysis. Also, very little has been published regarding the "measure of difficulty" of curve-mixture problem, although Hurn, Justel, and Robert (2003) provided a numerical Bayesian approach for mixtures involving "switching regression." The term "switching regression" describes the situation in which the likelihood is nearly unchanged when some

of the cluster labels are switched. For example, imagine that the clusters 1 and 2 were slightly closer in Figure 1c, and then consider changes to the likelihood if we switched some 2 and 1 labels. Clearly if curves are not well separated, we should not expect high clustering and classification success. In the case where groups are separated by mean shifts, it is clear how to define group separation. In the case where groups are curves that overlap to varying degrees, one could envision a few options for defining group separation. For example, the minimum distance between a point in one cluster and a point in another cluster could define the cluster separation and therefore also the measure of difficulty. Depending on how we define the optimum, is possible that performance can approach the theoretical optimum. We define performance by first determining whether a cluster was found, and then reporting the false positive and false negative rates for each found cluster.

Another area of valuable research would be to accommodate mixtures of local regression models (such as smooth curves obtained using splines or nonparametric kernel smoothers, Green and Silverman, 1996). Because local curve smoothers such as splines are extremely successful in the case where the mixture is known to contain only one curve, it is likely that the flexibility provided by local regression (parametric or nonparametric) would be desirable in the broader context of fitting a mixture of curves.

Existing software is fairly accessible for the methods described, assuming users have access to a statistical programming language such as S-PLUS (2003) or R. Executable code to accommodate a user-specified input format would be a welcome future contribution. A relatively recent R package (Boulerics, 2006), to fit "general nonlinear mixtures of curves" is freely available in R and includes several related functions.

CONCLUSION

Fitting mixtures of curves with noise in two dimensions is a specialized type of cluster analysis. It is a challenging cluster analysis task. Four options have been briefly described. Example performance results for these methods for one application are available (Burr et al., 2001). Results for methods 2-4 are also available in their respective references (on different data sets), and results for a numerical Bayesian approach using a mixture of regressions with attention to the case having nearly overlapping clusters has also been published (Hurn, Justel, and Robert, 2003).

KEY TERMS

Bayesian Information Criterion: An approximation to the Bayes Factor which can be used to estimate the Bayesian posterior probability of a specified model.

Bootstrap: A resampling scheme in which surrogate data is generated by resampling the original data or sampling from a model that was fit to the original data.

Probability Density Function Estimate: An estimate of the probability density function. One example is the histogram for densities that depend on one variable (or multivariate histograms for multivariate densities). However, the histogram has known deficiencies involving the arbitrary choice of bin width and locations. Therefore the preferred density function estimator is a smoother estimator that uses local weighted sums with weights determined by a smoothing parameter is free from bin width and location artifacts.

Estimation-Maximization Algorithm: An algorithm for computing maximum likelihood estimates from incomplete data. In the case of fitting mixtures, the group labels are the missing data.

Mixture of Distributions: A combination of two or more distributions in which observations are generated from distribution *i* with probability π_i and $\Sigma\pi_i = 1$.

Principal Curve: A smooth, curvilinear summary of p-dimensional data. It is a nonlinear generalization of the first principal component line that uses a local average of p-dimensional data.

Probability Density Function: A function that can be summed (for discrete-valued random variables) or integrated (for interval-valued random variables) to give the probability of observing values in a specified set.

Cluster Analysis with General Latent Class Model

Dingxi Qiu
University of Miami, USA

Edward C. Malthouse
Northwestern University, USA

INTRODUCTION

Cluster analysis is a set of statistical models and algorithms that attempt to find "natural groupings" of sampling units (e.g., customers, survey respondents, plant or animal species) based on measurements. The observable measurements are sometimes called *manifest* variables and cluster membership is called a *latent* variable. It is assumed that each sampling unit comes from one of K clusters or classes, but the cluster identifier cannot be observed directly and can only be inferred from the manifest variables. See Bartholomew and Knott (1999) and Everitt, Landau and Leese (2001) for a broader survey of existing methods for cluster analysis.

Many applications in science, engineering, social science, and industry require grouping observations into "types." Identifying typologies is challenging, especially when the responses (manifest variables) are categorical. The classical approach to cluster analysis on those data is to apply the latent class analysis (LCA) methodology, where the manifest variables are assumed to be independent conditional on the cluster identity. For example, Aitkin, Anderson and Hinde (1981) classified 468 teachers into clusters according to their binary responses to 38 teaching style questions. This basic assumption in classical LCA is often violated and seems to have been made out of convenience rather than it being reasonable for a wide range of situations. For example, in the teaching styles study two questions are "Do you usually allow your pupils to move around the classroom?" and "Do you usually allow your pupils to talk to one another?" These questions are mostly likely correlated even within a class.

BACKGROUND

This chapter focuses on the mixture-model approach to clustering. A mixture model represents a distribution composed of a mixture of component distributions, where each component distribution represents a different cluster. Classical LCA is a special case of the mixture model method. We fit probability models to each cluster (assuming a certain fixed number of clusters) by taking into account correlations among the manifest variables. Since the true cluster memberships of the subjects are unknown, an iterative estimation procedure applicable to missing data is often required.

The classical LCA approach is attractive because of the simplicity of parameter estimation procedures. We can, however, exploit the correlation information between manifest variables to achieve improved clustering. Magidson and Vermunt (2001) proposed the latent class factor model where multiple latent variables are used to explain associations between manifest variables (Hagenaars, 1988; Magidson & Vermunt, 2001; Hagenaars & McCutcheon, 2007). We will, instead, focus on generalizing the component distribution in the mixture model method.

MAIN FOCUS

Assume a random sample of n observations, where each comes from one of K unobserved classes. Random variable $Y \in \{1, \ldots, K\}$ is the latent variable, specifying the value of class membership. Let $P(Y=k) = \eta_k$ specify the *prior distribution* of class membership, where

$$\sum_{k=1}^{K} \eta_k = 1.$$

For each observation $i = 1, \ldots, n$, the researcher observes p manifest variables $\boldsymbol{X}_i = (X_{i1}, \ldots, X_{ip})'$. Given that an observation comes from class k (i.e., $Y = k$), the *class-conditional distribution* of $\boldsymbol{X}$, denoted as $f_k(\boldsymbol{x};\theta_{\boldsymbol{k}})$, is generally assumed to come from common distribution families. For example, classical LCA assumes that the components of $\boldsymbol{X}$ are each multinomial and independent of each other for objects within the same class. Suppose each manifest variable takes only 2 values, hereafter labeled generically "yes" and "no", then $P(X_j = x_j \mid Y)$ is a Bernoulli trial. Let π_{jk} be the probability that someone in class k has a "yes" value to manifest variable X_j. Then the class-conditional distribution, under the assumption of class-conditional independence, is

$$f_k(\boldsymbol{x};\theta_{\boldsymbol{k}}) = \prod_{j=1}^{p} P(x_j \mid Y=k) = \prod_{j=1}^{p} \pi_{jk}^{x_j} (1-\pi_{jk})^{1-x_j}. \quad (1)$$

This assumption greatly reduces the number of parameters that must be estimated. However, in many cases, more flexible distributions should be developed to allow for improved clustering.

Component Distributions

In general, $f_k(\boldsymbol{x};\theta_{\boldsymbol{k}})$ can take any component distribution. However, due to the constraint of identifiableness and the computing requirement for parameter estimation, only two component distributions, to our best knowledge, have been proposed in the literature to address the correlation structure within each cluster. Qu, Tan and Kutner (1996) proposed a random effects model that is a restricted version of the multivariate Probit model. The conditional dependence is modeled by subject-specific random variables. The manifest variables are correlated because of the correlations between the underlying normal random variables in addition to the class membership. The correlation matrix in the component distribution of the random effects model has a restricted structure which makes it less appealing (Tamhane, Qiu & Ankenman, 2006).

Tamhane, Qiu and Ankenman (2006) provide another general-purpose multivariate Bernoulli distribution, called the continuous latent variable (CLV) model, based on subject-specific uniform random variables. This proposed distribution can handle both positive and negative correlations for each component cluster. It is relatively flexible in the sense that the correlation matrix does not have any structural restrictions as in the random effects model. This approach has been applied to two real data sets (Tamhane, Qiu & Ankenman, 2006) and provided easily interpretable results.

Parameter Estimation

The model parameters (η_k and $\boldsymbol{\theta}_k$) are estimated with maximum likelihood. The probability density function of the mixture is

$$f(\boldsymbol{x};\psi) = \sum_{k=1}^{K} \eta_k f_k(\boldsymbol{x};\theta_k),$$

where the vector ψ of unknown parameters consists of the mixture proportions η_k and class-conditional distribution parameters $\theta_{\boldsymbol{k}}$. Under the assumption that $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n$ are independent observations, the incomplete log-likelihood function is given by

$$\log L = \sum_{i=1}^{n} \log \sum_{k=1}^{K} \eta_k f_k(\boldsymbol{x}_i, \theta_k),$$

which must be maximized with respect to parameters η_k and $\boldsymbol{\theta}_k$. Due to the summation inside the logarithm, direct maximization is difficult, and the expectation-maximization (EM) algorithm of Dempster, Laird and Rubin (1977) is generally used to obtain the parameter estimators. See Bartholomew and Knott (1999, pp. 137-139) for details. The EM algorithm is convenient to construct if there exist closed-form solutions to the maximum likelihood estimators (MLEs). When closed-form solutions do not exist, the more general optimization procedures, such as quasi-Newton method, will be used. Generally speaking, there are no known ways of finding starting values that guarantee a global optimum, and different starting values will often produce different local maxima. One solution to the starting-value problem is to run the optimization with multiple random starting values and select the one with the largest log-likelihood value. Commercial software package such as Knitro® and LatentGold® solve this type of optimization problem. There are also software packages in the public domain.[a]

Assignment of Units to Clusters

The researcher often seeks to infer the class membership based on the observed data. This inference is made with the *posterior distribution*, which gives the probability of belonging to class *k* given the observed measurements $\boldsymbol{x}$

$$P(Y=k \mid \boldsymbol{x}) = \frac{f_k(\boldsymbol{x};\theta_k)}{\sum_{h=1}^{K} f_h(\boldsymbol{x};\theta_h)\eta_k}. \qquad (2)$$

Objects are usually assigned by the *maximum posterior rule* to the class with the highest posterior probability computed from (2). Assigning sampling units to a single class is called *hard assignment*. In contrast to the hard assignment, *soft assignment* is based on the probabilities. Sampling units are allowed to have partial membership in multiple classes. Probabilities allow the researcher to distinguish between cases that almost certainly come from a particular class and those that could plausibly come from several.

Number of Clusters

Determining of the number of clusters *K* is a special case of the model selection problem. The problem becomes difficult when the clusters overlap with each other, which is typical in cluster analysis of categorical data. Various approaches have been proposed in the statistics literature to determine the "true" number of clusters in a data set. Examples include the silhouette statistic (Kaufman and Rousseeuw 1990), gap statistics (Tibshirani, Walther, and Hastie 2001) and jump method (Sugar and Kames 2003). However, these statistics are mainly designed for continuous data where the distance measure between objects can easily be defined. For the categorical data, the general-purpose approach is to estimate mixture models for various values of *K* and then compare model summaries such as Akaike's Information Criterion (AIC) and Bayesian Information Criterion (BIC), which are defined as

$$\text{AIC} = -2 \log L + 2m \text{ and BIC} = -2 \log L + m \log n,$$

where *m* is the number of parameters. Both criteria penalize the log-likelihood value based on the number of the parameters in the model. However, the AIC criterion satisfies the optimality condition if the underlying "true" model is infinite dimensional (Hoeting, Davis, Merton, and Thompson, 2004), which is not true for the general latent class model. In addition, the best model selected by AIC depends on the sample size (Burnham and Anderson, 1998). BIC, on the other hand, is consistent in the sense that if the true model is among the candidates, the probability of selecting the true model approaches 1 as the sample size increases (Keribin, 2000). In fact, BIC is the only criterion implemented in the commercial software such as Latent Gold®[b].

In applied contexts, the usefulness of a clusters solution should be considered when determining the number of clusters. However, usefulness is often subjective and the researcher must combine domain knowledge with the fit statistics mentioned earlier to decide the optimal number of clusters. The ultimate objective of a cluster analysis is to identify a typology that is "useful" or "actionable" in some way, and the number of discrete clusters must serve that purpose. See Malthouse (2003, pp. 179-180) and Malthouse and Calder (2005) for specific discussion of this question for customer relationship management (CRM) applications.

Selection of Manifest Variables

The researcher can measure a large number of attributes (manifest variables), but not all should be included as $\boldsymbol{X}$ variables in a cluster analysis. As indicated above, the objective of cluster analysis is to identify "useful" groups. The meaning of useful, however, depends on the particular application. Which variables are used depends on how the typology will be used, not on the data set itself. Consider the task of grouping animals such as mice, elephants, sharks, whales, ostriches, goldfish, and cardinals. The variables that should be used in the analysis depend entirely on the application. Whales, elephants, and mice are all mammals based on them having warm blood, hair, nursing their young, etc. Yet if the objective is to separate "large" animals from "small" ones, manifest variables such as weight, height, and length should be used in the clustering, grouping elephants and whales with sharks and ostriches.

Noisy variables tend to mask the cluster structure of the data and empirical variable selection methods have also been proposed. For example, Raftery and Dean (2006) proposed a general purpose variable selection procedure for model-based clustering. Their application to simulated data and real examples show

that removing irrelevant variables improves clustering performance.

Simulation Study

The performances of different clustering methods are often compared via simulated data because with most real observed data sets there is usually no way to identify the true class membership of observations. Simulated data enables researchers to understand how robust the newly proposed methods are even if the data at hand do not follow the assumed distribution. The performance of a clustering method is often evaluated by a measure called *correct classification rate* (*CCR*) (Tamhane, Qiu and Ankenman 2006), which is the proportion of correctly classified observations. The observation cluster identities are known in advance in simulation, and hence the correctly classified objects can be easily counted.

The CCR has lower (LCCR) and upper bounds (UCCR) that are functions of simulated data (Tamhane, Qiu & Ankenman, 2006). Sometimes, it is better to evaluate the normalized CCR, which is called the correct classification score (CCS):

$$CCS = \frac{CCR - LCCR}{UCCR - LCCR}.$$

The CCS falls between 0 and 1, and larger values of CCS are desirable.

FUTURE TRENDS

Cluster analysis with latent class model is a well-plowed field that is still relatively fast moving. The classical approaches have been implemented in specialized[c] commercial and free software. Recent developments have focused on finding a novel way of modeling conditional dependence structure under the framework of the mixture model. Both the random effects model and the CLV model have been proposed to model the dependence structure in the component clusters. The main limitation of these two methods is that they are computationally intensive. For example, a PC with 2.8 GHz clock speed requires nearly six hours to estimate the parameters in a CLV model with 7 responses and 2 clusters. Recent model developments include the binary latent variable model (Al-Osh & Lee, 2001) and the latent variable model for attitude data measured on Likert scales (Javaras and Ripley, 2007). Future research directions in the general latent class model include constructing new parsimonious distributions to handle the conditional dependence structure of the manifest variables and proposing better parameter estimation methods.

The problem of finding the optimal number of clusters is difficult even for continuous data, where the distance measures between objects can be easily defined. The problem becomes even more acute when all manifest variables are categorical. Opportunities certainly exist for researchers to develop new statistic customized for categorical data.

CONCLUSION

The latent class models can be used as a model-based approach to clustering categorical data. It can classify objects into clusters through fitting a mixture model. Objects are assigned to clusters with the maximum posterior rule. The local independence assumption in the classical LCA is too strong in many applications. However, the classical LCA method can be generalized to allow for modeling the correlation structure between manifest variables. Applications to real data sets (Hadgu and Qu, 1998; Tamhane, Qiu and Ankenman, 2006) show a promising future.

KEY TERMS

Cluster Analysis: The classification of objects with measured attributes into different unobserved groups so that objects within the same group share some common trait.

Hard Assignment: Observations are assigned to clusters according to the maximum posterior rule.

Latent Variable: A variable that describes an unobservable construct and cannot be observed or measured directly. Latent variables are essential elements of latent variable models. A latent variable can be categorical or continuous.

Manifest Variable: A variable that is observable or measurable. A manifest variable can be continuous or categorical. Manifest variables are defined in contrast with the latent variable.

Mixture Model: A mixture model represents a sample distribution by a mixture of component distributions, where each component distribution represents one cluster. It is generally assumed that data come from a finite number of component distributions with fixed but unknown mixing proportions.

Simulation: An imitation of a real-life or hypothetical situation on a computer so that it can be studied to see how the system or a proposed model works.

Soft Assignment: Probabilities of belonging to different clusters are calculated and objects are assigned to clusters according to these probabilities as if objects can be divided into fractions.

Cluster Validation

Ricardo Vilalta
University of Houston, USA

Tomasz Stepinski
Lunar and Planetary Institute, USA

INTRODUCTION

Spacecrafts orbiting a selected suite of planets and moons of our solar system are continuously sending long sequences of data back to Earth. The availability of such data provides an opportunity to invoke tools from machine learning and pattern recognition to extract patterns that can help to understand geological processes shaping planetary surfaces. Due to the marked interest of the scientific community on this particular planet, we base our current discussion on Mars, where there are presently three spacecrafts in orbit (e.g., NASA's Mars Odyssey Orbiter, Mars Reconnaissance Orbiter, ESA's Mars Express). Despite the abundance of available data describing Martian surface, only a small fraction of the data is being analyzed in detail because current techniques for data analysis of planetary surfaces rely on a simple visual inspection and descriptive characterization of surface landforms (Wilhelms, 1990).

The demand for automated analysis of Mars surface has prompted the use of machine learning and pattern recognition tools to generate geomorphic maps, which are thematic maps of landforms (or topographical expressions). Examples of landforms are craters, valley networks, hills, basins, etc. Machine learning can play a vital role in automating the process of geomorphic mapping. A learning system can be employed to either fully automate the process of discovering meaningful landform classes using *clustering* techniques; or it can be used instead to predict the class of unlabeled landforms (after an expert has manually labeled a representative sample of the landforms) using *classification* techniques. The impact of these techniques on the analysis of Mars topography can be of immense value due to the sheer size of the Martian surface that remains unmapped.

While it is now clear that machine learning can greatly help in automating the detailed analysis of Mars' surface (Stepinski et al., 2007; Stepinski et al., 2006; Bue and Stepinski, 2006; Stepinski and Vilalta, 2005), an interesting problem, however, arises when an automated data analysis has produced a novel classification of a specific site's landforms. The problem lies on the interpretation of this new classification as compared to traditionally derived classifications generated through visual inspection by domain experts. Is the new classification novel in all senses? Is the new classification only partially novel, with many landforms matching existing classifications? This article discusses how to assess the value of clusters generated by machine learning tools as applied to the analysis of Mars' surface.

BACKGROUND ON CLUSTER VALIDATION

We narrow our discussion to patterns in the form of clusters as produced by a clustering algorithm (a form of unsupervised learning). The goal of a clustering algorithm is to partition the data such that the average distance between objects in the same cluster (i.e., the average intra-distance) is significantly less than the distance between objects in different clusters (i.e., the average inter-distance). The goal is to discover how data objects gather into natural groups (Duda at el., 2001; Bishop, 2006). The application of clustering algorithms can be followed by a post-processing step, also known as cluster validation; this step is commonly employed to assess the quality and meaning of the resulting clusters (Theodoridis and Koutroumbas, 2003).

Cluster validation plays a key role in assessing the value of the output of a clustering algorithm by computing statistics over the clustering structure. Cluster validation is called *internal* when statistics are devised

to capture the quality of the induced clusters using the available data objects only (Krishnapuran et al., 1995; Theodoridis and Koutroumbas, 2003). As an example, one can measure the quality of the resulting clusters by assessing the degree of compactness of the clusters, or the degree of separation between clusters.

On the other hand, if the validation is performed by gathering statistics comparing the induced clusters against an external and independent classification of objects, the validation is called *external*. In the context of planetary science, for example, a collection of sites on a planet constitutes a set of objects that are classified manually by domain experts (geologists) on the basis of their geological properties. In the case of planet Mars, the resultant division of sites into the so-called *geological units* represents an external classification. A clustering algorithm that is invoked to group sites into different clusters can be compared to the existing set of geological units to determine the novelty of the resulting clusters.

Current approaches to external cluster validation are based on the assumption that an understanding of the output of the clustering algorithm can be achieved by finding a resemblance of the clusters with existing classes (Dom, 2001). Such narrow assumption precludes alternative interpretations; in some scenarios high-quality clusters are considered novel if they do not resemble existing classes. After all, a large separation between clusters and classes can serve as clear evidence of cluster novelty (Cheeseman and Stutz, 1996); on the other hand, finding clusters resembling existing classes serves to confirm existing theories of data distributions. Both types of interpretations are legitimate; the value of new clusters is ultimately decided by domain experts after careful interpretation of the distribution of new clusters and existing classes.

In summary, most traditional metrics for external cluster validation output a single value indicating the degree of match between the partition induced by the known classes and the one induced by the clusters. We claim this is the wrong approach to validate patterns output by a data-analysis technique. By averaging the degree of match across all classes and clusters, traditional metrics fail to identify the potential value of individual clusters.

CLUSTER VALIDATION IN MACHINE LEARNING

The question of how to validate clusters appropriately without running the risk of missing crucial information can be answered by avoiding any form of averaging or smoothing approach; one should refrain from computing an average of the degree of cluster similarity with respect to external classes. Instead, we claim, one should compute the distance between each individual cluster and its most similar external class; such comparison can then be used by the domain expert for an informed cluster-quality assessment.

Traditional Approaches to Cluster Validation

More formally, the problem of assessing the degree of match between the set **C** of predefined classes and the set **K** of new clusters is traditionally performed by evaluating a metric where high values indicate a high similarity between classes and clusters. For example, one type of statistical metric is defined in terms of a **2x2** table where each entry $\mathbf{E}_{ij}$, $i,j \in \{1,2\}$, counts the number of object pairs that agree or disagree with the class and cluster to which they belong; $\mathbf{E}_{11}$ corresponds to the number of object pairs that belong to the same class and cluster, $\mathbf{E}_{12}$ corresponds to same class and different cluster, $\mathbf{E}_{21}$ corresponds to different class and same cluster, and $\mathbf{E}_{22}$ corresponds to different class and different cluster. Entries along the diagonal denote the number of object pairs contributing to high similarity between classes and clusters, whereas elements outside the diagonal contribute to a high degree of dissimilarity. A common family of statistics used as metrics simply average correctly classified class-cluster pairs by a function of all possible pairs. A popular similarity metric is Rand's metric (Theodoridis and Koutroumbas, 2003):

$$(\mathbf{E}_{11} + \mathbf{E}_{22}) / (\mathbf{E}_{11} + \mathbf{E}_{12} + \mathbf{E}_{21} + \mathbf{E}_{22})$$

Other metrics are defined as follows:

Jaccard:

$$\mathbf{E}_{11} / (\mathbf{E}_{11} + \mathbf{E}_{12} + \mathbf{E}_{21})$$

Fowlkes and Mallows:

$$\mathbf{E}_{11} / [(\mathbf{E}_{11} + \mathbf{E}_{12}) (\mathbf{E}_{21} + \mathbf{E}_{22})]^{1/2}$$

A different approach is to work on a contingency table **M**, defined as a matrix of size **m**x**n** where each row corresponds to an external class and each column to a cluster. An entry $\mathbf{M}_{ij}$ indicates the number of objects covered by class $\mathbf{C}_i$ and cluster $\mathbf{K}_j$. Using **M**, the similarity between **C** and **K** can be quantified into a single number in several forms (Kanungo et al., 1996; Vaithyanathan and Dom, 2000).

Limitations of Current Metrics

In practice, a quantification of the similarity between sets of classes and clusters is of limited value; we claim any potential discovery provided by the clustering algorithm is only identifiable by analyzing the meaning of each cluster individually. As an illustration, assume two clusters that bear a strong resemblance with two real classes, with a small novel third cluster bearing no resemblance to any class. Averaging the similarity between clusters and classes altogether disregards the potential discovery carried by the third cluster. If the third cluster is small enough, most metrics would indicate a high degree of class-cluster similarity.

In addition, even when in principle one could analyze the entries of a contingency matrix to identify clusters having little overlap with existing classes, such information cannot be used in estimating the intersection of the true probability models from which the objects are drawn. This is because the lack of a probabilistic model in the representation of data distributions precludes estimating the extent of the intersection of a class-cluster pair; probabilistic expectations can differ significantly from actual counts because the probabilistic model introduces substantial a priori information.

Proposed Approach to Cluster Validation

We show our approach to cluster validation in the context of the analysis of Mars' surface (Vilalta et al., 2007). The current qualitative means of classifying Martian surfaces is by assigning each site to what is called a *geological unit*. One shortcoming of such classification is that it cannot be automated because it is normally assigned subjectively by a domain expert. On the other hand, an automated classification of Martian surfaces is possible using digital topography data. Martian topography data is currently available from the Mars Orbiter Laser Altimeter (MOLA) instrument (Smith et al., 2003). This data can be used to construct a digital elevation model (DEM) of a site on Mars' surface. The DEM is a regular grid of cells with assigned elevation values. Such grid can be processed to generate a dataset of feature vectors (each vector component stands as a topographic feature). The resulting training data set can be used as input to a clustering algorithm.

If the clustering algorithm produces **N** clusters, and there exists **M** externals classes (in our case study **M=16** sixteen Martian geological units), we advocate validating the quality of the clusters by computing the degree of overlap between each cluster and each of the existing external classes. In essence, one can calculate an **NxM** matrix of distances between the clusters and classes. This approach to pattern validation enables us to assess the value of each cluster independently of the rest, and can lead to important discoveries.

A practical implementation for this type of validation is as follows. One can model each cluster and each class as a multivariate Gaussian distribution; the degree of separation between both distributions can then be computed using an information-theoretic measure known as relative entropy or Kullback-Leibler distance (Cover and Thomas, 2006). The separation of two distributions can be simplified if it is done along a single dimension that captures most of the data variability (Vilalta et al., 2007). One possibility is to project all data objects over the vector that lies orthogonal to the hyper-plane that maximizes the separation between cluster and class, for example, by using Fisher's Linear Discriminant (Duda, et al., 2001). The resulting degree of overlap can be used as a measure of the similarity of class and cluster. As mentioned before, this approach enables us to assess clusters individually. In some cases a large separation (low overlap) may indicate domain novelty, whereas high overlap or similarity may serve to reinforce current classification schemes.

A CASE STUDY IN PLANETARY SCIENCE

In the analysis of Mars' surface, our clustering algorithm produced **N=9** clusters. Using the method for external cluster assessment explained above, we were able to determine that partitioning the dataset of Martian sites on the basis of the resulting clusters produced a novel classification that does not match the traditional classification based on (**M=16**) geological units. We could conclude this by analyzing each cluster individually,

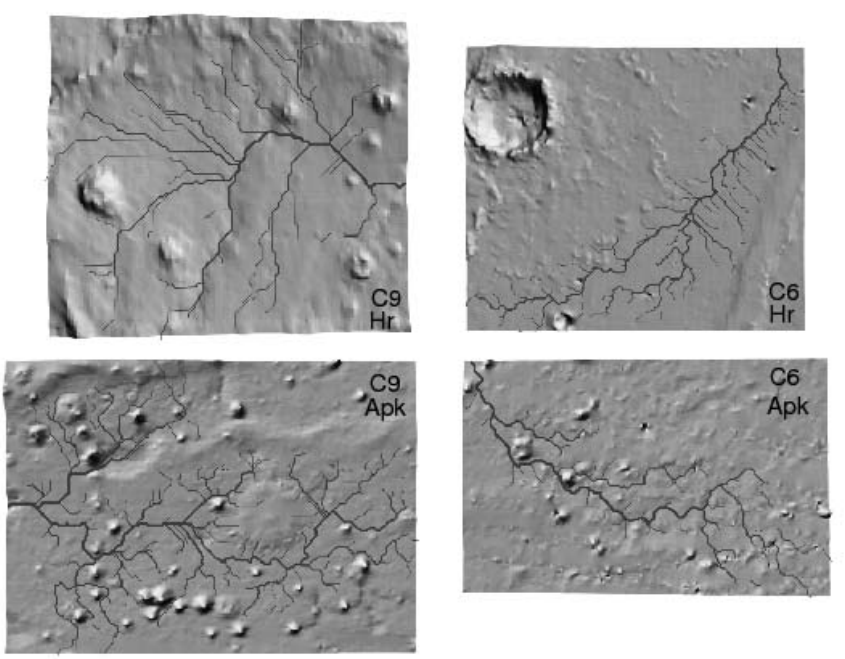
observing no close resemblance with existing classes (in addition our methodology indicates which clusters are more dissimilar than others when compared to the set of classes).

Figure 1 shows an example of the difference between patterns found by clusters and those pertaining to more traditional geomorphic attributes. Four Martian surfaces are shown in a **2x2** matrix arrangement. Surfaces in the same row belong to the same geological unit, whereas surfaces in the same column belong to the same cluster. The top two sites show two surfaces from a geological unit that is described as "ridged plains, moderately cratered, marked by long ridges." These features can indeed be seen in the two surfaces. Despite such texture similarity they exhibit very different shape for their drainage (blue river-like features). The bottom two sites show two surfaces from a geological unit described as "smooth plain with conical hills or knobs." Again, it is easy to see the similarity between these two surfaces based on that description. Nevertheless, the two terrains have drainage with markedly different character. On the basis of the cluster distinction, these four surfaces could be divided vertically instead of horizontally. Such division corresponds to our cluster partition where the drainage is similar for sites within the same cluster. Our methodology facilitates this type of comparisons because clusters are compared individually to similar classes. Domain experts can then provide a scientific explanation of the new data categorization by focusing on particular differences or similarities between specific class-cluster pairs.

FUTURE TRENDS

Future trends include assessing the value of clusters obtained with alternative clustering algorithms (other than probabilistic algorithms). Another trend is to devise modeling techniques for the external class distribution (e.g., as a mixture of Gaussian models). Finally, one line of research is to design clustering algorithms that search for clusters in a direction that maximizes a metric of relevance or *interestingness* as dictated by an external classification scheme. Specifically, a clustering algorithm can be set to optimize a metric that rewards clusters exhibiting little (conversely strong) resemblance to existing classes.

Figure 1. Four Martian surfaces that belong to two different geological units (rows), and two different clusters (columns). Drainage networks are drawn on top of the surfaces.



CONCLUSION

Cluster validation looks for methods to assess the value of patterns output by machine learning techniques. In the context of unsupervised learning or clustering, data objects are grouped into new categories that convey potentially meaningful and novel domain interpretations. When the same data objects have been previously framed into a particular classification scheme, the value of each cluster can be assessed by estimating the degree of separation between the cluster and its most similar class. In this document we criticize common approaches to pattern validation where the mechanism consists of computing an average of the degree of similarity between clusters and classes. Instead we advocate an approach to external cluster assessment based on modeling each cluster and class as a probabilistic distribution; the degree of separation between both distributions can then be measured using an information-theoretic approach (e.g., relative entropy or Kullback-Leibler distance). By looking at each cluster individually, one can assess the degree of novelty (large separation to other classes) of each cluster, or instead the degree of validation (close resemblance to other classes) provided by the same cluster.

KEY TERMS

Cluster Validation: A post-processing step after clustering used to assess the value of the resulting clusters.

Digital Elevation Model: A digital elevation model (DEM) is a regular grid of cells with assigned elevation values. It characterizes a particular site based on the shape of the terrain.

External Cluster Validation: Cluster validation is called *external* if the validation is performed by gathering statistics comparing the induced clusters against an external and independent classification of objects.

Fisher's Linear Discriminant: Fisher's linear discriminant finds a hyperplane that separates two data clusters by searching for a normal vector **w** that maximizes the separation between clusters when the data is projected over **w**.

Internal Cluster Validation: Cluster validation is called *internal* when statistics are devised to capture the quality of the induced clusters using the available data objects only.

MOLA Instrument: MOLA is the Mars Orbiter Laser Altimeter; it is an instrument attached to the Mars Global Surveyor spacecraft sent to Mars in 1996.

Relative Entropy: The relative entropy or Kullback-Leibler distance between two probability mass functions $\mathbf{p(x)}$ and $\mathbf{q(x)}$ is defined as $\mathbf{D(p \,||\, q) = \Sigma_x\, p(x) \log [p(x)/q(x)]}$ (Cover & Thomas, 2006).

Clustering Analysis of Data with High Dimensionality

INTRODUCTION

Clustering analysis has been widely applied in diverse fields such as data mining, access structures, knowledge discovery, software engineering, organization of information systems, and machine learning. The main objective of cluster analysis is to create groups of objects based on the degree of their association (Kaufman & Rousseeuw, 1990; Romesburg, 1990).

There are two major categories of clustering algorithms with respect to the output structure: partitional and hierarchical (Romesburg, 1990). K-means is a representative of the partitional algorithms. The output of this algorithm is a flat structure of clusters. The K-means is a very attractive algorithm because of its simplicity and efficiency, which make it one of the favorite choices to handle large datasets. On the flip side, it has a dependency on the initial choice of number of clusters. This choice may not be optimal, as it should be made in the very beginning, when there may not exist an informal expectation of what the number of natural clusters would be. Hierarchical clustering algorithms produce a hierarchical structure often presented graphically as a dendrogram. There are two main types of hierarchical algorithms: agglomerative and divisive. The agglomerative method uses a bottom-up approach, i.e., starts with the individual objects, each considered to be in its own cluster, and then merges the clusters until the desired number of clusters is achieved. The divisive method uses the opposite approach, i.e., starts with all objects in one cluster and divides them into separate clusters. The clusters form a tree with each higher level showing higher degree of dissimilarity. The height of the merging point in the tree represents the similarity distance at which the objects merge in one cluster. The agglomerative algorithms are usually able to generate high-quality clusters but suffer a high computational complexity compared with divisive algorithms.

In this paper, we focus on investigating the behavior of agglomerative hierarchical algorithms. We further divide these algorithms into two major categories: group based and single-object based clustering methods. Typical examples for the former category include Unweighted Pair-Group using Arithmetic averages (UPGMA), Centroid Linkage, and WARDS, etc. Single LINKage (SLINK) clustering and Complete LINKage clustering (CLINK) fall into the second category. We choose UPGMA and SLINK as the representatives of each category and the comparison of these two representative techniques could also reflect some similarity and difference between these two sets of clustering methods. The study examines three key issues for clustering analysis: (1) the computation of the degree of association between different objects; (2) the designation of an acceptable criterion to evaluate how good and/or successful a clustering method is; and (3) the adaptability of the clustering method used under different statistical distributions of data including random, skewed, concentrated around certain regions, etc. Two different statistical distributions are used to express how data objects are drawn from a 50-dimensional space. This also differentiates our work from some previous ones, where a limited number of dimensions for data features (typically up to three) are considered (Bouguettaya, 1996; Bouguettaya & LeViet, 1998). In addition, three types of distances are used to compare the resultant clustering trees: Euclidean, Canberra Metric, and Bray-Curtis distances. The results of an exhaustive set of experiments that involve data derived from 50-dimensional space are presented. These experiments indicate a surprisingly high level of similarity between the two clustering techniques under most combinations of parameter settings.

The remainder of this paper is organized as follows. Section 2 discusses the clustering techniques used in our evaluation and describes the various distributions

used to derive our experimental data. Section 3 outlines the experimental methodology and Section 4 presents a summary of our results. Finally, concluding remarks are drawn in Section 5.

BACKGROUND

In this section, we outline a set of key elements for conducting clustering analysis. These include *distances of similarity, coefficients of correlation, clustering methods, and statistical distributions of data objects.* In what follows, we will give a detailed discussion of each of these elements. Finally, we present a general algorithm, which outlines the procedure of constructing clustering in our study.

Distances of Similarity

To cluster data objects in a database system or in any other environment, some means of quantifying the degree of associations between items is needed. This can be a measure of distances or similarities. There are a number of similarity measures available and the choice may have an effect on the results obtained. Multi-dimensional objects may use relative or normalized weight to convert their distance to an arbitrary scale so they can be compared. Once the objects are defined in the same measurement space as the points, it is then possible to compute the degree of similarity. In this respect, the smaller the distance the more similar two objects are. The most popular choice in computing distance is the Euclidean distance with:

$$d(i, j) = \sqrt{(x_{i_1} - x_{j_1})^2 + (x_{i_2} - x_{j_2})^2 + ... + (x_{i_n} - x_{j_n})^2} \quad (1)$$

Euclidean distance belongs to the family of Minkowski's distances, which is defined as

$$d(i, j) = (| x_{i_1} - x_{j_1} |^m + | x_{i_2} - x_{j_2} |^m + ... + | x_{i_n} - x_{j_n} |^m)^{\frac{1}{m}} \quad (2)$$

When m = 2, Minkowski's distance becomes Euclidean distance. Another widely used distance, called Manhattan distance, is also a special case of Minkowski's distance (when m is set to 1).

In addition to Euclidean distance, we also use another two types of distances to investigate how this element could affect clustering analysis: *Canberra Metric* and *Bray-Curtis distances*. Canberra Metric distance, a(i, j), has a range between 0.0 and 1.0. The data objects i and j are identical when a(i, j) takes value 0.0. Specifically, a(i, j) is defined as:

$$a(i, j) = \frac{1}{n}\left(\frac{| x_{i_1} - x_{j_1} |}{(x_{i_1} + x_{j_1})} + \frac{| x_{i_2} - x_{j_2} |}{(x_{i_2} + x_{j_2})} + ... + \frac{| x_{i_n} - x_{j_n} |}{(x_{i_n} + x_{j_n})}\right) \quad (3)$$

Similarly, Bray-Curtis distance, b(i, j), also has values ranged from 0.0 to 1.0. The value 0.0 indicates the maximum similarity between two data objects. b(i, j) is defined as:

$$b(i, j) = \frac{| x_{i_1} - x_{j_1} | + | x_{i_2} - x_{j_2} | + ... + | x_{i_n} - x_{j_n} |}{(x_{i_1} + x_{j_1}) + (x_{i_2} + x_{j_2}) + ... + (x_{i_n} + x_{j_n})} \quad (4)$$

Coefficients of Correlation

Coefficients of correlation are the measurements that describe the strength of the relationship between two variables X and Y. It essentially answers the question *"how similar are X and Y?"*. In our study, coefficients of correlation will be used to compare outcomes (i.e., hierarchical trees) of different clustering techniques. The values of the coefficients of correlation range from 0 to 1 where the value 0 points to *no similarity* and the value 1 points *high similarity*. The coefficient of correlation is used to find the similarity among (clustering) objects. The correlation r of two random variables X and Y where: X = (x_1, x_2, x_3, . . . , x_n) and Y = (y_1, y_2, y_3, . . . , y_n) is given by the formula:

$$r = \frac{| E(X,Y) - E(X) \times E(Y) |}{\sqrt{(E(X^2) - E^2(X)}\sqrt{(E(Y^2) - E^2(Y)}} \quad (5)$$

where

$E(X) = (\sum_{i=1}^{n} x_i)/n$,

$E(Y) = (\sum_{i=1}^{n} y_i)/n$, and

$E(X,Y) = (\sum_{i=1}^{n} x_i \times y_i)/n.$

Clustering Methods

Clustering methods can be classified as partitioning and hierarchical methods according to the type of the group structures they produce. Here, we focus on hierarchical methods which work in a bottom–up and are appropriate for data-intensive environment (Zupan, 1982). The algorithm proceeds by performing a series of successive fusion. This produces a nested data set in which pairs of items or clusters are successively linked until every item in the data set is linked to form one cluster, known also as hierarchical tree. This tree is often presented as a *dendrogram*, in which pairwise couplings of the objects in the data set are shown and the length of the branches (vertices) or the value of the similarity is expressed numerically. In this study, we focus on two methods that enjoy wide usage: Unweighted Pair-Group using Arithmetic Averages (UPGMA) and Single LINKage (SLINK) clustering. UPGMA is based on comparing groups of data objects, whereas SLINK is based on single object comparison.

- *Unweighted Pair-Group using Arithmetic Averages*: This method uses the average values pair-wise distance, denoted $D_{X,Y}$, within each participating cluster to determine similarity. All participating objects contribute to inter-cluster similarity. This methods is also known as one of "average linkage" clustering methods (Lance and Williams 1967; Everitt 1977; Romesburg 1990). The distance between two clusters is

$$D_{X,Y} = \frac{\sum D_{x,y}}{n_X \times n_Y} \qquad (6)$$

  where X and Y are two clusters, x and y are objects from X and Y , Dx,y is the distance between x and y, and n_X and n_Y are the respective sizes of the clusters.
- *Single LINKage Clustering:* This method is also known as the nearest neighbor method. The distance between two clusters is the smallest distance of all distances between two items *(x, y)*, denoted $d_{i,j}$, such that x is a member of a cluster and y is a member of another cluster. The distance $d_{I,J}$ is computed as follows:

$$d_{I,J} = min\{d_{i,j}\} \text{ with } i \in I, j \in J \qquad (7)$$

  where (I, J) are clusters, and (i, j) are objects in the corresponding clusters. This method is the simplest among all clustering methods. It has some attractive theoretical properties (Jardine and Sibson 1971). However, it tends to form long or chaining clusters. This method may not be very suitable for objects concentrated around some centers in the measurement space.

Statistical Distributions

As mentioned above, objects that participate in the clustering process are randomly selected from a designated area (i.e., [0, 1] × [0, 1] × [0, 1]...). There are several random distributions. We chose two of them that closely model real world distributions (Zupan, 1982). Our aim is to examine whether clustering is dependent on the way objects are generated. These two distributions are uniform and Zipf's distributions. Below, we describe these statistical distributions in terms of density functions.

- *Uniform Distribution* whose density function is $f(x) = 1$ for all x in $0 \le x \le 1$.
- *Zipf's Distribution* whose density function is $f(x) = C/x^{\alpha}$ for x in $1 \le x \le N$ where C is the normalization constant (i.e., $\sum f(x) = 1$).

A General Algorithm

Before the grouping commences, objects following the chosen probabilistic guidelines are generated. In this paper, each dimension of the objects are randomly drawn from the interval [0, 1]. Subsequently, the objects are compared to each other by computing their distances. The distance used in assessing the similarity between two clusters is called the similarity coefficient. This is not to be confused with *coefficient of correlations* as the latter are used to compare outcomes (i.e., hierarchical trees) of the clustering process. The way objects and clusters of objects coalesce together to form larger clusters varies with the approach used. Below, we outline a generic algorithm that is applicable to all clustering methods (initially, every cluster consists of exactly one object).

1. Create all possible cluster formulations from the existing ones.

2. For each such candidate compute its corresponding similarity coefficient.
3. Find out the minimum of all similarity coefficients and then join the corresponding clusters.
4. If the number of clusters is not equal to one (i.e., not all clusters have coalesced into one entity), then go to (1).

Essentially, the algorithm consists of two phases: the first phase records the similarity coefficients.

The second phase computes the minimum coefficient and then performs the clustering.

There is a case when using average-based methods ambiguity may arise. For instance, let us suppose that when performing Step 1 (of the above algorithmic skeleton), three successive clusters are to be joined. All these three clusters have the same minimum similarity value. When performing Step 2, the first two clusters are joined. However, when computing the similarity coefficient between this new cluster and the third cluster, the similarity coefficient value may now be different from the minimum value. The question at this stage is what the next step should be. There are essentially two options:

- Continue by joining clusters using a recomputation of the similarity coefficient every time we find ourselves in Step 2, or
- Join all those clusters that have the same similarity coefficient at once and do not recompute the similarity in Step 2.

In general, there is no evidence that one is better than the other (Romesburg, 1990). For our study, we selected the first alternative.

MAJOR FOCUS

The sizes of data objects presented in this study range from 50 to 400. Data objects are drawn from a 50-dimensional space. The value of each attribute value ranges from 0 and 1 inclusive. Each experiment goes through the following steps that result in a clustering tree.

- Generate lists of objects with a statistical distribution method (Uniform or Zipf's).
- Carry out the clustering process with a clustering method (UPGMA or SLINK).
- Calculate the coefficient of correlation for each clustering method.

For statistical validation, each experiment is repeated 100 times. The correlation coefficient is used as the main vehicle for comparing two trees obtained from lists of objects. The notion of distance used in the computation of the correlation coefficients could be realized in three ways: Euclidean distance (linear distance), Canberra Metric distance, and Bray-Curtis distance. Once a distance type is chosen, we may proceed with the computation of the correlation coefficient. This is accomplished by first selecting a pair of identifiers (two objects) from a list (linearized tree) and calculating their distance and then by selecting the pair of identifiers from the second list (linearized tree) and computing their distance. We repeat the same process for all remaining pairs in the second list.

There are numerous families of correlation coefficients that could be examined. This is due to the fact that various parameters are involved in the process of evaluating clustering of objects in the two-dimensional space. More specifically, the clustering method is one parameter (i.e., UPGMA and SLINK); the method of computing the distances is another one (i.e., linear, Canberra Metric, and Bray-Curtis); and finally, the distribution followed by the data objects (i.e., uniform and Zipf's) is a third parameter. In total, there are 12 (e.g., 2*3*2=12) possible ways to compute correlation coefficients for any two lists of objects. In addition, the dimensional space and the input size may also have a direct influence on the clustering. This determines what kinds of data are to be compared and what their sizes are.

We have identified a number of cases to check the sensitivity of each clustering method with regard to the input data. For every type of coefficient of correlation mentioned above, four types of situations (hence, four coefficients of correlation) have been isolated. All these types of situations are representative of a wide range of practical settings (Bouguettaya, 1996) and can help us understand the major factors that influence the choice of a clustering method (Jardine & Sibson, 1971; Kaufman & Rousseeuw, 1990; Tsangaris & Naughton, 1992).

We partition these settings in three major groups, represented by three templates or blocks of correlation coefficients.

First Block: the coefficients presented in this set examine the influence of context in how objects are finally clustered. In particular, the correlation coefficients are between:

- Pairs of objects drawn from a set *S* and pairs of objects drawn from the first half of the same set *S*. The first half of S is used before the set is sorted.
- Pairs of objects drawn from the first half of *S*, say S_2, and pairs of objects drawn from the first half of another set *S'*, say S'_2. The two sets are given ascending identifiers after being sorted. The first object of S_2 is given as identifier the number 1 and so is given the first object of S'_2. The second object of S_2 is given as identifier the number 2 and so is given the second object of S'_2 and so on.

Second Block: This set of coefficients determines the influence of the data size. Coefficients of correlation are drawn between:

- Pairs of objects drawn from S and pairs of objects drawn from the union of a set *X* and *S*. The set *X* contains 10% new randomly generated objects.

Third Block: The purpose of this group of coefficients is to determine the relationship that may exist between two lists of two-dimensional objects derived using different distributions. More specifically, the coefficients of correlation are drawn between:

- Pairs of objects drawn from *S* using the uniform distribution and pairs of objects drawn from *S'* using the Zipf's distribution.

In summary, all the above four types of coefficients of correlation are meant to analyze different settings in the course of our evaluation.

Results and Interpretation

We annotate all the figures below using a shorthand notation as follows: UPGMA (U), SLINK (S), Zipf (Z), Uniform (U), Linear distance (L), Canberra Metric distance (A), Bray-Curtis distance (B), Coefficient of correlation (CC), and Standard deviation (SD). For example, the abbreviation ZUL is used to represent the input with the following parameters: Zipf's distribution, UPGMA method, and Linear distance. In what follows, we provide a thorough interpretation of the results.

Figure 1 depicts the first coefficient of correlation for UPGMA and SLINK. The top two graphs depict the coefficient of correlation (CC) and standard deviation (SD) from UPGMA clustering method. In each graph, the three CC curves are above the three SD curves. The top left graph in Figure 1 is based on Zifp's distribution whereas the top right graph is based on uniform distribution. The choice of distribution does not seem to have any influence in the clustering process. However, the distance type seems to have some impact on the clustering. By examining these two graphs, we notice that the correlations are a bit stronger in the case of the Euclidean distance. Because of the high correlation in all cases depicted in these two graphs,

Figure 1. The first coefficient of correlation

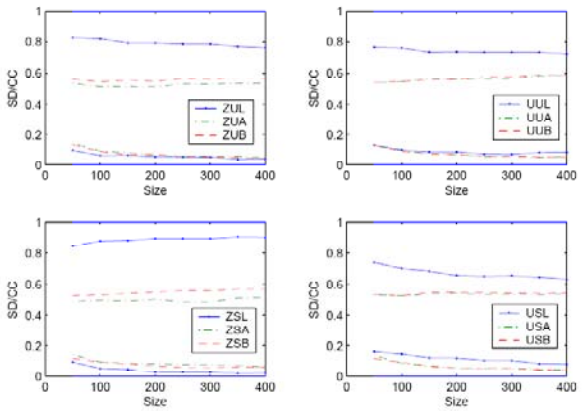

Figure 2. The third coefficient of correlation

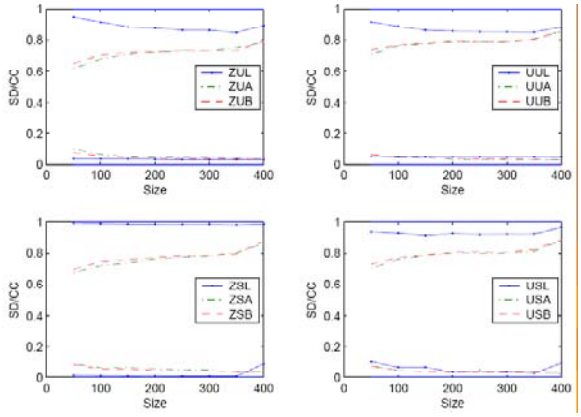

the context in this specific case does not seem to make strong significant difference in the clustering process. However, Canberra Metric and Bray-Curtis distances seem to be more sensitive to the context change in this case than Euclidian distance. The three curves in the bottom of these two graphs show the standard deviation of UPGMA method. The low value justifies the stability of this method. If we look at bottom two graphs in Figure 1, which depict the clustering possibilities using SLINK method, the results are very similar. This strengthens the conjecture that no matter what the context of the clustering is, the outcome is almost invariably the same.

The third coefficient of correlation checks the influence of the data size on clustering. They are shown in Figure 2. There are no significant differences when using these two clustering methods respectively. Similar to the situation of the first coefficient of correlation, Euclidian distance generates stronger correlation than the other two types of distances. This shows that Canberra Metric and Bray-Curtis distances seem to be more sensitive to data size change than Euclidian distance. The high correlation and low standard deviation in all cases also indicate that SLINK and UPGMA are relatively stable for multidimensional objects. The perturbation represented by the insertion of new data objects does not seem to have any significant effect on the clustering process.

The experiments regarding the second coefficient of correlation show some surprising results. The previous study results using low dimensionality show above average correlation. In contrast, in this study as shown in Figure 3, the correlation values are low. It is a strong indication that in high dimensions, almost no correlation exists between the two sets of objects. In the case of the first coefficient of correlation, the data objects are drawn from the same initial set. However, the second coefficient of correlation draws the values from different initial sets. The difference with the previous study is that we now randomly select one dimension from multiple dimensions as our reference dimension. As a result, the order of data points is dependent on the value of the selected dimension. The two clustering methods have very similar performance on different types of distances. Since the coefficients of correlation have very small values, the CC curves and SD curves would be mixed with each other. Therefore, we separate CC and SD curves by drawing them in different graphs. This is also applied in the final coefficient of correlation.

The final coefficient of correlation is used to check the influence of the statistical distributions on the clustering process. Figure 4 shows the result of the experiments. It is quite obvious that almost no correlation can be drawn between the two differently generated lists of objects. Simply put, the clustering process is influenced by the statistical distribution used to generate objects.

In order to validate our interpretation of the results, we ran the same experiments for different input size (50-400). The results show the same type of behavior over all these input sizes. The fact that the slope value is close to 0 is the most obvious evidence. Therefore, the input size has essentially no role in the clustering process.

Figure 3. The second coefficient of correlation

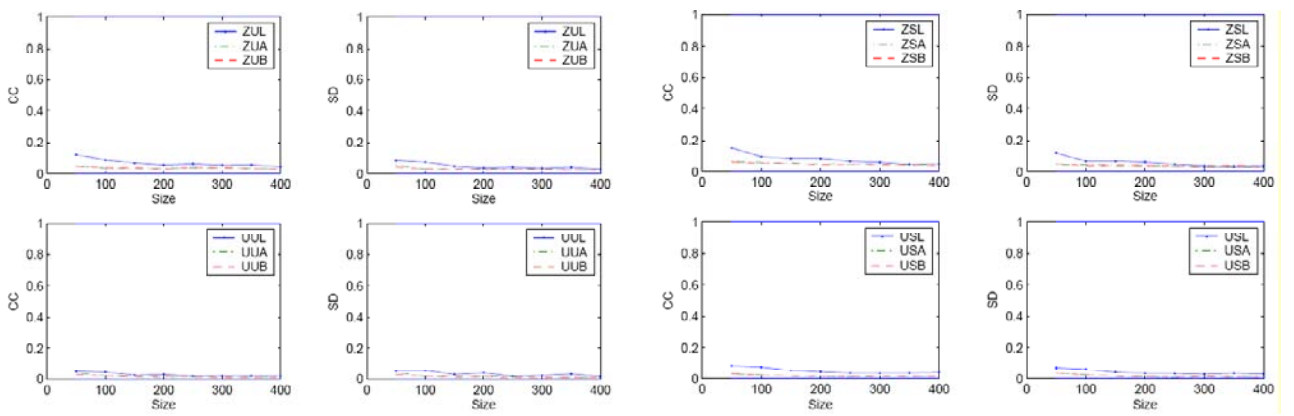

Figure 4. The fourth coefficient of correlation

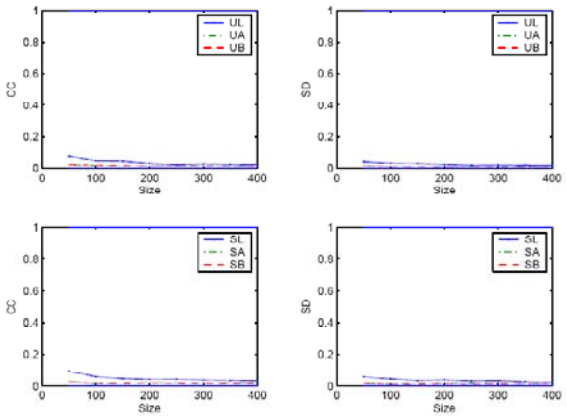

Figure 5. Processing time of UPGMA and SLINK

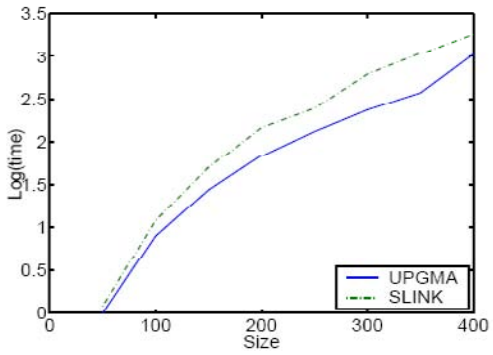

As a final set of measurements, we also recorded the computation time for various methods. Figure 5 shows the average logarithmic computation time of all experiments varying the dimensions. The considered data input sizes are 50, 100, 150, 200, 250, 300, 350, and 400. The time unit is in (logarithmic) seconds. We can see that UPGMA is slightly more efficient than SLINK. It is interesting to note that both methods exhibit the same computational behavior when varying the dimensions and data input size.

The results obtained in this study confirm several findings from previous studies focusing on low-dimension data objects (1-D, 2-D, and 3-D) (Bouguettaya, 1996). Like previous studies, this set of experiments strongly indicate that there is a basic inherent way for data objects to cluster and independently from the clustering method used. Especially, the dimensionality does not play a significant role in the clustering of data objects. This is compelling evidence that clustering methods in general do not seem to influence the outcome of the clustering process. It is worth indicating that the experiments presented in this paper were computationally intensive. We used 12 Sun Workstations running Solaris 8.0. The complete set of experiments for each clustering methods took on average 5 days to complete.

FUTURE TRENDS

Clustering techniques are usually computing and resource hungry (Romesburg, 1990; Jain, Murty, & Flynn, 1999). In previous research, sample datasets were limited in size because of the high computational requirements of the clustering methods. It has been even more problematic when multidimensional data is analyzed. One research direction has been the investigation of efficient approaches to allow larger datasets to be analyzed. One key requirement is the ability of these techniques to produce good quality clusters while running efficiently and with reasonable memory requirements. Robust algorithms such as hierarchical techniques, that work well with different data types and produce adequate clusters, are quite often not efficient (Jain, Murty et al. 1999). Other algorithms, like partitional techniques, are more efficient but have more limited applicability (Jain, Murty, & Flynn, 1999). For example, some of the most popular clustering algorithms such as SLINK, UPGMA fall in the first category (hierarchical), while others such as K-means fall in this second category (partitional). While SLINK and UPGMA can produce good results, their time complexity is O(n2logn), where n is the size of the dataset. K-means runs in time linear to the number of input data objects but has a number of limitations such the dependency of the data input order, i.e., it is better suited for isotropic input data (Bradley & Fayyad 1998). As a result, the idea of combining the best of both worlds needs to be explored (Gaddam, Phoha, Kiran, & Balagani, 2007; Lin & Chen, 2005). The idea of this new approach is the ability to combine hierarchical and partitional algorithms into a two-stage method so that individual algorithm's strengths are leveraged and the overall drawbacks are minimized.

CONCLUSION

In this study, we analyzed two clustering methods, UPGMA and SLINK. We ran a wide array of experiments to test the stability of sensibility of the clustering methods for high dimensional data objects. The obtained results strengthen previous study result considering low dimensional data objects. The results seem to suggest that if the data is drawn from the same context, then any clustering methods will yield approximately the same highly correlated outcome. The Canberra Metric and Bray-Curtis distances seem to be more sensitive to the context and data size change than the Euclidian distance. When the contexts are different, the results are the same for the two clustering techniques. However, in this case the correlation values are quite low. This is indicative of the significance of choosing different contexts for clustering. The other factors, including the choice of a clustering technique, did not have any bearing on the outcome.

KEY TERMS

Coefficients of Correlation: The measurements that describe the strength of the relationship between two variables X and Y.

Data Clustering: Partitioning of a data set into subsets (clusters), so that the data in each subset shares some common features.

Hierarchical Clustering: Building (agglomerative), or breaking up (divisive), a hierarchy of clusters. It finds successive clusters using previously established clusters.

Similarity Coefficient: The distance used in assessing the similarity between two clusters.

Single LINKage (SLINK): A representative of single-object based clustering methods, where only one data object is used for inter-cluster distance computation.

Unweighted Pair-Group using Arithmetic Averages (UPGMA): A representative of group based clustering methods, where all data objects in a cluster will participate in the computation of inter-cluster distances.

Zipf Distribution: A discrete power-law distribution, the most famous example of which is the description of the frequency of words in the English language.

Clustering Categorical Data with k-Modes

Joshua Zhexue Huang
The University of Hong Kong, Hong Kong

INTRODUCTION

A lot of data in real world databases are categorical. For example, gender, profession, position, and hobby of customers are usually defined as categorical attributes in the CUSTOMER table. Each categorical attribute is represented with a small set of unique categorical values such as {Female, Male} for the gender attribute. Unlike numeric data, categorical values are discrete and unordered. Therefore, the clustering algorithms for numeric data cannot be used to cluster categorical data that exists in many real world applications.

In data mining research, much effort has been put on development of new techniques for clustering categorical data (Huang, 1997b; Huang, 1998; Gibson, Kleinberg, & Raghavan, 1998; Ganti, Gehrke, & Ramakrishnan, 1999; Guha, Rastogi, & Shim, 1999; Chaturvedi, Green, Carroll, & Foods, 2001; Barbara, Li, & Couto, 2002; Andritsos, Tsaparas, Miller, & Sevcik, 2003; Li, Ma, & Ogihara, 2004; Chen, & Liu, 2005; Parmar, Wu, & Blackhurst, 2007). The k-modes clustering algorithm (Huang, 1997b; Huang, 1998) is one of the first algorithms for clustering large categorical data. In the past decade, this algorithm has been well studied and widely used in various applications. It is also adopted in commercial software (e.g., Daylight Chemical Information Systems, Inc, http://www.daylight.com/).

BACKGROUND

In data mining, k-means is the mostly used algorithm for clustering data because of its efficiency in clustering very large data. However, the standard k-means clustering process cannot be applied to categorical data due to the Euclidean distance function and use of means to represent cluster centers. To use k-means to cluster categorical data, Ralambondrainy (1995) converted each unique category to a dummy binary attribute and used 0 or 1 to indicate the categorical value either absent or present in a data record. This approach is not suitable for high dimensional categorical data.

The k-modes approach modifies the standard k-means process for clustering categorical data by replacing the Euclidean distance function with the simple matching dissimilarity measure, using modes to represent cluster centers and updating modes with the most frequent categorical values in each of iterations of the clustering process. These modifications guarantee that the clustering process converges to a local minimal result. Since the k-means clustering process is essentially not changed, the efficiency of the clustering process is maintained. The k-modes clustering algorithm was first published and made publicly available in 1997 (Huang, 1997b). An equivalent approach was reported independently in (Chaturvedi, Green, Carroll, & Foods, 2001). The relationship of the two k-modes methods is described in (Huang & Ng, 2003).

In the past decade, a few other methods for clustering categorical data were also proposed, including the dynamic system approach (Gibson, Kleinberg, & Raghavan, 1998), Cactus (Ganti, Gehrke, & Ramakrishnan, 1999), ROCK (Guha, Rastogi, & Shim, 1999), Coolcat (Barbara, Li, & Couto, 2002), and LIMBO (Andritsos, Tsaparas, Miller, & Sevcik, 2003). However, these methods have largely stayed in research stage and not been widely applied to real world applications.

MAIN FOCUS

The k-modes clustering algorithm is an extension to the standard k-means clustering algorithm for clustering categorical data. The major modifications to k-means include distance function, cluster center representation and the iterative clustering process (Huang, 1998).

Distance Function

To calculate the distance (or dissimilarity) between two objects X and Y described by m categorical attributes, the distance function in k-modes is defined as

$$d(X,Y)=\sum_{j=1}^{m}\delta(x_j,y_j) \quad (1)$$

where

$$\delta(x_j,y_j)=\begin{cases}0, & x_j=y_j\\ 1, & x_j\neq y_j.\end{cases} \quad (2)$$

Here, x_j and y_j are the values of attribute j in X and Y. This function is often referred to as simple matching dissimilarity measure or Hemming distance. The larger the number of mismatches of categorical values between X and Y is, the more dissimilar the two objects.

A new distance function for k-modes defines the dissimilarity measure between an object X and a cluster center Z_l as (Ng, Li, Huang, & He, 2007):

$$\phi(x_j,z_j)=\begin{cases}1-\dfrac{n_j^r}{n_l}, & x_j=z_j\\ 1, & x_j\neq z_j\end{cases} \quad (3)$$

where z_j is the categorical value of attribute j in Z_l, n_l is the number of objects in cluster l and n_j^r is the number of objects whose attribute value is r. In this function, when the categorical value of an object is same as the value of cluster center, its distance depends on the frequency of the categorical value in the cluster.

Cluster Modes

In k-modes clustering, the cluster centers are represented by the vectors of modes of categorical attributes. In statistics, the mode of a set of values is the most frequent occurring value. For example, the mode of set {*a*, *b*, *a*, *a*, *c*, *b*} is the most frequent value *a*. There can be more than one mode in a set of values. If a data set has m categorical attributes, the mode vector Z consists of m categorical values ($z_1, z_2, \ldots, z_m$), each being the mode of an attribute. The mode vector of a cluster minimizes the sum of the distances between each object in the cluster and the cluster center (Huang, 1998).

Clustering Process

To cluster a categorical data set $\boldsymbol{X}$ into k clusters, the k-modes clustering process consists of the following steps:

Step 1: Randomly select k unique objects as the initial cluster centers (modes).

Step 2: Calculate the distances between each object and the cluster mode; assign the object to the cluster whose center has the shortest distance to the object; repeat this step until all objects are assigned to clusters.

Step 3: Select a new mode for each cluster and compare it with the previous mode. If different, go back to Step 2; otherwise, stop.

This clustering process minimizes the following k-modes objective function

$$F(U,Z)=\sum_{l=1}^{k}\sum_{i=1}^{n}\sum_{j=1}^{m}u_{i,l}d(x_{i,j},z_{l,j})$$

where $U=[u_{i,j}]$ is an $n\times k$ partition matrix, $Z = \{Z_1, Z_2, \ldots, Z_k\}$ is a set of mode vectors and the distance function $d(.,.)$ is defined as either (2) or (3). Since it is essentially same as k-means, the k-modes clustering algorithm is efficient in clustering large categorical data and also produces locally minimal clustering results.

Fuzzy k-Modes and Other Variants

The fuzzy k-modes clustering algorithm is an extension to k-modes (Huang & Ng, 1999). Instead of assigning each object to one cluster, the fuzzy k-modes clustering algorithm calculates a cluster membership degree value for each object to each cluster. Similar to the fuzzy k-means, this is achieved by introducing the fuzziness factor in the objective function (Huang & Ng, 1999). The fuzzy k-modes clustering algorithm has found new applications in bioinformatics (Thornton-Wells, Moore, & Haines, 2006). It can improve the clustering result whenever the inherent clusters overlap in a data set.

The k-prototypes clustering algorithm combines k-means and k-modes to cluster data with mixed numeric and categorical values (Huang, 1997a). This is achieved

by defining a new distance function that combines both squared Euclidean distance and the simple matching dissimilarity measure as

$$d(X,Y) = \sum_{j=1}^{p}(x_j - y_j)^2 + \gamma \sum_{j=p+1}^{m}\delta(x_j, y_j) \qquad (5)$$

where the first term is the sum of the distances of the p numeric attributes and the second term is the sum of the distances of the (m-p) categorical attributes. Here, γ is a weighting factor to balance the importance of numeric and categorical attributes in the clustering result. In the clustering process, the means and the modes are used to represent the cluster centers for numeric and categorical attributes, respectively.

The W-k-means clustering algorithm was a recent extension that can automatically calculate the attribute weights in the clustering process (Huang, Ng, Rong, & Li, 2005). In W-k-means, a set of weights $V=\{v_1, v_2, \ldots, v_m\}$ is introduced to the objective function as

$$F(U,Z,V) = \sum_{l=1}^{k}\sum_{i}^{n}\sum_{j}^{m} u_{i,l} v_j^{\beta}\, d(x_{i,j}, z_{l,j}) \qquad (6)$$

where v_j is the weight for attribute j and

$$\sum_{j=1}^{m} v_j = 1.$$

β (>1) is a given factor. This function is minimized by the k-means clustering process with an additional step to calculate the attribute weights in each of iterations as

$$v_j = \begin{cases} 0 & \text{if } D_j = 0 \\ \dfrac{1}{\sum_{t=1}^{h}\left(\frac{D_j}{D_t}\right)^{\frac{1}{\beta-1}}} & \text{if } D_j \neq 0 \end{cases} \qquad (7)$$

where

$$D_j = \sum_{l=1}^{k}\sum_{i=1}^{n} u_{i,l} d(x_{i,j}, z_{l,j}) \qquad (8)$$

The weight of an attribute is inversely proportional to the dispersion of its values in the clusters. The less the dispersion is, the more important the attribute. Therefore, the weights can be used to select important attributes in cluster analysis.

FUTURE TRENDS

A simple Web survey with Google can reveal that a lot of k-modes related research is on-going in many organizations. The research directions can be summarized as follows:

1. Methods for selection of initial modes to generate better clustering results (Khan & Kant, 2007),
2. How to determine the number of clusters,
3. New distance functions to consider more factors such as the structure of the categorical attribute values,
4. Subspace clustering of categorical data (Jing, Ng, & Huang, 2007),
5. Clustering validation methods for categorical data, and
6. New application problems.

CONCLUSION

Over a decade development and applications, the k-modes clustering algorithm has become an important data mining technique for categorical data clustering. As the complexity of data and analysis increases in many application domains, further enhancements to the standard k-modes clustering algorithm will continue in the future and new variants will come out to tackle new problems such as automatic discovery of the number of clusters and subspace clustering of categorical data. The k-modes related techniques will continue finding new applications in broad application areas where categorical data is heavily involved. More commercial and research software will adopt the k-modes technique as its function for categorical data clustering.

KEY TERMS

Categorical Data: Data with values taken from a finite set of categories without orders.

Cluster Validation: Process to evaluate a clustering result to determine whether the "true" clusters inherent in the data are found.

Clustering: A process of grouping data objects into clusters according to some similarity measure.

Fuzzy k-Modes: A fuzzy version of k-modes to cluster categorical data.

k-Means: A partitional clustering technique that partitions data objects into *k* clusters by iteratively minimizing the sum of the within cluster dispersions.

k-Modes: A modification of k-means to cluster categorical data.

k-Prototypes: A combination of k-means and k-modes to cluster data with mixed numeric and categorical values.

W-k-Means: An extension to k-prototypes to enable automatic calculation of attribute weights in the clustering process for attribute selection.

Clustering Data in Peer-to-Peer Systems

Mei Li
Microsoft Corporation, USA

Wang-Chien Lee
Pennsylvania State University, USA

INTRODUCTION

With the advances in network communication, many large scale network systems have emerged. Peer-to-peer (P2P) systems, where a large number of nodes self-form into a dynamic information sharing system, are good examples. It is extremely valuable for many P2P applications, such as market analysis, scientific exploration, and smart query answering, to discover the knowledge hidden in this distributed data repository. In this chapter, we focus on clustering, one of the most important data mining tasks, in P2P systems. We outline the challenges and review the start-of-the-art in this area.

Clustering is a data mining technique to group a set of data objects into classes of similar data objects. Data objects within the same class are similar to each other, while data objects across classes are considered as dissimilar. Clustering has a wide range of applications, e.g., pattern recognition, spatial data analysis, custom/market analysis, document classification and access pattern discovery in WWW, etc.

Data mining community have been intensively studying clustering techniques for the last decade. As a result, various clustering algorithms have been proposed. Majority of these proposed algorithms is designed for traditional centralized systems where all data to be clustered resides in (or is transferred to) a central site. However, it is not desirable to transfer all the data from widely spread data sources to a centralized server for clustering in P2P systems. This is due to the following three reasons: 1) there is no central control in P2P systems; 2) transferring all data objects to a central site would incur excessive communication overheads, and 3) participants of P2P systems reside in a collaborating yet competing environment, and thus they may like to expose as little information as possible to other peers for various reasons. In addition, these existing algorithms are designed to minimize disk access cost. In P2P system, the communication cost is a dominating factor. Therefore, we need to reexamine the problem of clustering in P2P systems.

A general idea to perform clustering in P2P systems is to first cluster the local data objects at each peer and then combine the local clustering results to form a global clustering result. Based on this general idea, clustering in P2P systems essentially consists of two steps, i.e., *local clustering* and *cluster assembly*. While local clustering can be done by employing existing clustering techniques, cluster assembly is a nontrivial issue, which concerns *representation model* (what should be communicated among peers) and *communication model* (how peers communicate with each other).

In this chapter, we review three representation models (including two *approximate representation models* and an *exact representation model*) and three communication models (including *flooding-based communication model*, *centralized communication model*, and *hierarchical communication model*).

The rest of this chapter is organized as follows. In next section, we provide some background knowledge on P2P systems and clustering techniques. The details of representation models and communication models are presented in Section 3. We discuss future trend and draw the conclusion in Section 4 and Section 5, respectively.

BACKGROUND

P2P Systems

Different from traditional client-server computing model, P2P systems have no central control. Each participant (peer) has equal functionality in P2P systems. Peers are autonomous and can join and leave the system at any time, which makes the systems highly dynamic. In addition, the number of peers in P2P sys-

tems is normally very large (in the range of thousands or even millions).

P2P systems display the following two nice features. First, they do not have performance bottlenecks and single points of failure. Second, P2P systems incur low deployment cost and have excellent scalability. Therefore, P2P systems have become a popular media for sharing voluminous amount of information among millions of users.

Current works in P2P systems have been focusing on efficient search. As a result, various proposals have emerged. Depending on whether some structures are enforced in the systems, existing proposals can be classified into two groups: *unstructured overlays* and *structured overlays*.

Unstructured Overlays

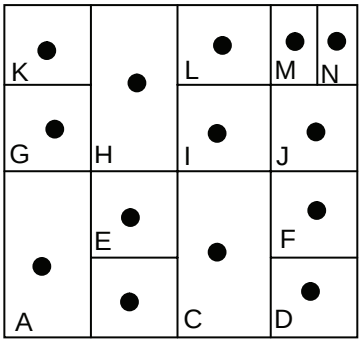
In unstructured overlays, a peer does not maintain any information about data objects stored at other peers, e.g., Gnutella. To search for a specific data object in unstructured overlays, the search message is flooded (with some constrains) to other peers in the system. While unstructured overlays are simple, they are not efficient in terms of search.

Structured Overlays

In structured overlays, e.g., CAN (Ratnasamy, 2001), CHORD (Stoica, 2001), SSW (Li, 2004), peers collaboratively maintain a distributed index structure, recording the location information of data objects shared in the system. Besides maintaining location information for some data objects, a peer also maintains a routing table with pointers pointing to a subset of peers in the system following some topology constraints. In the following, we give more details on one representative structured overlay, content addressable network (CAN).

Content Addressable Network (CAN): CAN organizes the logical data space as a *k*-dimensional Cartesian space and partitions the space into *zones*, each of which is taken charge of by a peer, called as *zone owner*. Data objects are mapped as points in the *k*-dimensional space, and the index of a data object is stored at the peer whose zone covers the corresponding point. In addition to indexing data objects, peers maintain routing tables, which consist of pointers pointing to neighboring subspaces along each dimension. Figure 1 shows one example of CAN, where data objects and peers are mapped to a 2-dimensional Cartesian space. The space is partitioned to 14 zones, and each has one peer as the zone owner.

Figure 1. Illustrative example of CAN



Clustering Algorithms

In the following, we first give a brief overview on existing clustering algorithms that are designed for centralized systems. We then provide more details on one representative density-based clustering algorithm, i.e., DBSCAN (Ester, 1996), since it is well studied in distributed environments. Nevertheless, the issues and solutions to be discussed are expected to be applicable to other clustering algorithms as well.

Overview

The existing clustering algorithms proposed for centralized systems can be classified into five classes: partition-based clustering, hierarchical clustering, grid-based clustering, density-based clustering, and model-based clustering. In the following, we provide a brief overview on these algorithms. Partition-based clustering algorithms (e.g., k-mean, MacQueen, 1967) partition *n* data objects into *k* partitions, which optimize some predefined objective function (e.g., sum of Euclidean distances to centroids). These algorithms iteratively reassign data objects to partitions and terminate when the objective function can not be improved further. Hierarchical clustering algorithms (Duda, 1973; Zhang, 1996) create a hierarchical decomposition of the data set, represented by a tree structure called dendrogram. Grid-based clustering algorithms (Agrawal, 1998; Sheikholeslami, 1998) divide the data

space into rectangular grid cells and then conduct some statistic analysis on these grid cells. Density-based clustering algorithms (Agrawal, 1998; Ankerst, 1999; Ester, 1996) cluster data objects in densely populated regions by expanding a cluster towards neighborhood with high density recursively. Model-based clustering algorithms (Cheeseman, 1996) fit the data objects to some mathematical models.

DBSCAN

The key idea of DBSCAN algorithm is that if the *r-neighborhood* of a data object (defined as the set of data objects that are within distance *r*) has a cardinality exceeding a preset threshold value *T*, this data object belongs to a cluster. In the following, we list some definition of terminologies for convenience of presentation.

Definition 1: (directly density-reachable) (Ester, 1996) An object *p* is directly density-reachable from an object *q* wrt. *r* and *T* in the set of objects *D* if

1. $p \in N_r(q)$ (where $N_r(q)$ is the subset of *D* contained in the *r*-neighborhood of *q*).
2. $N_r(q) \geq T$

Objects satisfying Property 2 in the above definition are called *core objects*. This property is called *core object property* accordingly. The objects in a cluster that are not core objects are called *border objects*. Different from noise objects that are not density-reachable from any other objects, border objects are density-reachable from some core object in the cluster.

The DBSCAN algorithm efficiently discovers clusters and noise in a dataset. According to Ester (1996), a cluster is uniquely determined by any of its core objects (Lemma 2 in Ester, 1996). Based on this fact, the DBSCAN algorithm starts from any arbitrary object *p* in the database *D* and obtains all data objects in *D* that are density-reachable from *p* through successive region queries. If *p* is a core object, the set of data objects obtained through successive region queries form a cluster in *D* containing *p*. On the other hand, if *p* is either a border object or noise object, the obtained set is empty and *p* is assigned to the noise. The above procedure is then invoked with next object in *D* that has not been examined before. This process continues till all data objects are examined.

MAIN FOCUS

In the following, we first discuss the challenging issues raised by clustering on P2P systems in Section 3.1. The solutions to these issues are then presented in Section 3.2 and 3.3.

Challenges for Clustering in P2P Systems

Clustering in P2P systems essentially consists of two steps:

- **Local clustering:** A peer (*i*) conducts clustering on its local data objects n_i.
- **Cluster assembly:** Peers collaboratively combine local clustering results to form a global clustering model.

After local clustering, some data objects form into *local clusters* while others become *local noise objects*. A local cluster is a cluster consisting of data objects that reside on one single peer. The local noise objects are data objects that are not included in any local cluster. Accordingly, we call the clusters obtained after cluster assembly as *global clusters*. A global cluster consists of one or more local clusters and/or some local noise objects.

While local clustering can adopt any existing clustering algorithm developed for centralized systems, cluster assembly is nontrivial in distributed environments. Cluster assembly algorithms in P2P systems need to overcome the following challenges:

1. **Communication efficient:** The large scale of the P2P systems and the vast amount of the data mandate the algorithm to be communication scalable in terms of the network size and data volume.
2. **Robust:** Peers might join/leave the systems or even fail at any time. Therefore, the algorithm should be sufficiently robust to accommodate these dynamic changes.
3. **Privacy Preserving:** The participants of P2P systems might come from different organizations, and they have their own interests and privacy concerns. Therefore, they would like to collaborate to obtain a global cluster result without exposing too much information to other peers from different organizations.

4. **Incremental:** The vast amount of information available in P2P systems and the dynamic change of this information repository mandate the clustering algorithm to be incremental. Any algorithms that require clustering from scratch would not be applicable in this dynamic environment.

All the above challenges concern the following two major issues:

- **Representation model:** What should be communicated among peers during cluster assembly, i.e., how the local clustering results and/or other information necessary for cluster assembly to be represented for communication among peers.
- **Communication model:** How peers communicate with each other during cluster assembly.

For completeness, in addition to reviewing solutions that are proposed for P2P systems, we also review solutions that are proposed for distributed systems. The difference between distributed systems and P2P systems is that distributed systems have much smaller scale, and a centralized server is normally present to perform certain coordination in distributed systems. If necessary, we explicitly point out the deficiency of the solutions proposed for distributed systems.

Representation Model

Ideally, a representation model should satisfy the following two criterions:

- The size of the representation model should be small.
- The model should accurately represent local clustering results and/or necessary information for cluster assembly.

In this section, we review three representation models, i.e., two approximate models based on core objects (Januzaj, 2004) and one exact model based on spatial boundary (Li, 2006). While core object based models tradeoff accuracy for compactness through approximation, spatial boundary based model leverages spatial properties to compactly represent necessary information for cluster assembly.

Approximate Representation Model: Core Object based Model

Januzaj (2004) proposed two models, i.e., Rep_{scor} and $\text{Rep}_{\text{k-means}}$, which approximate local clustering results using some representatives. Both of these two models are based on the concept of *specific core objects*. A set of specific core objects is defined as the set of core objects of a local cluster satisfying the following two conditions:

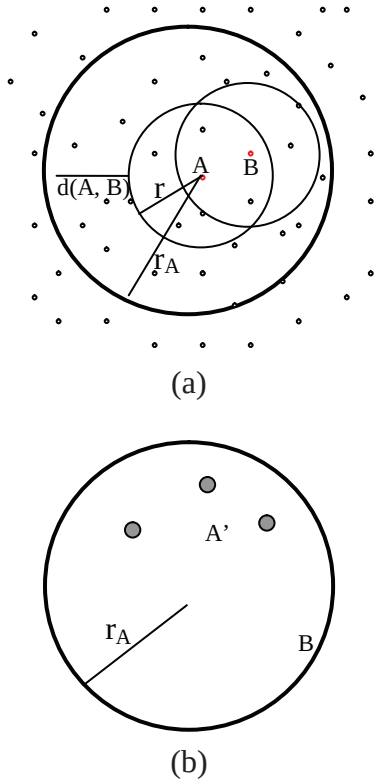
- Each data object in the local cluster is directly density reachable from one of the specific core objects.
- Any pair of specific objects is not directly density reachable from each other.

The set of specific core objects might not be unique, and which data objects are included in the set depends on the visiting order of data objects during clustering. For instance, in Figure 2(a), both *A* and *B* are core objects, and they are in each other's *r*-neighborhood. Assuming *A* is examined first during clustering process and it is included in the set of specific core objects, *B* will not be included in the set.

Rep_{scor}. Rep_{scor} represents each local cluster by a set of specific core data objects, which not only represent the data objects in its *r*-neighborhood, but also represent the data objects in the r-neightbood of the core data obects within its r-neighborhood.

$\text{Rep}_{\text{k-means}}$ Rep_{scor}can not always represent the data objects in a local cluster accurately. As shown in Figure 2(b), *A* is a specific core object. The combination of *A* and its *r*-range (A, r_A) represent the data objects in the *e*-neighborhood of *A* (i.e., *A* itself and the other 4 data objects depicted by grey circles). However, the five data objects are not uniformly distributed in the neighborhood. This motivates the proposal of another representation model, $\text{Rep}_{\text{k-means}}$, which represents a local cluster using the centroids obtained by k-mean clustering over the data objects of this local cluster. Figure 2(b) shows one example for $\text{Rep}_{\text{k-means}}$. After k-mean clustering, *A'* is obtained as the centroid to represent the data objects in the *r*-neighborhood of *A*. It is obvious that *A'* can better represent these data objects than *A* can.

Figure 2. An illustrative example of Rep_{scor} and $Rep_{k\text{-}means}$



Exact Representation Model: Spatial Boundary Based Model

When the peers and data objects are organized systematically as in structured overlays, not all local clustering results are necessary for cluster assembly. Instead, only the data objects residing along the zone boundary might affect clustering. This motivates Li (2006) to propose a spatial boundary based model, which represents the information necessary for cluster assembly in a compact format by leveraging the structures among peers and data objects in structured overlays.

We define the region inside Zone *i* that is within *r* to the boundary of Zone *i* as the *r-inner-boundary* of Zone *i*, and the region outside of Zone *i* that is within *r* to the boundary of Zone *i* as the *r-outer-boundary* of Zone *i*. Li (2006) has the following two observations about structured overlays, or more specifically CAN overlays:

- If a local cluster (within a zone) has no data object residing in the *r*-inner-boundary of the zone, this local cluster is *non-expandable*, i.e., it is a global cluster.
- If a local cluster within a zone can be expanded to other zones (i.e., this local cluster is *expandable*), there must exist some data objects belong to this local cluster in the *r*-inner-boundary of this zone, and the *r*-neighborhood of such data objects contains some data objects in the *r*-outer-boundary of this zone.

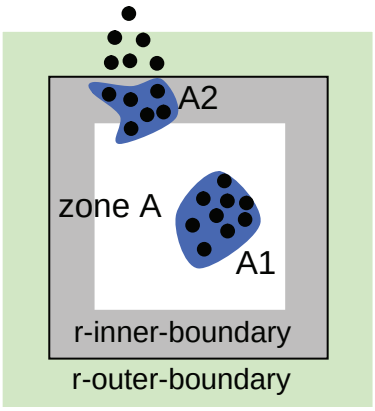
Figure 3 illustrates examples of an expandable cluster (*A2*) and a non-expendable cluster (*A1*) within Zone *A* (depicted by the rectangle).

Based on these observations, spatial boundary based model is represented by *cluster expansion set (CES)*, which consists of *present coverage (Pcoverage)* and *expandable coverage (Ecoverage)*, where Pcoverage includes the LocalClusterID (a tuple of <zoneID, clusterID>) for a local expandable cluster within the zone, and Ecoverage includes the zoneID and LocalClusterIDs for the local clusters or noise objects in the *r*-outer-boundary that this local cluster can be expanded to.

Communication Model

For completeness, we review three possible communication models, namely flooding-based communication model, centralized communication model, and hierarchical communication model. While the former two are proposed for distributed systems, the latter one is proposed for P2P systems.

Figure 3. Expandable and non-expandable clusters.



Flooding-Based Communication Model

In flooding-based communication model (e.g., Dhillon (1999) and Forman (2000)), each peer floods its local clustering result to all other peers. Eventually every peer has a global view of local clustering results on all peers and can form global clustering result individually. The disadvantage of flooding-based communication model is the excessive communication overheads incurred by multiple rounds of message flooding.

Centralized Communication Model

In centralized communication model (e.g., Januzaj (2004), Johnson (1999), Samatova (2002) and Xu (1999)), each peer forwards its local clustering result to a designated central site. This central site combines the local clustering results to form global clustering result. Although centralized communication model is simple, it requires a designated server.

Hierarchical Communication Model

Motivated by the above deficiencies of flooding-based communication model and centralized communication model, Li (2006) proposed a hierarchical communication model for cluster assembly. This hierarchical communication model does not require a central site, nor does it require system-wide flooding. By leveraging CAN overlay (where data objects are mapped to zones), this hierarchical communication model enables peers to assemble local clusters within smaller regions, which are then recursively assembled to form global clusters. The proposed hierarchical communication model does not impose high processing load at the root or nodes at the high levels of the hierarchy.

FUTURE TRENDS

The new challenges and opportunities raised by data mining over the newly emerged networked systems will attract a rich body of interdisciplinary studies from data mining and networking communities. While various data mining tasks will have specific issues of their own to address, performing the localized data mining and assembly of local mining results in an integrated manner is an important research issue to address and certainly needs more research effort from both research communities. We anticipate a growing number of studies on developing new techniques for addressing these issues.

CONCLUSION

The emergence of networked data sources (e.g., P2P systems, sensor networks) brings new challenges and opportunities for data mining. The large scale and high dynamics of P2P systems mandate the data mining algorithms designed for such systems to be communication efficient, robust, privacy preserving, and incremental.

In this chapter, we investigate clustering issue, one of the important data mining tasks, in P2P systems. We identify two important issues, i.e., representation model and communication model, raised by clustering in P2P systems, and review the start-of-the-art solutions in the literature to address these two issues.

KEY TERMS

Cluster Assembly: The process of assembling local cluster results into global cluster results.

Clustering: One of the most important data mining tasks. Clustering is to group a set of data objects into classes consisting of similar data objects.

Data Mining: The process of extracting previous unknown and potentially valuable knowledge from a large set of data.

Density-based Clustering: An representative clustering technique that treats densely populated regions separated by sparsely populated regions as clusters.

Overlay Networks: A computer network built on top of other networks, where the overlay nodes are connected by logical links corresponding to several physical links in the underlying physical networks. Peer-to-peer systems are one example of overlay networks.

Peer-To-Peer Systems: A system consisting of a large number of computer nodes, which have relatively equal responsibility.

P2P Data Mining: The process of data mining in peer-to-peer systems.

Clustering of Time Series Data

Anne Denton
North Dakota State University, USA

INTRODUCTION

Time series data is of interest to most science and engineering disciplines and analysis techniques have been developed for hundreds of years. There have, however, in recent years been new developments in data mining techniques, such as frequent pattern mining, that take a different perspective of data. Traditional techniques were not meant for such pattern-oriented approaches. There is, as a result, a significant need for research that extends traditional time-series analysis, in particular clustering, to the requirements of the new data mining algorithms.

BACKGROUND

Time series clustering is an important component in the application of data mining techniques to time series data (Roddick, Spiliopoulou, 2002) and is founded on the following research areas:

- **Data Mining:** Besides the traditional topics of classification and clustering, data mining addresses new goals, such as frequent pattern mining, association rule mining, outlier analysis, and data exploration (Tan, Steinbach, and Kumar 2006).
- **Time Series Data:** Traditional goals include forecasting, trend analysis, pattern recognition, filter design, compression, Fourier analysis, and chaotic time series analysis. More recently frequent pattern techniques, indexing, clustering, classification, and outlier analysis have gained in importance.
- **Clustering:** Data partitioning techniques such as k-means have the goal of identifying objects that are representative of the entire data set. Density-based clustering techniques rather focus on a description of clusters, and some algorithms identify the most common object. Hierarchical techniques define clusters at multiple levels of granularity. A survey of clustering that includes its application to time series data is provided in (Gan, Ma, and Wu, 2007).
- **Data Streams:** Many applications, such as communication networks, produce a stream of data (Muthukrishnan, 2003). For real-valued attributes such a stream is amenable to time series data mining techniques.

Time series clustering draws from all of these areas. It builds on a wide range of clustering techniques that have been developed for other data, and adapts them while critically assessing their limitations in the time series setting.

MAIN THRUST OF THE CHAPTER

Many specialized tasks have been defined on time series data. This chapter addresses one of the most universal data mining tasks, clustering, and highlights the special aspects of applying clustering to time series data. Clustering techniques overlap with frequent pattern mining techniques, since both try to identify typical representatives.

Clustering Time Series

Clustering of any kind of data requires the definition of a similarity or distance measure. A time series of length n can be viewed as a vector in an n-dimensional vector space. One of the best-known distance measures, Euclidean distance, is frequently used in time series clustering. The Euclidean distance measure is a special case of an L_p norm. L_p norms may fail to capture similarity well when being applied to raw time series data because differences in the average value and average derivative affect the total distance. The problem is typically addressed by subtracting the mean and dividing the resulting vector by its L_2 norm, or by working with normalized derivatives of the data

(Gavrilov et al., 2000). Several specialized distance measures have been used for time series clustering, such as dynamic time warping, DTW (Berndt and Clifford 1996), longest common subsequence similarity, LCSS (Vlachos, Gunopulos, and Kollios, 2002), and a distance measure based on well-separated geometric sets (Bollabas, Das, Gunopulos, and Mannila 1997).

Some special time series are of interest. A strict white noise time series is a real-valued sequence with values $X_t = e_t$ where e_t is Gaussian distributed random variable. A random walk time series satisfies $X_t - X_{t-1} = e_t$ where e_t is defined as before.

Time series clustering can be performed on whole sequences or on subsequences. For clustering of whole sequences, high dimensionality is often a problem. Dimensionality reduction may be achieved through Discrete Fourier Transform (DFT), Discrete Wavelet Transform (DWT), and Principal Component Analysis (PCA), as some of the most commonly used techniques. DFT (Agrawal, Falutsos, and Swami, 1993) and DWT have the goal of eliminating high-frequency components that are typically due to noise. Specialized models have been introduced that ignore some information in a targeted way (Jin, Lu, and Shi 2002). Others are based on models for specific data such as socioeconomic data (Kalpakis, Gada, and Puttagunta, 2001).

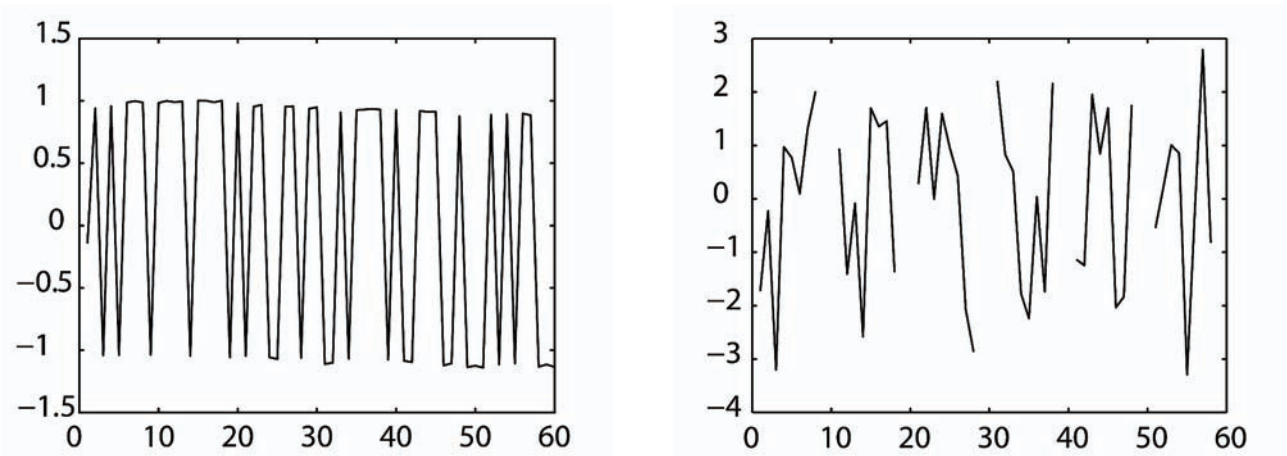
A large number of clustering techniques have been developed, and for a variety of purposes (Halkidi, Batistakis, and Vazirgiannis, 2001). Partition-based techniques are among the most commonly used ones for time series data. The k-means algorithm, which is based on a greedy search, has recently been generalized to a wide range of distance measures (Banerjee et al., 2004).

Clustering Subsequences of a Time Series

A variety of data mining tasks require clustering of subsequences of one or more time series as preprocessing step, such as Association Rule Mining (Das et al., 1998), outlier analysis and classification. Partition-based clustering techniques have been used for this purpose in analogy to vector quantization (Gersho and Gray, 1992) that has been developed for signal compression. It has, however, been shown that when a large number of subsequences are clustered, the resulting cluster centers are very similar for different time series (Keogh, Lin, and Truppel, 2003). Figure 1 illustrates how k-means clustering may find cluster centers that do not represent any part of the actual time series. Note how the short sequences in the right panel (cluster centers) show patterns that do not occur in the time series (left panel) which only has two possible values. A mathematical derivation why cluster centers in k-means are expected to be sinusoidal in certain limits has been provided for k-means clustering (Ide, 2006).

Several solutions have been proposed, which address different properties of time series subsequence data, including trivial matches that were observed in

Figure 1. Time series glassfurnace (left) and six cluster centers that result from k-means clustering with k=6 and window size w=8.



(Keogh, Lin, and Truppel, 2003), the relationship to dynamical systems (Chen, 2005), and the frequently occurring similarity to random walk noise (Denton, 2005). One approach is based on adapting density-based clustering techniques (Hinneburg and Keim, 2003) which are robust to noise, to time series data (Denton, 2004) and (Denton, 2005). Partition-based techniques aim at finding representatives for all objects. Cluster centers in kernel-density-based clustering, in contrast, are sequences that are in the vicinity of the largest number of similar objects. The goal of kernel-density-based techniques is thereby similar to frequent-pattern mining techniques such as Motif-finding algorithms (Patel et al., 2002). The concept of cluster cores (Peker, 2005) also captures the idea of identifying representative sequences, and the work furthermore suggests that using a large number of clusters can alleviate problems in time series subsequence data, in domains where that is an acceptable result. Other solutions exist, such as ones based on techniques that were developed for dynamical systems (Chen, 2005). These techniques work well for time series, in which patterns occur at regular intervals. Pattern mining concepts have also been successfully applied to time series subsequence clustering (Fu, Chung, Luk, and Ng, 2005) and an unfolding preprocessing method has been developed (Simon, Lee, and Verleysen, 2006). Finally the problem has been discussed from the perspective of distinguishing entire clusterings (Goldin, Mardales, and Nagy, 2006).

Related Problems

One time series clustering problem of particular practical relevance is clustering of gene expression data (Eisen, Spellman, Brown, and Botstein, 1998). Gene expression is typically measured at several points in time (time course experiment) that may not be equally spaced. Hierarchical clustering techniques are commonly used. Density-based clustering has recently been applied to this problem (Jiang, Pei, and Zhang, 2003)

Time series with categorical data constitute a further related topic. Examples are log files and sequences of operating system commands. Some clustering algorithms in this setting borrow from frequent sequence mining algorithms (Vaarandi, 2003).

Mining of data streams is also closely related. Common applications are computer network traffic, sensor networks, and web logs (Gaber, Zaslavsky, and Krishnaswamy, 2005).

FUTURE TRENDS

Storage grows exponentially at rates faster than Moore's law for microprocessors. A natural consequence is that old data will be kept when new data arrives leading to a massive increase in the availability of the time-dependent data. Data mining techniques will increasingly have to consider the time dimension as an integral part of other techniques. Much of the current effort in the data mining community is directed at data that has a more complex structure than the simple tabular format initially covered in machine learning (Džeroski and Lavrač, 2001). Examples, besides time series data, include data in relational form, such as graph- and tree-structured data, and sequences. A major step towards integrating diverse data into a combined data mining framework consists in finding symbolic representations for different types of data. Time series subsequence clustering constitutes one such approach towards defining a mapping to a symbolic representation (Das et al., 1998). When addressing new settings it will be of major importance to not only generalize existing techniques and make them more broadly applicable but to also critically assess problems that may appear in the generalization process.

CONCLUSION

Despite the maturity of both clustering and time series analysis, time series clustering is an active and fascinating research topic. New data mining applications are constantly being developed and require new types of clustering results. Clustering techniques from different areas of data mining have to be adapted to the time series context. Noise is a particularly serious problem for time series data, thereby adding challenges to clustering process. Considering the general importance of time series data, it can be expected that time series clustering will remain an active topic for years to come.

KEY TERMS

Dynamic Time Warping (DTW): Sequences are allowed to be extended by repeating individual time series elements, such as replacing the sequence X={x1,x2,x3} by X'={x1,x2,x2,x3}. The distance between two sequences under dynamic time warping is the minimum distance that can be achieved in by extending both sequences independently.

Kernel-Density Estimation (KDE): Consider the vector space in which the data points are embedded. The influence of each data point is modeled through a kernel function. The total density is calculated as the sum of kernel functions for each data point.

Longest Common Subsequence Similarity (LCSS): Sequences are compared based on the assumption that elements may be dropped. For example, a sequence X={x1,x2,x3} may be replaced by X"={x1,x3}. Similarity between two time series is calculated as the maximum number of matching time series elements that can be achieved if elements are dropped independently from both sequences. Matches in real-valued data are defined as lying within some predefined tolerance.

Partition-Based Clustering: The data set is partitioned into k clusters, and cluster centers are defined based on the elements of each cluster. An objective function is defined that measures the quality of clustering based on the distance of all data points to the center of the cluster to which they belong. The objective function is minimized.

Principle Component Analysis (PCA): The projection of the data set to a hyper plane that preserves the maximum amount of variation. Mathematically PCA is equivalent to singular value decomposition on the covariance matrix of the data.

Random Walk: A sequence of random steps in an n-dimensional space, where each step is of fixed or randomly chosen length. In a random walk time series, time is advanced for each step and the time series element is derived using the prescription of a 1-dimensional random walk of randomly chosen step length.

Sliding Window: A time series of length n has $(n-w+1)$ subsequences of length w. An algorithm that operates on all subsequences sequentially is referred to as a sliding window algorithm.

Time Series: Sequence of real numbers, collected at equally spaced points in time. Each number corresponds to the value of an observed quantity.

Vector Quantization: A signal compression technique in which an n-dimensional space is mapped to a finite set of vectors. Each vector is called a codeword and the collection of all codewords a codebook. The codebook is typically designed using Linde-Buzo-Gray (LBG) quantization, which is very similar to k-means clustering.

On Clustering Techniques

Sheng Ma

School of Computer Science, Florida International University, USA

INTRODUCTION

Clustering data into sensible groupings, as a fundamental and effective tool for efficient data organization, summarization, understanding and learning, has been the subject of active research in several fields such as statistics (Jain & Dubes, 1988; Hartigan, 1975), machine learning (Dempster, Laird & Rubin, 1977), Information theory (Linde, Buzo & Gray, 1980), databases (Guha, Rastogi & Shim, 1998; Zhang, Ramakrishnan & Livny, 1996) and Bioinformatics (Cheng & Church, 2000) from various perspectives and with various approaches and focuses. From application perspective, clustering techniques have been employed in a wide variety of applications such as customer segregation, hierarchal document organization, image segmentation, microarray data analysis and psychology experiments.

Intuitively, the clustering problem can be described as follows: Let $\boldsymbol{W}$ be a set of n entities, finding a partition of $\boldsymbol{W}$ into groups such that the entities within each group are **similar** to each other while entities belonging to different groups are **dissimilar**. The entities are usually described by a set of measurements (attributes). Clustering does not use category information that labels the objects with prior identifiers. The absence of label information distinguishes cluster analysis from classification and indicates that the goals of clustering is just finding a hidden structure or compact representation of data instead of discriminating future data into categories.

BACKGROUND

Generally clustering problems are determined by five basic components:

- **Data representation:** What's the (physical) representation of the given data set? What kind of attributes (e.g., numerical, categorical or ordinal)?
- **Data generation:** The formal model for describing the generation of the data set. For example, Gaussian mixture model is a model for data generation.
- **Criterion/objective function:** What are the objective functions or criteria that the clustering solutions should aim to optimize? Typical examples include entropy, maximum likelihood and within-class or between-class distance (Li, Ma & Ogihara, 2004a).
- **Optimization procedure:** What is the optimization procedure for finding the solutions? Clustering problem is known to be NP-complete (Brucker, 1977) and many approximation procedures have been developed. For instance, Expectation-Maximization (EM) type algorithms have been widely used to find local minima of optimization.
- **Cluster validation and interpretation**: Cluster validation evaluates the clustering results and judges the cluster structures. Interpretation is often necessary for applications. Since there is no label information, clusters are sometimes justifies by ad hoc methods (such as exploratory analysis) based on specific application areas.

For a given clustering problem, the five components are tightly coupled. The formal model is induced from the physical representation of the data, the formal model along with the objective function determines the clustering capability and the optimization procedure decides how efficiently and effectively the clustering results can be obtained. The choice of the optimization procedure depends on the first three components. Validation of cluster structures is a way of verifying assumptions on data generation and evaluating the optimization procedure.

MAIN THRUST

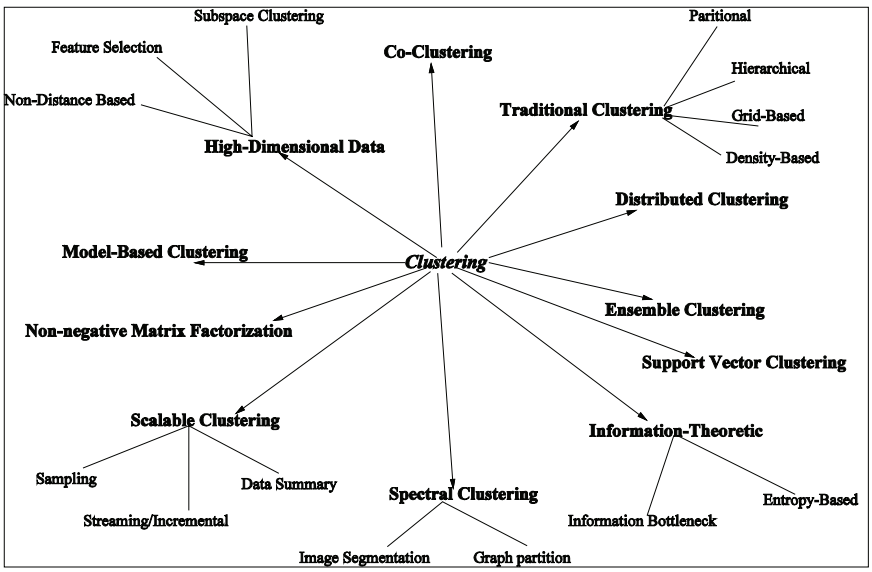
We review some of current clustering techniques in the section. Figure 1 gives the summary of clustering techniques. The following further discusses traditional clustering techniques, spectral based analysis, model-based clustering and co-clustering.

Traditional clustering techniques focus on one-sided clustering and they can be classified into partitional, hierarchical, density-based, and grid-based (Han & Kamber, 2000). Partitional clustering attempts to directly decompose the data set into disjoint classes such that the data points in a class are nearer to one another than the data points in other classes. Hierarchical clustering proceeds successively by building a tree of clusters. Density-based clustering is to group the neighboring points of a data set into classes based on density conditions. Grid-based clustering quantizes the data space into a finite number of cells that form a grid-structure and then performs clustering on the grid structure. Most of these algorithms use distance functions as objective criteria and are not effective in high dimensional spaces.

As an example, we take a closer look at K-means algorithms. The typical K-means type algorithm is a widely-used partitional-based clustering approach. Basically, it first chooses a set of K data points as initial cluster representatives (e.g., centers), and then performs an iterative process that alternates between assigning the data points to clusters based on their distances to the cluster representatives and updating the cluster representatives based on new cluster assignments. The iterative optimization procedure of K-means algorithm is a special form of EM-type procedure. The K-means type algorithm treats each attribute equally and computes the distances between data points and cluster representatives to determine cluster memberships.

A lot of algorithms have been developed recently to address the efficiency and performance issues presented in traditional clustering algorithms. Spectral analysis has been shown to tightly relate to clustering task. Spectral clustering (Weiss, 1999; Ng, Jordan & Weiss, 2001), closely related to the latent semantics index (LSI), uses selected eigenvectors of the data affinity matrix to obtain a data representation that can be easily clustered or embedded in a low-dimensional space. Model-based clustering attempts to learn generative models, by which the cluster structure is determined, from the data. (Tishby, Pereira & Bialek, 1999; Slonim & Tishby, 2000) develop information bottleneck formulation, in which given the empirical joint distribution of two variables, one variable is compressed so that the mutual information about the other is preserved as much as possible. Other recent developments of clustering techniques include ensemble clustering, support vector clustering, matrix factorization, high-dimensional data clustering, distributed clustering and etc.

Figure 1. Summary of clustering techniques



Another interesting development is co-clustering that conducts simultaneous, iterative clustering of both data points and their attributes (features) through utilizing the canonical duality contained in the point-by-attribute data representation. The idea of co-clustering of data points and attributes dates back to (Anderberg, 1973; Nishisato, 1980). Govaert (1985) researches simultaneous block clustering of the rows and columns of contingency table. The idea of co-clustering has been also applied to cluster gene expression and experiments (Cheng & Church, 2000). Dhillon (2001) presents a co-clustering algorithm for documents and words using bipartite graph formulation and a spectral heuristic. Recently Dhillon et al. (2003) propose an information-theoretic co-clustering method for two-dimensional contingency table. By viewing the non-negative contingency table as a joint probability distribution between two discrete random variables, the optimal co-clustering then maximizes the mutual information between the clustered random variables. Li and Ma (2004) recently develop Iterative Feature and Data clustering (IFD) by representing the data generation with data and feature coefficients. IFD enables an iterative co-clustering procedure for both data and feature assignments. However, unlike previous co-clustering approaches, IFD performs clustering using the mutually reinforcing optimization procedure that has proven convergence property. IFD only handles data with binary feature. Li, Ma and Ogihara (2004b) further extend the idea for general data.

FUTURE TRENDS

Although clustering has been studied for many years, many issues such as cluster validation still need more investigation. In addition, new challenges such as scalability, high-dimensionality and complex data types, have been brought by the ever-increasing growth of information exposure and data collection.

- **Scalability and efficiency:** With the collection of huge amount of data, clustering faces the problems of scalability in terms of both computation time and memory requirements. To resolve the scalability issues, methods such as incremental and streaming approaches, sufficient statistics for data summary and sampling techniques have been developed.
- **Curse of dimensionality**: Another challenge is the high dimensionality of data. It has been shown that in a high dimensional space, the distance between every pair of points is almost the same for a wide variety of data distributions and distance functions (Beyer et al., 1999). Hence most algorithms do not work efficiently in high dimensional spaces due to the **curse of dimensionality**. Many feature selection techniques have been applied to reduce the dimensionality of the space. However, as demonstrated in (Aggarwal et al., 1999), in many case, the correlations among the dimensions are often specific to data locality; in other words, some data points are correlated with a given set of features and others are correlated with respect to different features. As pointed out in (Hastie, Tibshirani & Friedman, 2001; Domeniconi, Gunopulos & Ma, 2004), all methods that overcome the dimensionality problems use a metric for measuring neighborhoods, which is often implicit and/or adaptive.
- **Complex data types:** The problem of clustering becomes more challenging when the data contains complex types. For example, when the attributes contain both categorical and numerical values. There are no inherent distance measures between data values. This is often the case in many applications where data are described by a set of descriptive or presence/absence attributes, many of which are not numerical. The presence of complex types also makes the cluster validation and interpretation difficult.

More challenges also include clustering with multiple criteria (where clustering problems often require optimization over more than one criterion), clustering relation data (where data is represented with multiple relation tables) and distributed clustering (where data sets are geographically distributed across multiple sites).

CONCLUSION

Clustering is a classical topic to segment and group similar data objects. Many algorithms have been developed in the past. Looking ahead, many challenges drawn from real-word applications will drive the search for efficient algorithms that are able to handle hetero-

geneous data, to process a large volume, and to scale to deal with a large number of dimensions.

KEY TERMS

Cluster: A cluster is the set of entities that are *similar* between themselves and *dissimilar* to entities from other clusters.

Clustering: Clustering is the process of dividing the data into clusters.

Cluster Validation: Cluster validation evaluates the clustering results and judges the cluster structures

Co-clustering: Co-clustering performs simultaneous clustering of both points and their attributes by way of utilizing the canonical duality contained in the point-by-attribute data representation.

C**urse of Dimensionality:** The expression ``curse of dimensionality'' is due to Bellman and in statistics it relates to the fact that the convergence of any estimator to the true value of a smooth function defined on a space of high dimension is very slow. It has been used in various scenarios to refer to the fact that the complexity of learning grows significantly with the dimensions.

Spectral Clustering: Spectral clustering is the collection of techniques that perform clustering tasks using eigenvectors of matrices derived from the data.

Subspace Clustering: Subspace clustering is an extension of traditional clustering techniques that seeks to find clusters in different subspaces within a given dataset.

Comparing Four-Selected Data Mining Software

C

Richard S. Segall
Arkansas State University, USA

Qingyu Zhang
Arkansas State University, USA

INTRODUCTION

This chapter discusses four-selected software for data mining that are not available as free open-source software. The four-selected software for data mining are SAS® Enterprise Miner™, Megaputer PolyAnalyst® 5.0, NeuralWare Predict® and BioDiscovery GeneSight®, each of which was provided by partnerships with our university. These software are described and compared by their existing features, characteristics, and algorithms and also applied to a large database of forest cover types with 63,377 rows and 54 attributes. Background on related literature and software are also presented. Screen shots of each of the four-selected software are presented, as are future directions and conclusions.

BACKGROUND

Historical Background

Han and Kamber (2006), Kleinberg and Tardos (2005), and Fayyad et al. (1996) each provide extensive discussions of available algorithms for data mining.

Algorithms according to StatSoft (2006b) are operations or procedures that will produce a particular outcome with a completely defined set of steps or operations. This is opposed to heuristics that according to StatSoft (2006c) are general recommendations or guides based upon theoretical reasoning or statistical evidence such as "data mining can be a useful tool if used appropriately."

The Data Intelligence Group (1995) defined data mining as the extraction of hidden predictive information form large databases. According to The Data Intelligence Group (1995), "data mining tools scour databases for hidden patterns, finding predictive information that experts may miss because it lies outside their expectations."

Brooks (1997) describes rules-based tools as opposed to algorithms. Witten and Frank (2005) describe how data mining algorithms work including covering algorithms, instance-based learning, and how to use the WEKA, an open source data mining software that is a machine learning workbench.

Segall (2006) presented a chapter in the previous edition of this Encyclopedia that discussed microarray databases for biotechnology that included a extensive background on microarray databases such as that defined by Schena (2003), who described a microarray as "an ordered array of microscopic elements in a planar substrate that allows the specific binding of genes or gene products." The reader is referred to Segall (2006) for a more complete discussion on microarray databases including a figure on the overview of the microarray construction process.

Piatetsky-Shapiro (2003) discussed the challenges of data mining specific to microarrays, while Grossman et al. (1998) reported about three NSF (National Science Foundation) workshops on mining large massive and distributed data, and Kargupta at al. (2005) discussed the generalities of the opportunities and challenges of data mining.

Segall and Zhang (2004, 2005) presented funded proposals for the premises of proposed research on applications of modern heuristics and data mining techniques in knowledge discovery whose results are presented as in Segall and Zhang (2006a, 2006b) in addition to this chapter.

Software Background

There is a wealth of software today for data mining such as presented in American Association for Artificial Intelligence (AAAI) (2002) and Ducatelle (2006) for teaching data mining, Nisbet (2006) for CRM (Customer Relationship Management) and software review of Deshmukah (1997). StatSoft (2006a) presents screen shots of several softwares that are used for exploratory data analysis (EDA) and various data mining techniques. Proxeon Bioinformatics (2006) manufactures bioinformatics software for proteomics the study of protein and sequence information.

Lazarevic et al. (2006) discussed a software system for spatial data analysis and modeling. Leung (2004) compares microarray data mining software.

National Center for Biotechnology Information (NCBI) (2006) provides tools for data mining including those specifically for each of the following categories of nucleotide sequence analysis, protein sequence analysis and proteomics, genome analysis, and gene expression. Lawrence Livermore National Laboratory (LLNL) (2005) describes their Center for Applied Scientific Computing (CASC) that is developing computational tools and techniques to help automate the exploration and analysis of large scientific data sets.

MAIN THRUST

Algorithms of Four-Selected Software

This chapter specifically discusses four-selected data mining software that were chosen because these software vendors have generously offered their services and software to the authors at academic rates or less for use in both the classroom and in support of the two faculty summer research grants awarded as Segall and Zhang (2004, 2005).

SAS Enterprise Miner™ is a product of SAS Institute Inc. of Cary, NC and is based on the SEMMA approach that is the process of Sampling (S), Exploring (E), Modifying (M), Modeling (M), and Assessing (A) large amounts of data. SAS Enterprise Miner™ utilizes

a workspace with a drop-and-drag of icons approach to constructing data mining models.

SAS Enterprise Miner™ utilizes algorithms for decision trees, regression, neural networks, cluster analysis, and association and sequence analysis.

PolyAnalyst® 5 is a product of Megaputer Intelligence, Inc. of Bloomington, IN and contains sixteen (16) advanced knowledge discovery algorithms as described in Table 1 that was constructed using its User Manual by Megaputer Intelligence Inc. (2004; p. 163, p. 167, p.173, p.177, p. 186, p.196, p.201, p.207, p. 214, p. 221, p.226, p. 231, p. 235, p. 240, p.263, p. 274.).

NeuralWorks Predict® is a product of NeuralWare of Carnegie, PA. This software relies on neural networks, According to NeuralWare (2003, p.1):

"One of the many features that distinguishes Predict® from other empirical modeling and neural computing tools is that is automates much of the painstaking and time-consuming process of selecting and transforming the data needed to build a neural network."

NeuralWorks Predict® has a direct interface with Microsoft Excel that allows display and execution of the Predict® commands as a drop-down column within Microsoft Excel.

GeneSight™ is a product of BioDiscovery, Inc. of El Segundo, CA that focuses on cluster analysis using two main techniques of hierarchical and partitioning both of which are discussed in Prakash and Hoff (2002) for data mining of microarray gene expressions.

Both SAS Enterprise Miner™ and PolyAnalyst® 5 offer more algorithms than either GeneSight™ or NeuralWorks Predict®. These two software have algorithms for statistical analysis, neural networks, decision trees, regression analysis, cluster analysis, self-organized maps (SOM), association (e.g. market-basket) and sequence analysis, and link analysis. GeneSight™ offers mainly cluster analysis and NeuralWorks Predict® offers mainly neural network applications using statistical analysis and prediction to support these data mining results. PolyAnalyst® 5 is the only software of these that provides link analysis algorithms for both numerical and text data.

Applications of the Four-Selected Software to Large Database

Each of the four-selected software have been applied to a large database of forest cover type that is available on the same website of the Machine Learning Repository at the University of California at Irvine by Newman et al. (1998) for which results are shown in Segall and Zhang (2006a, 2006b) for different datasets of numerical abalone fish data and discrete nominal-valued mushroom data.

The forest cover type's database consists of 63,377 records each with 54 attributes that can be used to as inputs to predictive models to support decision-making processes of natural resource managers. The 54 columns of data are composed of 10 quantitative variables, 4 binary variables for wilderness areas, and 40 binary variables of soil types. The forest cover type's classes include Spruce-Fir, Lodgepole Pine, Ponderosa Pine, Cottonwood/Willow, Aspen, Douglas-Fir, Krummholz, and other.

The workspace of SAS Enterprise Miner™ is different than the other software because it uses icons that are user-friendly instead of only using spreadsheets of data. The workspace in SAS Enterprise Miner™ is constructed by using a drag-and-drop process from the icons on the toolbar which again the other software discussed do not utilize.

Figure 1 shows a screen shot of cluster analysis for the forest cover type data using

SAS Enterprise Miner™. From Figure 1 it can be seen using a slice with a standard deviation measurement, height of frequency, and color of the radius that this would yield only two distinct clusters: one with normalized mean of 0 and one with normalized mean of 1. If different measure of measurement, different slice height, and different key for color were selected than a different cluster figure would have resulted.

A screen shot of PolyAnalyst® 5.0 showing the input data of the forest cover type data with attribute columns of elevation, aspect, scope, horizontal distance to hydrology, vertical distance to hydrology, horizontal distance to roadways, hillshade 9AM, hillshade Noon, etc. PolyAnalyst® 5.0 yielded a classification probability of 80.19% for the forest cover type database.

Figure 2 shows the six significant classes of clusters corresponding to the six major cover types: Spruce-Fir, Lodgepole Pine, Ponderosa Pine, Cottonwood/Willow, Aspen, and Douglas-Fir. One of the results that can be seen from Figure 2 is that the most significant cluster for the aspect variable is the cover type of Douglas-Fir.

NeuralWare Predict® uses a Microsoft Excel spreadsheet interface for all of its input data and many of its outputs of computational results. Our research using NeuralWare Predict® for the forest type cover

Figure 1. SAS Enterprise Miner™ screen shot of cluster analysis

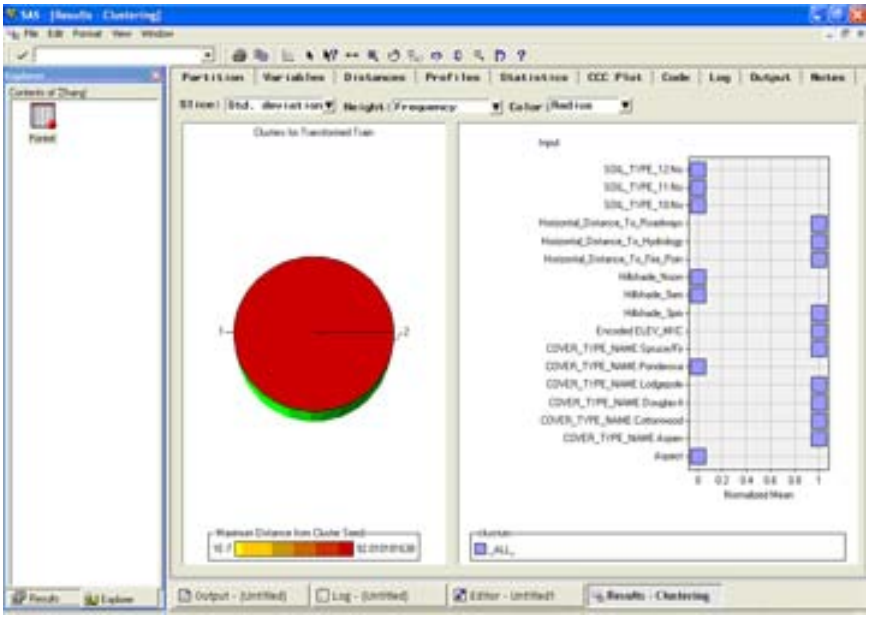

Figure 2. PolyAnalyst® 5.0 screen shot of cluster analysis

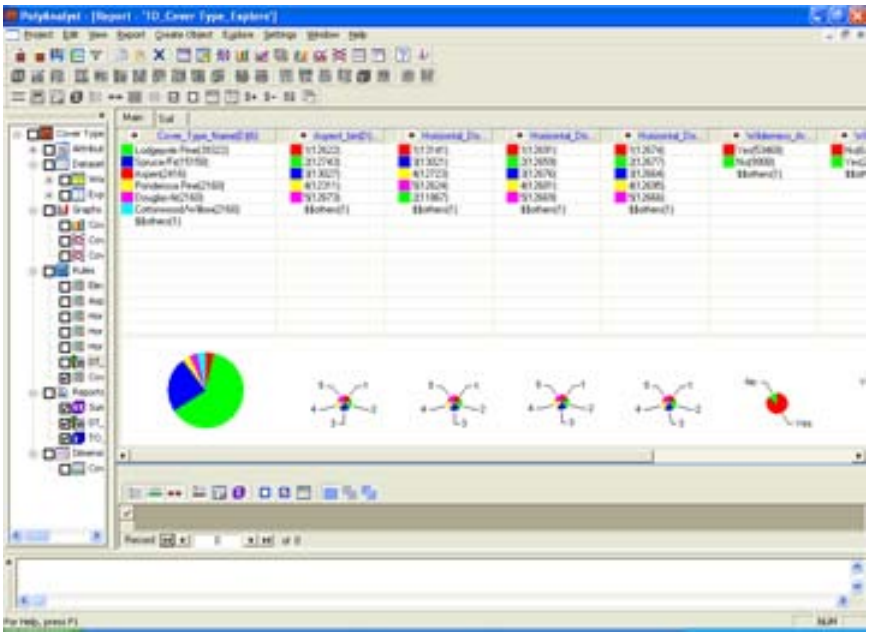

data indicates an accuracy of 70.6% with 70% of the sample for training and 30% of the sample for test in 2 minutes and 26 seconds of execution time.

Figure 3 is a screen shot of NeuralWare Predict® for the forest type cover data that indicates that an improved accuracy of 79.2% can be obtained using 100% of the 63,376 records for both training and testing in 3 minutes 21 seconds of execution time in evaluating model. This was done to investigate what could be the maximum accuracy that could be obtained

using NeuralWare Predict® for the same forest cover type database for comparison purposes to the other selected software.

Figure 4 is a screen shot using GeneSight® software by BioDiscovery Incorporated. That shows hierarchical clustering using the forest cover data set. As noted earlier, GeneSight® only performs statistical analysis and cluster analysis and hence no regression results for the forest cover data set can be compared with those of NeuralWare® Predict and PolyAnalyst®. It should be noted that from Figure 4 that the hierarchical clustering performed by GeneSight® for the forest cover type data set produced a multitude of clusters using the Euclidean distance metric.

FUTURE TRENDS

These four-selected software as described will be applied to a database that already has been collected of a different dimensionality. The database that has been presented in this chapter is of a forest cover type data set with 63,377 records and 54 attributes. The other database is a microarray database at the genetic level for a human lung type of cancer consisting of 12,600 records and 156 columns of gene types. Future simulations are to be performed for the human lung cancer data for each of the four-selected data mining software with their respective available algorithms and compared versus those obtained respectively for the larger database of 63,377 records and 54 attributes of the forest cover type.

CONCLUSION

The conclusions of this research include the fact that each of the software selected for this research has its own unique characteristics and properties that can be displayed when applied to the forest cover type database. As indicated, each software has it own set of algorithm types to which it can be applied. NeuralWare Predict® focuses on neural network algorithms, and Biodiscovery GeneSight® focuses on cluster analysis. Both SAS Enterprise Miner™ and Megaputer PolyAnalyst® employ each of the same algorithms except that SAS has a separate software SAS TextMiner® for text analysis. The regression results for the forest cover type data set are comparable for those obtained using NeuralWare Predict® and Megaputer PolyAnalyst®. The cluster analysis results for SAS Enterprise Miner™, Megaputer PolyAnalyst®, and Biodiscovery GeneSight® are unique to each software as to how they represent their results. SAS Enterprise Miner™ and NeuralWare Predict® both utilize Self-Organizing Maps (SOM) while the other two do not.

Figure 3. NeuralWare Predict® screen shot of complete neural network training (100%)

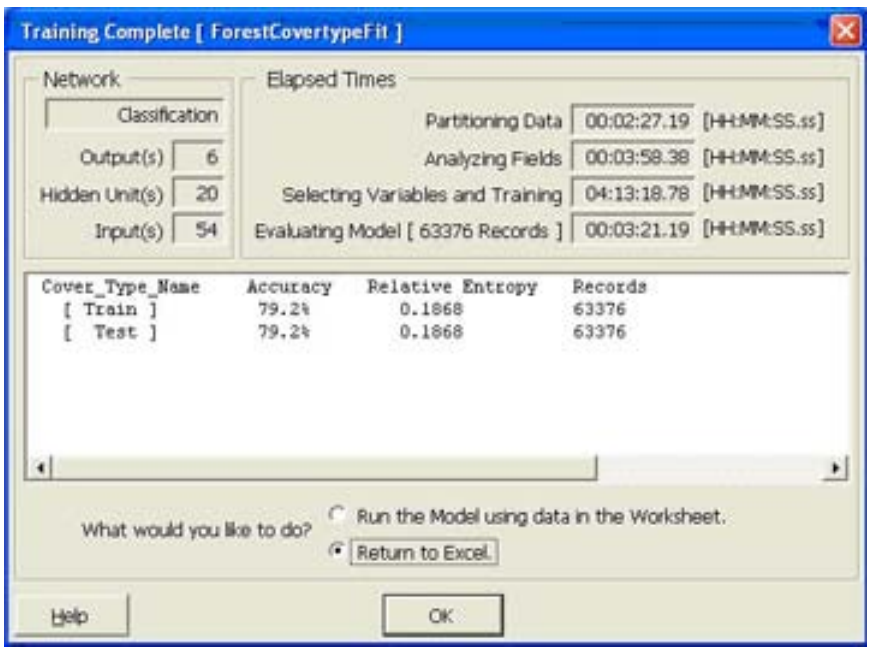

Figure 4. BioDiscovery GeneSight® screen shot of hierarchical clustering

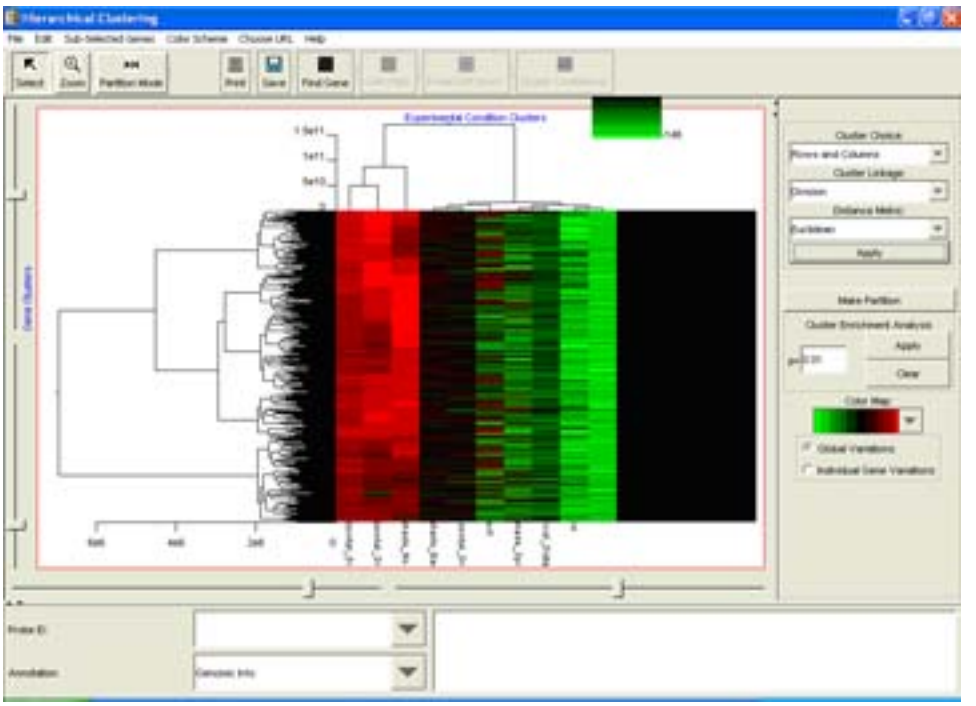

The four-selected software can also be compared with respect to their cost of purchase. SAS Enterprise Miner™ is the most expensive and NeuralWare Predict® is the least expensive. Megaputer PolyAnalyst® and Biodiscovery GeneSight® are intermediate in cost to the other two software.

In conclusion, SAS Enterprise Miner™ and Megaputer PolyAnalyst® offer the greatest diversification of data mining algorithms.

ACKNOWLEDGMENT

The authors want to acknowledge the support provided by a 2006 Summer Faculty Research Grant as awarded to them by the College of Business of Arkansas State University. The authors also want to acknowledge each of the four software manufactures of SAS, Megaputer Intelligence, Inc., BioDiscovery, Inc., and NeuralWare, for their support of this research.

KEY TERMS

Algorithm: That which produces a particular outcome with a completely defined set of steps or operations.

ARNAVAC: An underlying machine language algorithm used in PolyAnalyst® for the comparison of the target variable distributions in approximately homogeneously equivalent populated multidimensional hyper-cubes.

Association and sequence analysis: A data mining method that relates first a transaction and an item and secondly also examines the order in which the products are purchased.

BioDiscovery GeneSight®: A program for efficient data mining, visualization, and reporting tool that can analyze massive gene expression data generated by microarray technology.

Data Mining: The extraction of interesting and potentially useful information or patterns from data in large databases; also known as Knowledge Discovery in Data (KDD).

Link Analysis (LA): A technique used in data mining that reveals and visually represents complex patterns between individual values of all categorical and Boolean attributes.

Link Terms (LT): A technique used in text mining that reveals and visually represents complex patterns of relations between terms in textual notes.

Market and transactional basket analysis: Algorithms that examine a long list of transactions to determine which items are most frequently purchased together, as well as analysis of other situations such as identifying those sets of questions of a questionnaire that are frequently answered with the same categorical answer.

Megaputer PolyAnalyst® 5.0: A powerful multistrategy data mining system that implements a broad variety of mutually complementing methods for the automatic data analysis.

Microarray Databases: Store large amounts of complex data as generated by microarray experiments (e.g. DNA)

NeuralWare NeuralWorks Predict®: A software package that integrates all the capabilities needed to apply neural computing to a wide variety of problems.

SAS® Enterprise Miner™: Software that that uses an drop-and-drag object oriented approach within a workspace to performing data mining using a wide variety of algorithms.

Symbolic Knowledge Acquisition Technology (SKAT): An algorithm developed by Megaputer Intelligence and used in PolyAnalyst® 5.0 that uses methods of evolutionary programming for high-degree rational expressions that can efficiently represent nonlinear dependencies.

WEKA: Open-source data mining software that is a machine learning workbench.

Compression-Based Data Mining

INTRODUCTION

Compression-based data mining is a universal approach to clustering, classification, dimensionality reduction, and anomaly detection. It is motivated by results in bioinformatics, learning, and computational theory that are not well known outside those communities. It is based on an easily computed compression dissimilarity measure (CDM) between objects obtained by compression. The basic concept is easy to understand, but its foundations are rigorously formalized in information theory. The similarity between any two objects (XML files, time series, text strings, molecules, etc.) can be obtained using a universal lossless compressor. The compression dissimilarity measure is the size of the compressed concatenation of the two objects divided by the sum of the compressed sizes of each of the objects. The intuition is that if two objects are similar, lossless compressor will remove the redundancy between them and the resulting size of the concatenated object should be close the size of the larger of the two compressed constituent objects. The larger the CDM between two objects, the more dissimilar they are.

Classification, clustering and anomaly detection algorithms can then use this dissimilarity measure in a wide variety of applications. Many of these are described in (Keogh et al., 2004), (Keogh et al. 2007), and references therein. This approach works well when (1) objects are large and it is computationally expensive to compute other distances (e.g., very long strings); or (2) there are no natural distances between the objects or none that are reasonable from first principles. CDM is "parameter-free" and thus avoids over-fitting the data or relying upon assumptions that may be incorrect (Keogh et al., 2004).

CDM enjoys the following properties:

1. Because it makes no distributional or modeling assumptions about the data, it allows true exploratory data mining.
2. The accuracy of CDM is often greatly superior to those of parameter-laden or model-based algorithms, even if we allow these algorithms to search exhaustively over their parameter spaces.
3. CDM uses compression algorithms which are typically space and time efficient. As a consequence, CDM can be much more efficient than other algorithms, in some cases by three or four orders of magnitude.
4. CDM makes no assumption about the format of the data, nor does it require extensive data cleaning to be effective.

BACKGROUND

The use of data compression to classify sequences is also closely related to the Minimum Description Length (MDL) and Minimum Message Length (MML) principles (Grünwald, 2007), (Wallace, 2005). See keyword definitions at the end of the article. The MDL/MML principle has generated an extensive body of literature in the data mining community. CDM is a related concept, but it requires no probabilistic concepts and can be universally applied.

CDM is based on the concept of Kolmogorov complexity, a measure of randomness of strings based on their information content (Li & Vitanyi, 1997). It was proposed by Kolmogorov in 1965 to quantify the randomness of strings and other objects in an objective

and absolute manner. The Kolmogorov complexity K(x) of a string x is defined as the length of the shortest program capable of producing x on a universal computer — such as a Turing machine. Different programming languages will give rise to distinct values of K(x), but one can prove that the differences are only up to a fixed additive constant. Intuitively, K(x) is the minimal quantity of information required to generate x by an algorithm. The conditional Kolmogorov complexity K(x|y) of x to y is defined as the length of the shortest program that computes x when y is given as an auxiliary input to the program. The function K(xy) is the length of the shortest program that outputs y concatenated to x. In Li et al. (2001), the authors consider the distance between two strings, x and y, defined as

$$d_k(x,y) = \frac{K(x \mid y) + K(y \mid x)}{K(xy)} \quad (1)$$

which satisfies the triangle inequality, up to a small error term. A more mathematically precise distance was proposed in Li et al. (2003). Kolmogorov complexity is without a doubt the ultimate lower bound among all measures of information content. Unfortunately, it cannot be computed in the general case (Li and Vitanyi, 1997). As a consequence, one must approximate this distance. It is easy to realize that universal compression algorithms give an upper bound to the Kolmogorov complexity. In fact, K(x) is the best compression that one could possibly achieve for the text string x. Given a data compression algorithm, we define C(x) as the size of the compressed size of x, C(xy) as the size of the compressed size of the concatenation of x and y and C(x|y) as the compression achieved by first training the compression on y, and then compressing x. For example, if the compressor is based on a textual substitution method, one could build the dictionary on y, and then use that dictionary to compress x. We can approximate (1) by the following distance measure

$$d_c(x,y) = \frac{C(x \mid y) + C(y \mid x)}{C(xy)} \quad (2)$$

The better the compression algorithm, the better the approximation of d_c for d_k is. Li et al., (2003) have shown that d_c is a similarity metric and can be successfully applied to clustering DNA and text. However, the measure would require hacking the chosen compression algorithm in order to obtain C(x|y) and C(y|x). CDM simplifies this distance even further. In the next section, we will show that a simpler measure can be just as effective.

A comparative analysis of several compression-based distances has been recently carried out in Sculley and Brodley (2006). The idea of using data compression to classify sequences over finite alphabets is not new. For example, in the early days of computational biology, lossless compression was routinely used to classify and analyze DNA sequences. Refer to, e.g., Allison et al. (2000), Baronchelli et al. (2005), Farach et al. (1995), Frank et al. (2000), Gatlin (1972), Kennel (2004), Loewenstern and Yianilos (1999), Needham and Dowe (2001), Segen (1990), Teahan et al. (2000), Ferragina et al. (2007), Melville et al. (2007) and references therein for a sampler of the rich literature existing on this subject. More recently, Benedetto et al. (2002) have shown how to use a compression-based measure to classify fifty languages. The paper was featured in several scientific (and less-scientific) journals, including Nature, Science, and Wired.

MAIN FOCUS

CDM is quite easy to implement in just about any scripting language such as Matlab, Perl, or R. All that is required is the ability to programmatically execute a lossless compressor, such as gzip, bzip2, compress, WinZip and the like and store the results in an array. Table 1 shows the complete Matlab code for the compression-based dissimilarity measure.

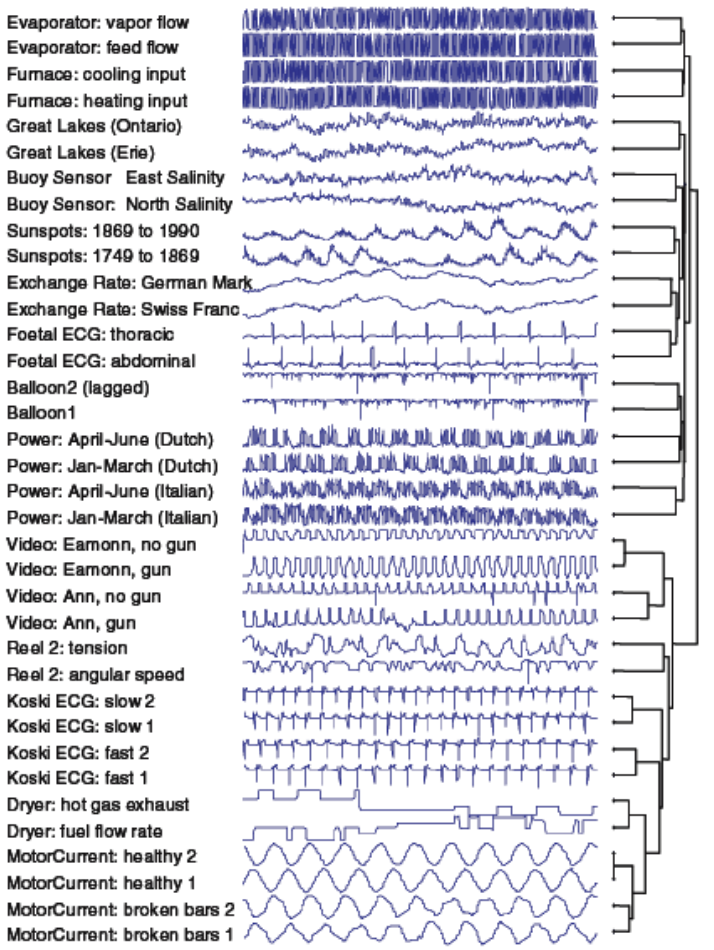
Once pairwise dissimilarities have been computed between objects, the dissimilarity matrix can be used for clustering (e.g. hierarchical agglomerative clustering), classification (e.g., k-nearest neighbors), dimensionality reduction (e.g., multidimensional scaling), or anomaly detection.

The best compressor to capture the similarities and differences between objects is the compressor that compresses the data most. In practice, one of a few easily obtained lossless compressors works well and the best one can be determined by experimentation. In some specialized cases, a lossless compressor designed for the data type provides better results (e.g., DNA clustering, Benedetto et al. 2002). The theoretical relationship between optimal compression and features for clustering is the subject of future research.

Table 1. Matlab code for compression dissimilarity measure

```
function Dist = CDM(A,B)
save A.txtA–ASCII                                          % Save variable A as A.txt
zip('A.zip', 'A.txt');                                     % Compress A.txt
A_file = dir('A.zip');                                     % Get file information
save B.txt B –ASCII                                        % Save variable B as B.txt
zip('B.zip', 'B.txt');                                     % Compress B.txt
B_file = dir('B.zip');                                     % Get file information
A_n_B = [A; B];                                            % Concatenate A and B
save A_n_B.txt A_n_B –ASCII                                % Save A_n_B.txt
zip('A_n_B.zip', 'A_n_B.txt');                             % Compress A_n_B.txt
A_n_B_file = dir('A_n_B.zip');                             % Get file information
dist = A_n_B_file.bytes / (A_file.bytes + B_file.bytes);   % Return CDM dissimilarity
```

Figure 1. Thirty-six time series (in 18 pairs) clustered using CDM.



To illustrate the efficacy of CDM, consider three examples: two experiments and a real-world application which was unanticipated by researchers in this field.

Time Series

The first experiment examined the UCR Time Series Archive (Keogh and Folias, 2002) for datasets that come in pairs. For example, in the Foetal-ECG dataset, there are two time series, thoracic and abdominal, and in the Dryer dataset, there are two time series, hot gas exhaust and fuel flow rate. There are 18 such pairs, from a diverse collection of time series covering the domains of finance, science, medicine, industry, etc.

While the correct hierarchical clustering at the top of a classification tree is somewhat subjective, at the lower level of the tree, we would hope to find a single bifurcation separating each pair in the dataset. Our metric, Q, for the quality of clustering is therefore the number of such correct bifurcations divided by 18, the number of datasets. For a perfect clustering, Q = 1, and because the number of dendrograms of 36 objects is greater than 3×10^{49}, for a random clustering, we would expect $Q \approx 0$.

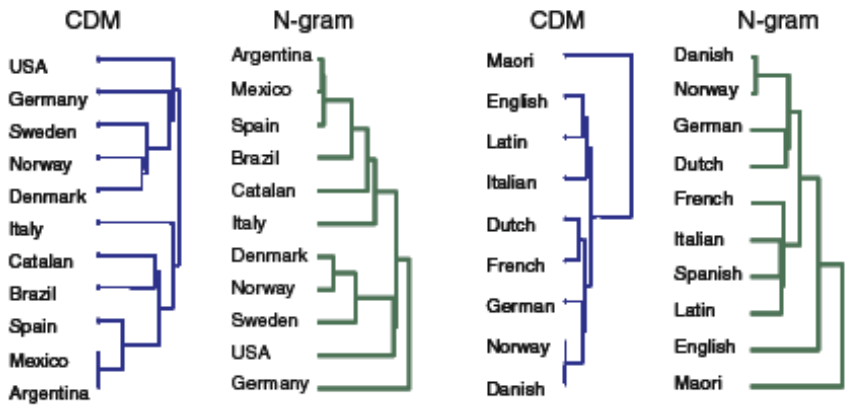
For many time series distance/dissimilarity/similarity measures that has appeared in major journals within the last decade, including dynamic time warping and longest common subsequence, we used hierarchical agglomerative clustering with single linkage, complete linkage, group average linkage, and Wards methods, and reported only the best performing results (Keogh et al., 2007). Figure 1 shows the resulting dendrogram for CDM, which achieved a perfect clustering with Q = 1. Although the higher level clustering is subjective, CDM seems to do very well. For example, the appearance of the Evaporator and Furnace datasets in the same subtree is quite intuitive, and similar remarks can be made for the two Video datasets and the two Motor-Current datasets. For more details on this extensive experiment, see (Keogh et al., 2007).

Natural Language

A similar experiment is reported in Benedetto et al. (2002). We clustered the text of various countries' Yahoo portals, only considering the first 1,615 characters, which is the size of the smallest webpage (excluding white spaces). Figure 2 (left) shows the clustering result. Note that the first bifurcation correctly divides the tree into Germanic and Romance languages.

The clustering shown is much better than that achieved by the ubiquitous cosine similarity measure

Figure 2 (Left) The clustering achieved by our approach and n-gram cosine measure (Rosenfeld, 2000) on the text from various Yahoo portals (January 15, 2004). The smallest webpage had 1,615 characters, excluding white spaces. (Right) The clustering achieved by our approach on the text from the first 50 chapters of Genesis. The smallest file had 132,307 characters, excluding white spaces. Maori, a Malayo–Polynesian language, is clearly identified as an "outlier."



used at the word level. In retrospect, this is hardly surprising. Consider the following English, Norwegian, and Danish words taken from the Yahoo portals:

English: {England, information, addresses}
Norwegian: {Storbritannia, informasjon, adressebok}
Danish: {Storbritannien, informationer, adressekartotek}

Because there is no single word in common to all (even after stemming), the three vectors are completely orthogonal to each other. Inspection of the text is likely to correctly conclude that Norwegian and Danish are much more similar to each other than they are to English. CDM can leverage off the same cues by finding repeated structure within and across texts. To be fairer to the cosine measure, we also tried an n-gram approach at the character level. We tested all values of N from 1 to 5, using all common linkages. The results are reported in Figure 2. While the best of these results are produces an intuitive clustering, other settings do not. We tried a similar experiment with text from various translations of the first 50 chapters of the Bible, this time including what one would expect to be an outlier, the Maori language of the indigenous people of New Zealand. As shown in Figure 2 (right) the clustering is correct, except for an inclusion of French in the Germanic subtree.

This result does not suggest that CDM replaces the vector space model for indexing text or a linguistic aware method for tracing the evolution of languages – it simply shows that for a given dataset which we know nothing about, we can expect CDM to produce reasonable results that can be a starting point for future study.

Questionnaires

CDM has proved successful in clustering semi-structured data not amenable to other methods and in an application that was unanticipated by its proponents. One of the strengths of Xerox Corporation sales is it comprehensive line of products and services. The sheer diversity of its offerings makes it challenging to present customers with compelling configurations of hardware and software. The complexity of this task is reduced by using a configuration tool to elicit responses from a customer about his or her business and requirements. The questionnaire is an online tool with which sales associates navigate based on customer responses. Different questions are asked based on how previous questions are answered. For example, if a customer prints only transactions (e.g., bills), a different sequence of questions is presented than if the customer prints annual reports with color content. The resulting data is a tree-structured responses represented in XML as shown in Figure 3.

As set of rules was hand-crafted to generate a configuration of products and feature options given the responses. What is desired was a way to learn which configurations are associated with which responses. The first step is to cluster the responses, which we call case logs, into meaningful groups. This particular "semi-structured" data type is not amenable to traditional text clustering, neither by a vector space approach like latent semantic indexing (Deerwester et al 1990) nor by

Figure 3. A sample case log fragment.

```

a probabilistic generative model such as probabilistic latent semantic analysis (Hoffmann, 2001). This because frequencies of terms (responses such as 'yes' or 'no') carry little information – the information is contained in which questions were asked and in what order. String (or graph) edit distance would seem to be another appropriate choice. However, the logs, even with many XML tags stripped, are 10-24 kilobytes in size, posing computational problems. Due to the inapplicability of the classic distance measurements, we used CDM for our clustering task. Based on 200 logs, a CDM-based approach using hierarchical agglomerative clustering resulted in clusters that were meaningful (a pleasant surprise for a purely algorithmic approach with no encoded domain knowledge). The clusters were used to build a nearest neighbor classification system with errors of 4%. See Wei et al. (2006) for details.

FUTURE TRENDS

Although a rich and diverse set of applications is emerging, a rigorous theoretical analysis of compression-based dissimilarity measure has yet to be done. The interplay between feature extraction and compression is not fully understood.

The compression-based dissimilarity measure could be modified to be a distance measure, or better still, a distance metric in which the distance between two identical objects is zero and the triangle inequality holds, we could avail of a wealth of pruning and indexing techniques to speed up classification Ratanamahatana and Keogh (2004), clustering Elkan (2003), and similarity search Vlachos et al. (2003). While it is unlikely that CDM can be transformed in a true metric, it may be possible to prove a weaker version of the triangular inequality, which can be bounded and used to prune the search space (Elkan 2003). A step in this direction is demonstrated in the recent paper (Sculley and Brodley 2006).

Finally, we note that our approach is clearly not suitable for classifying or clustering low dimensionality data (although Figure 2 shows exceptionally good results on time series with only 1,000 data points).We plan to theoretically and empirically investigate the limitations on object sizes that we can meaningfully work with using our proposed approach.

CONCLUSION

CDM produces interpretable and accurate clustering and classification results across a wide variety of data types and serves as an easy-to-use first try at data exploration. It often works when no natural metrics are available or the computational complexity of an appropriate method is too great (e.g., an edit distance between very long strings). We expect the body of successful applications to continue to grow.

KEY TERMS

Anomaly Detection: From a set of normal behaviors, detect when an observed behavior is unusual or abnormal, often by using distances between behaviors and detecting unusually large deviations.

Compression Dissimilarity Measure: Given two objects x and y and a universal, lossless compressor

C, the compression dissimilarity measure is the compressed size C(xy) of the concatenated objects divided by the sum C(x) + C(y) of the sizes of the compressed individual objects.

Kolmogorov Complexity: The Kolmogorov complexity of a string x of symbols from a finite alphabet is defined as the length of the shortest program capable of producing x on a universal computer such as a Turing machine.

Lossless Compression: A means of data compression such that the data can be encoded and decoded in its entirety with no loss of information or data. Examples include Lempel-Ziv encoding and its variants.

Minimum Description Length: The Minimum Description Length principle for modeling data states that the best model, given a limited set of observed data, is the one that can be describes the data as succinctly as possible, or equivalently that delivers the greatest compression of the data.

Minimum Message Length: The Minimum Message Length principle, which is formalized in probability theory, holds that given models for a data set, the one generating the shortest message that includes both a description of the fitted model and the data is probably correct.

Multidimensional Scaling: A method of visualizing high dimensional data in fewer dimensions. From a matrix of pairwise distances of (high dimensional) objects, objects are represented in a low dimensional Euclidean space, typically a plane, such that the Euclidean distances approximate the original pairwise distances as closely as possible.

Parameter-Free Data Mining: An approach to data mining that uses universal lossless compressors to measure differences between objects instead of probability models or feature vectors.

Universal Compressor: A compression method or algorithm for sequential data that is lossless and uses no model of the data. Performs well on a wide class of data, but is suboptimal for data with well-defined statistical characteristics.

Computation of OLAP Data Cubes

Amin A. Abdulghani
Data Mining Engineer, USA

INTRODUCTION

The focus of online analytical processing (OLAP) is to provide a platform for analyzing data (e.g., sales data) with multiple dimensions (e.g., product, location, time) and multiple measures (e.g., total sales or total cost). OLAP operations then allow viewing of this data from a number of perspectives. For analysis, the object or data structure of primary interest in OLAP is a data cube. A detailed introduction to OLAP is presented in (Han & Kambler, 2006).

BACKGROUND

Consider a 3-D cube model shown in Figure 1 representing sales data. It has three dimensions year, product and location. The measurement of interest is total sales. In olap terminology, since this cube models the base data, it forms a 3-D *base cuboid*. A *cuboid* in general is a group-by of a subset of dimensions of the base data, obtained by aggregating all tuples on these dimensions. So, for example for our sales data we have three 2-d cuboids namely (year, product), (product, location) and (year, location), three 1-d cuboids (year), (location) and (product) and one 0-d cuboid in which aggregation is performed on the whole data. A cuboid which is not a base cuboid is called an *aggregate cuboid* while a 0-D cuboid is called an *apex cuboid*. For base data, with n diemensions, the union of of all *k*-dimensional (k<=n) cuboids forms *an n-dimensional data cube*. A *cell* represents an association of a measure *m* (e.g., total sales) with a member of every dimension in a cuboid e.g. C1(product="toys", location="NJ", year="2004"). The dimensions not present in the cell are aggregated over all possible members. For example, you can have a two-dimensional (2-D) cell, C2(product="toys", year="2004"). Here, the implicit value for the dimension location is '*', and the measure *m* (e.g., total sales) is aggregated over all locations. Any of the standard

Figure 1. A 3-D base cuboid with an example 3-D cell.

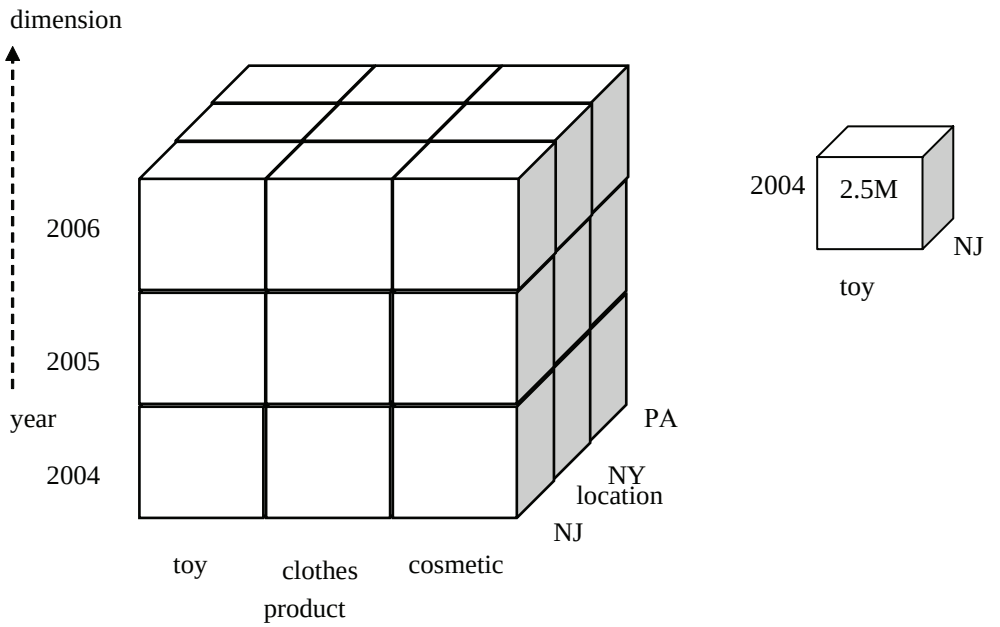

Figure 2. An example 2-D cuboid on (product, year) for the 3-D cube in Figure 1 (location=''); total sales needs to be aggregated (e.g., SUM)*

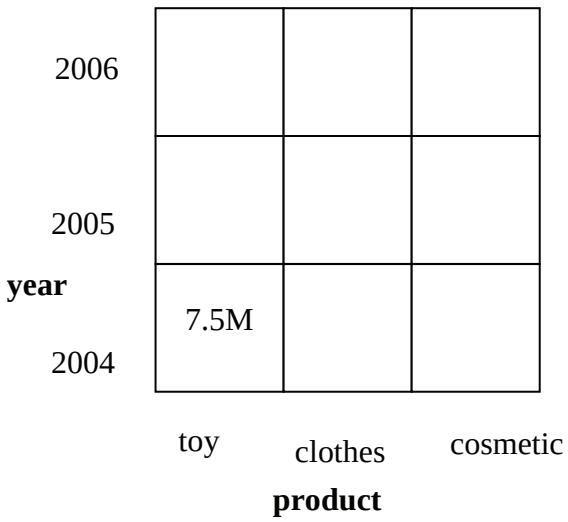

aggregate functions such as count, total, average, minimum, or maximum can be used for aggregating. Suppose the sales for toys in 2004 for NJ, NY, PA were $2.5M, $3.5M, $1.5M respectively and that the aggregating function is total. Then, the measure value for cell C2 is $7.5M.

In theory, no special operators or SQL extensions are required to take a set of records in the database and generate all the cells for the cube. Rather, the SQL group-by and union operators can be used in conjunction with dimensional sorts of the dataset to produce all cuboids. However, such an approach would be very inefficient, given the obvious interrelationships between the various group-bys produced.

MAIN THRUST

I now describe the essence of the major methods for the computation of OLAP cubes.

Top-Down Computation

In a seminal paper, Gray, Bosworth, Layman, and Pirahesh (1996) proposed the data cube operator.. The algorithm presented there forms the basis of the top-down approach.

The top-down cube computation works with non-holistic functions. An aggregate function F is called holistic if the value of F for an *n*-dimensional cell cannot be computed from a constant number of aggregates of the (*n*+1)–dimensional cell. Median and mode are examples of holistic functions, sum and avg are examples of non-holistic functions.The non-holistic functions have the property that more detailed aggregates (i.e., more dimensions) can be used to compute less detailed aggregates. This property induces a partial-ordering (i.e., a *lattice*) on all the group-bys of the cube. A group-by is called a child of some parent group-by if the parent can be used to compute the child (and no intermediate group-bys exist between the parent and child). Figure 3 depicts a sample lattice where A, B, C, and D are dimensions, nodes represent group-bys, and the edges show the parent-child relationship.

The basic idea for top-down cube construction is to start by computing the base cuboid (group-by for which no cube dimensions are aggregated). A single pass is made over the data, a record is examined, and the appropriate base cell is incremented. The remaining group-bys are computed by aggregating over already computed finer grade group-by. If a group-by can be computed from one or more possible parent group-bys, then the algorithm uses the parent smallest in size. For example, for computing the cube ABCD, the algorithm starts out by computing the base cuboid for ABCD. Then, using ABCD, it computes the cuboids for ABC, ABD, and BCD. The algorithm then repeats itself by computing the 2-D cuboids, AB, BC, AD, and

Figure 3. Cube lattice

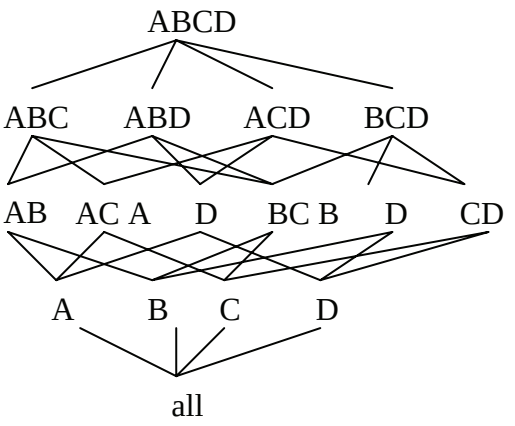

Figure 4. Top-down cube computation

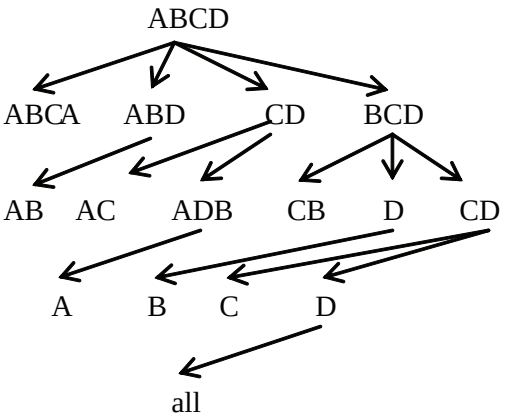


BD. Note that the 2-D–cuboids can be computed from multiple parents. For example, AB can be computed from ABC or ABD. The algorithm selects the smaller group-by (the group-by with the fewest number of cells). An example top-down cube computation is shown in Figure 4.

Variants of this approach optimize on additional costs. The well-known methods are the PipeSort and PipeHash (Agarwal, Agrawal, Deshpande, Gupta, Naughton, Ramakrishnan, et al., 1996). The basic idea in the work is to extend the sort-based and hash-based methods for computing group-bys to multiple group-bys from the lattice. The optimiziations they incorporate include: computing a group-by from the smallest previously computed-group-by, reducing disk I/O by caching group-bys, reducing disk reads by computing multiple group-bys from a single parent group-by, and sharing of sorting and hashing costs across multiple group-bys.

Both PipeSort and PipeHash are examples of ROLAP (Relational-OLAP) algorithms as they operate on multidimensional tables. An alternative is MOLAP (Multidimensional OLAP), where the approach is to store the cube directly as a multidimensional array. If the data are in relational form, then they are loaded into arrays, and the cube is computed from the arrays. The advantage is that no tuples are needed for comparison purposes; all operations are performed by using array indices.

A good example for a MOLAP-based cubing algorithm is the MultiWay algorithm (Zhao, Deshpande, & Naughton, 1997). Here, to make efficient use of memory, a single large *d*-dimensional array is divided into smaller *d*-dimensional arrays, called *chunks.* It is not necessary to keep all chunks in memory at the same time; only part of the group-by arrays are needed for a given instance. The algorithm starts at the base cuboid with a single chunk. The results are passed to immediate lower-level cuboids of the top-down cube computation tree allowing computation for multiple cuboids concurrently. After the chunk processing is complete, the next chunk is loaded. The process then repeats itself. An advantage of the MultiWay algorithm is that it also allows for shared computation, where intermediate aggregate values are reused for the computation of successive descendant cuboids. The disadvantage of MOLAP-based algorithms is that they are not scalable for a large number of dimensions. because the intermediate results become too large to fit in memory. (Xin, Han, Li, & Wah, 2003).

Bottom-Up Computation

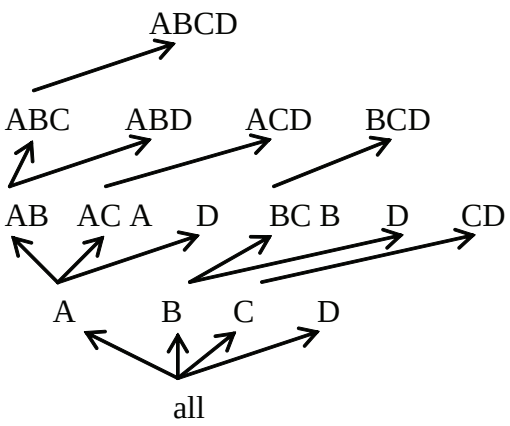
Computing and storing full data cubes may be overkill. Consider, for example, a dataset with 10 dimensions, each with a domain size of 9 (i.e., can have nine distinct values). Computing the full cube for this dataset would require computing and storing 10^{10} cuboids. Not all cuboids in the full cube may be of interest. For example, if the measure is total sales, and a user is interested in finding the cuboids that have high sales (greater than a given threshold), then computing cells with low total sales would be redundant. It would be more efficient here to only compute the cells that have total sales greater than the threshold. The group of cells that satisfies the given query is referred to as an *iceberg*

cube. The query returning the group of cells is referred to as an *iceberg query.*

Iceberg queries are typically computed using a *bottom-up* approach such as BUC (Beyer & Ramakrishnan, 1999). These methods work from the bottom of the cube lattice and then work their way up towards the cells with a larger number of dimensions. Figure 5 illustrates this approach. The approach is typically more efficient for high-dimensional, sparse datasets. The key observation to its success is in its ability to prune cells in the lattice that do not lead to useful answers. Suppose, for example, that the iceberg query is COUNT()>100. Also, suppose there is a cell X(A=a2) with COUNT=75. Then, clearly, C does not satisfy the query. However, in addition, you can see that any cell X' in the cube lattice that includes the dimensions (e.g. A=a2, B=b3) will also not satisfy the query. Thus, you need not look at any such cell after having looked at cell X. This forms the basis of support pruning. The observation was first made in the context of frequent sets for the generation of association rules (Agrawal, Imielinski, & Swami, 1993). For more arbitrary queries, detecting whether a cell is prunable is more difficult. However, some progress has been made in that front too. For example in Imielinski, Khachiyan, & Abdulghani, 2002 a method has been described for pruning arbitrary queries involving aggregates SUM, MIN, MAX, AVG and count functions.

Another feature of BUC-like algorithm is its ability to share costs during construction of different nodes. For example in Figure 5, BUC scans through the the records in a relation R and computes the aggregate cuboid node "ALL". It then sorts through R according to attribute A and finds the set of tuples for the cell X(A=a1), that share the same value a1 in A. It aggregates the measures of the tuples in this set and moves on to node AB. The input to this node are the set of tuples for the cell X(A=a1). Here, it sorts the input based on attribute B, and finds the set of tuples for the cell X(A=a1, B=b1) that share the same value b1 in B. It aggregates the measures of the tuples in this set and moves on to node ABC(assuming no pruning was performed). The input would be the set of tuples from the previous node. In node ABC, a new sort occurs on the tuples in the input set according to attribute C and set of tuples for cells X(A=a1, B=b1, C=c1), X(A=a1, B=b1, C=c2)…..X(A=a1,B=b1,C=cn) are found and aggregated. Once the node ABC is fully processed for the set of tuples in the cell X(A=a1, B=b1), the algorithm moves to the next set of tuples to process in node AB namely, the set of tuples for the cell X(A=a1, B=b2). And so on. Note, the computation occurs in a depth-first manner, and each node at a higher level uses the output of the node at the lower level. The work described in Morfonios, k. & Ioannidis, Y (2006), further generalizes this execution plan to dimensions with multiple hierarchies.

Figure 5. Bottom-up cube computation



Integrated Top-Down and Bottom-Up Approach

Typically, for low-dimension, low-cardinality, dense datasets, the top-down approach is more applicable than the bottom-up one. However, combining the two approaches leads to an even more efficient algorithm for cube computation (Xin, Han, Li, & Wah, 2003). On the global computation order, the work presented uses the top-down approach. At a sublayer underneath, it exploits the potential of the bottom-up model. Consider the top-down computation tree in Figure 4. Notice that the dimension ABC is included for all the cuboids in the leftmost subtree (the node labeled ABC).. Similarly, all the cuboids in the second and third left subtrees include the dimensions AB and A respectively. These common dimensions are termed the *shared dimensions* of the particular subtrees and enable bottom-up computation. The observation is that if a query is prunable on the cell defined by the shared dimensions, then the rest of the cells generated from this shared dimension are unneeded. The critical requirement is that for every cell X, the cell for the *shared dimensions* must be computed

first. The advantage of such an approach is that it allows for shared computation as in the top-down approach as well as for pruning, when possible.

The common theme amongst most of the algorithms discussed in literature for cube computation has been that the lattice space for computation are dimension-based. Shao, Han & Xin(2004) describes a different approach where the data density of the different dimensions in the data set are also considered in the computation order. The work factorizes the lattice space into one dense subspace and several sparse subspaces and each such subspace is handled separately. Their conclusions indicate that their approach provide efficient computation for both sparse and dense data sets.

Other Approaches

Until now, I have considered computing the cuboids from the base data. Another commonly used approach is to *materialize* the results of a selected set of group-bys and evaluate all queries by using the materialized results. Harinarayan, Rajaraman, and Ullman (1996) describe an approach to materialize a limit of k group-bys. The first group-by to materialize always includes the top group-by, as none of the group-bys can be used to answer queries for this group-by. The next group-by to materialize is included such that the *benefit* of including it in the set exceeds the benefit of any other nonmaterialized group-by. Let S be the set of materialized group-bys. This *benefit* of including a group-by v in the set S is the total savings achieved for computing the group-bys not included in S by using v versus the cost of computing them through some group-by already in S. Gupta, Harinarayan, Rajaraman, and Ullman (1997) further extend this work to include indices in the cost.

The subset of the cuboids selected for materialization is referred to as a *partial cube.* After a set of cuboids has been materialized, queries are evaluated by using the materialized results. Park, Kim, and Lee (2001) describe a typical approach. Here, the OLAP queries are answered in a three-step process. In the first step, it selects the materialized results that will be used for rewriting and identifies the part of the query (region) that the materialized result can answer. Next, query blocks are generated for these query regions. Finally, query blocks are integrated into a rewritten query.

Future Trends

In this paper, I focus on the basic aspects of cube computation. The field has matured in the last decade and a half. Some of the issues that I believe will get more attention in future work include:

- Making use of inherent property of the dataset to reduce computation of the data cubes. An example is the *range cubing algorithm,* which utilizes the correlation in the datasets to reduce the computation cost (Feng, Agrawal, Abbadi, & Metwally, 2004).
- Further work on compressing the size of the data cube and storing it efficiently. There is a realization that a great portion of the data stored in a cube is redundant and both storage and computation savings can be achieved by removing the redundancies. Examples of causes for the redundancy are repeating dimension values and repeating aggregation values across cells of the cube. Related to this issue, is also the storage format of the non-redundant data. For example, it is not very efficient storage wise if a ROLAP-based approach, stores the complete cube structure as a single relation with fixed-size tuples. Attempts to handle these issues have been described in Sismanis, Deligiannakis, Roussopoulus, and Kotidis (2002) and Morfonios, k. & Ioannidis, Y (2006) and Lakshmanan, L.V.S., Pei, J., & Zhao, Y. (2003).
- Support for indexing for answering certain cube queries fast.
- Computing cubes for richer data sets like XML–data (Wiwatwattana, N., Jagadish, H.V., Lakshmanan, L.V.S., & Srivastava, 2007).

CONCLUSION

This paper focuses on the methods for OLAP cube computation. Initial approaches shared the similarity that they make use of the ordering defined by the cube lattice to drive the computation. For the top-down approach, traversal occurs from the top of the lattice. This has the advantage that for the computation of successive descendant cuboids, intermediate node results are used. The bottom-up approach traverses the lattice in the reverse direction. The method can no longer rely on making

use of the intermediate node results. Its advantage lies in the ability to prune cuboids in the lattice that do not lead to useful answers. The integrated approach uses the combination of both methods, taking advantages of both. New alternatives have also been proposed that also take data density into consideration.

The other major option for computing the cubes is to materialize only a subset of the cuboids and to evaluate queries by using this set. The advantage lies in storage costs, but additional issues, such as identification of the cuboids to materialize, algorithms for materializing these, and query rewrite algorithms, are raised.

KEY TERMS

Bottom-Up Cube Computation: Cube construction that starts by computing from the bottom of the cube lattice and then working up toward the cells with a greater number of dimensions.

Cube Cell: Represents an association of a measure *m* with a member of every dimension.

Cuboid: A group-by of a subset of dimensions, obtained by aggregating all tuples on these dimensions.

Holistic Function: An aggregate function F is called holistic if the value of F for an *n*-dimensional cell cannot be computed from a constant number of aggregates of the (*n*+1)–dimensional cell'

Iceberg Cubes: Set of cells in a cube that satisfies an iceberg query.

Iceberg Query: A query on top of a cube that asks for aggregates above a certain threshold.

N-Dimensional Data Cube: A union of all of *k*-dimensional (k<=n) cuboids arranged by the n dimensions of the data.

Partial Cube: The subset of the cuboids selected for materialization.

Sparse Cube: A cube is sparse if a high ratio of the cube's possible cells does not contain any measure value.

Top-Down Cube Computation: Cube construction that starts by computing the base cuboid and then iteratively computing the remaining cells by aggregating over already computed finer-grade cells in the lattice.

Conceptual Modeling for Data Warehouse and OLAP Applications

Elzbieta Malinowski
Universidad de Costa Rica, Costa Rica

Esteban Zimányi
Université Libre de Bruxelles, Belgium

INTRODUCTION

The advantages of using conceptual models for database design are well known. In particular, they facilitate the communication between users and designers since they do not require the knowledge of specific features of the underlying implementation platform. Further, schemas developed using conceptual models can be mapped to different logical models, such as the relational, object-relational, or object-oriented models, thus simplifying technological changes. Finally, the logical model is translated into a physical one according to the underlying implementation platform.

Nevertheless, the domain of conceptual modeling for data warehouse applications is still at a research stage. The current state of affairs is that logical models are used for designing data warehouses, i.e., using *star* and *snowflake* schemas in the relational model. These schemas provide a multidimensional view of data where *measures* (e.g., quantity of products sold) are analyzed from different perspectives or *dimensions* (e.g., by product) and at different levels of detail with the help of *hierarchies*. On-line analytical processing (OLAP) systems allow users to perform automatic aggregations of measures while traversing hierarchies: the roll-up operation transforms detailed measures into aggregated values (e.g., daily into monthly sales) while the drill-down operation does the contrary.

Star and snowflake schemas have several disadvantages, such as the inclusion of implementation details and the inadequacy of representing different kinds of hierarchies existing in real-world applications. In order to facilitate users to express their analysis needs, it is necessary to represent data requirements for data warehouses at the conceptual level. A conceptual multidimensional model should provide a graphical support (Rizzi, 2007) and allow representing facts, measures, dimensions, and different kinds of hierarchies.

BACKGROUND

Star and snowflake schemas comprise relational tables termed *fact* and *dimension tables*. An example of star schema is given in Figure 1.

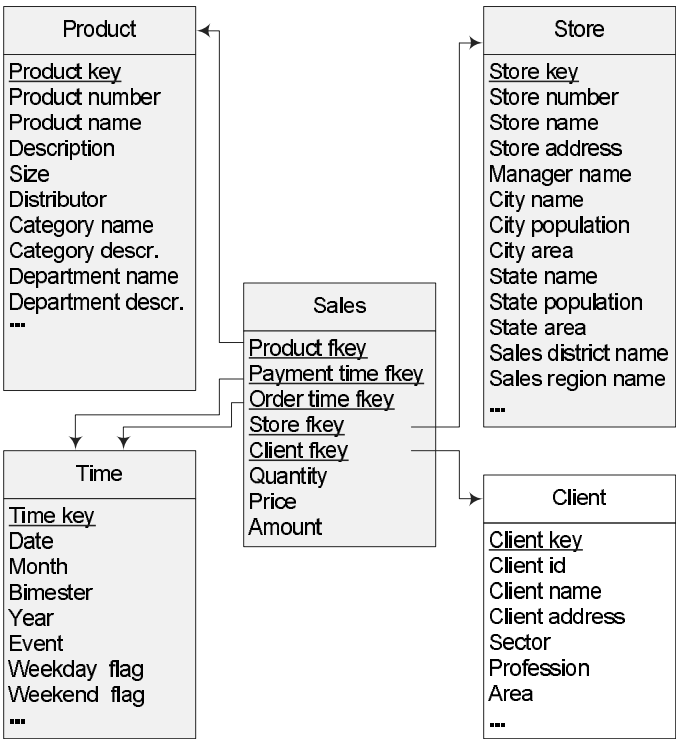
Fact tables, e.g., Sales in Figure 1, represent the focus of analysis, e.g., analysis of sales. They usually contain numeric data called *measures* representing the indicators being analyzed, e.g., Quantity, Price, and Amount in the figure. *Dimensions*, e.g., Time, Product, Store, and Client in Figure 1, are used for exploring the measures from different analysis perspectives. They often include attributes that form *hierarchies*, e.g., Product, Category, and Department in the Product dimension, and may also have descriptive attributes.

Star schemas have several limitations. First, since they use de-normalized tables they cannot clearly represent hierarchies: The hierarchy structure must be deduced based on knowledge from the application domain. For example, in Figure 1 is not clear whether some dimensions comprise hierarchies and if they do, what are their structures.

Second, star schemas do not distinguish different kinds of measures, i.e., additive, semi-additive, non-additive, or derived (Kimball & Ross, 2002). For example, Quantity is an additive measure since it can be summarized while traversing the hierarchies in all dimensions; Price is a non-additive measure since it cannot be meaningfully summarized across any dimension; Amount is a derived measure, i.e., calculated based on other measures. Although these measures require different handling during aggregation, they are represented in the same way.

Third, since star schemas are based on the relational model, implementation details (e.g., foreign keys) must be considered during the design process. This requires technical knowledge from users and also makes difficult the process of transforming the logical model to other models, if necessary.

Figure 1. Example of a star schema for analyzing sales



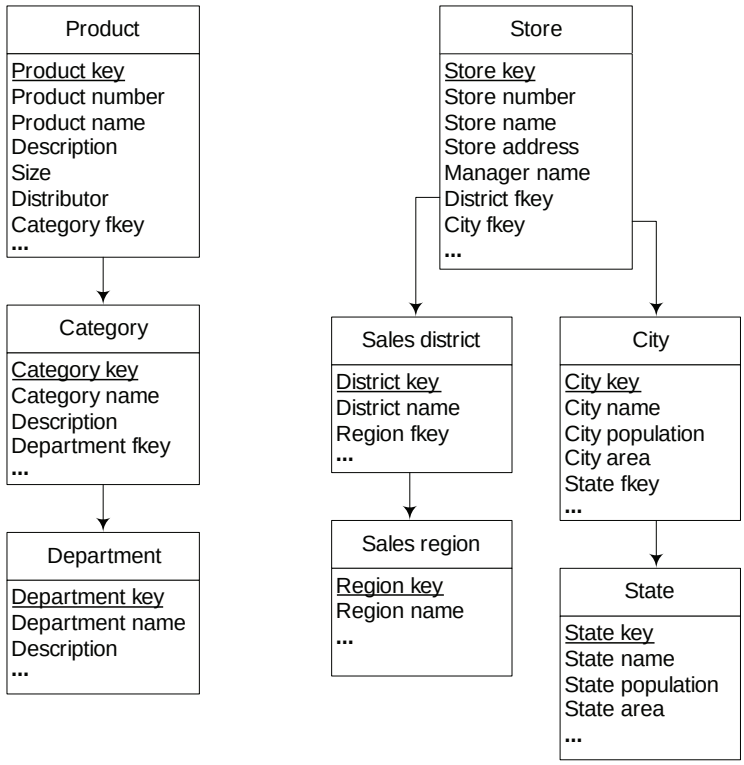
Fourth, dimensions may play different roles in a fact table. For example, the Sales table in Figure 1 is related to the Time dimension through two dates, the order date and the payment date. However, this situation is only expressed as foreign keys in the fact table that can be difficult to understand for non-expert users.

Snowflake schemas have the same problems as star schemas, with the exception that they are able to represent hierarchies. The latter are implemented as separate tables for every hierarchy level as shown in Figure 2 for the Product and Store dimensions. Nevertheless, snowflake schemas only allow representing simple hierarchies. For example, in the hierarchy in Figure 2 a) it is not clear that the same product can belong to several categories but for implementation purposes only the primary category is kept for each product. Furthermore, the hierarchy formed by the Store, Sales district, and Sales region tables does not accurately represent users' requirements: since small sales regions are not divided into sales districts, some stores must be analyzed using the hierarchy composed only of the Store and the Sales region tables.

Several conceptual multidimensional models have been proposed in the literature[1]. These models include the concepts of facts, measures, dimensions, and hierarchies. Some of the proposals provide graphical representations based on the ER model (Sapia, Blaschka, Höfling, & Dinter, 1998; Tryfona, Busborg, & Borch, 1999), on UML (Abelló, Samos, & Saltor, 2006; Luján-Mora, Trujillo, & Song, 2006), or propose new notations (Golfarelli & Rizzi, 1998; Hüsemann, Lechtenbörger, & Vossen, 2000), while other proposals do not refer to graphical representations (Hurtado & Gutierrez, 2007; Pourabbas, & Rafanelli, 2003; Pedersen, Jensen, & Dyreson, 2001; Tsois, Karayannidis, & Sellis, 2001).

Very few models distinguish the different types of measures and refer to role-playing dimensions (Kimball & Ross, 2002, Luján-Mora *et al.*, 2006). Some models do not consider the different kinds of hierarchies existing in real-world applications and only support simple hierarchies (Golfarelli & Rizzi, 1998; Sapia *et al.*, 1998). Other models define some of the hierarchies described in the next section (Abelló *et al.*, 2006; Bauer, Hümmer,

Figure 2. Snowflake schemas for the a) product and b) store dimensions from Figure 1



& Lehner, 2000; Hüsemann *et al.*, 2000; Hurtado & Gutierrez, 2007; Luján-Mora *et al.*, 2006; Pourabbas, & Rafanelli, 2003; Pedersen *et al.*, 2001; Rizzi, 2007). However, there is a lack of a general classification of hierarchies, including their characteristics at the schema and at the instance levels.

MAIN FOCUS

We present next the MultiDim model (Malinowski & Zimányi, 2004; Malinowski & Zimányi, 2008), a conceptual multidimensional model for data warehouse and OLAP applications. The model allows representing different kinds of hierarchies existing in real-world situations.

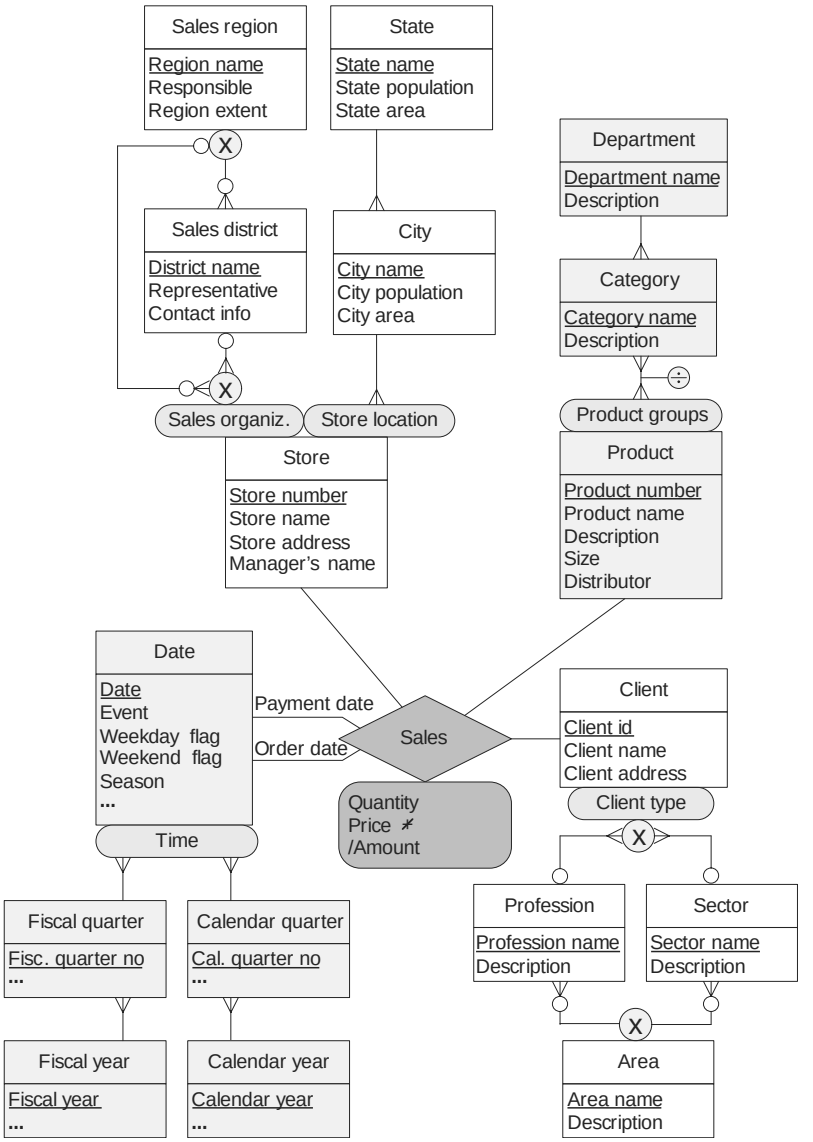
The MultiDim Model

To describe the MultiDim model we use the schema in Figure 3, which corresponds to the relational schemas in Figure 1. This schema also contains different types of hierarchies that are defined in next section.

A *schema* is composed of a set of levels organized into dimensions and a set of fact relationships. A *level* corresponds to an entity type in the ER model; instances of levels are called *members*. A level has a set of attributes describing the characteristics of their members. For example, the Product level in Figure 3 includes the attributes Product number, Product name, etc. In addition, a level has one or several keys (underlined in the figure) identifying uniquely the members of a level.

A *fact relationship* expresses the focus of analysis and represents an n-ary relationship between levels. For example, the Sales fact relationship in Figure 3 relates the Product, Date, Store, and Client levels. Further, the same level can participate several times in a fact relationship playing different roles. Each *role* is identified by a name and is represented by a separate link between the level and the fact relationship, as can be seen for the roles Payment date and Order date relating the Date level to the Sales fact relationship.

Figure 3. A conceptual multidimensional schema of a sales data warehouse



A fact relationship may contain attributes commonly called *measures*, e.g., Quantity, Price, and Amount in Figure 3. Measures are classified as *additive*, *semi-additive*, or *non-additive* (Kimball & Ross, 2002). By default we suppose that measures are additive. For semi-additive and non-additive measures we use, respectively, the symbols +! and ≠ (the latter is shown for the Price measure). For derived measures and attributes we use the symbol / in front of the measure name, as shown for the Amount measure.

A *dimension* is an abstract concept grouping data that shares a common semantic meaning within the domain being modeled. It is composed of either one level or one more hierarchies.

Hierarchies are used for establishing meaningful aggregation paths. A hierarchy comprises several related levels, e.g., the Product, Category, and Department levels. Given two related levels, the lower level is called *child*, the higher level is called *parent*, and the relationship between them is called *child-parent relationship*. Key attributes of a parent level define how

child members are grouped. For example, in Figure 3 the Department name in the Department level is used for grouping different category members during roll-up operations. A level that does not have a child level is called *leaf*; it must be the same for all hierarchies in a dimension. The leaf level name is used for defining the dimension's name. The level that does not have a parent level is called *root*.

Child-parent relationships are characterized by *cardinalities*, indicating the minimum and the maximum number of members in one level that can be related to members in another level. The notations used for representing cardinalities are as follows: —< (1,n), —o< (0,n), —— (1,1), and —o (0,1). For example, in Figure 3 the child level Store is related to the parent level City with a many-to-one cardinality, which means that every store belongs to only one city and each city can have many stores.

Since the hierarchies in a dimension may express different conceptual structures used for analysis purposes, we include an *analysis criterion* to differentiate them. For example, the Store dimension includes two hierarchies: Store location and Sales organization.

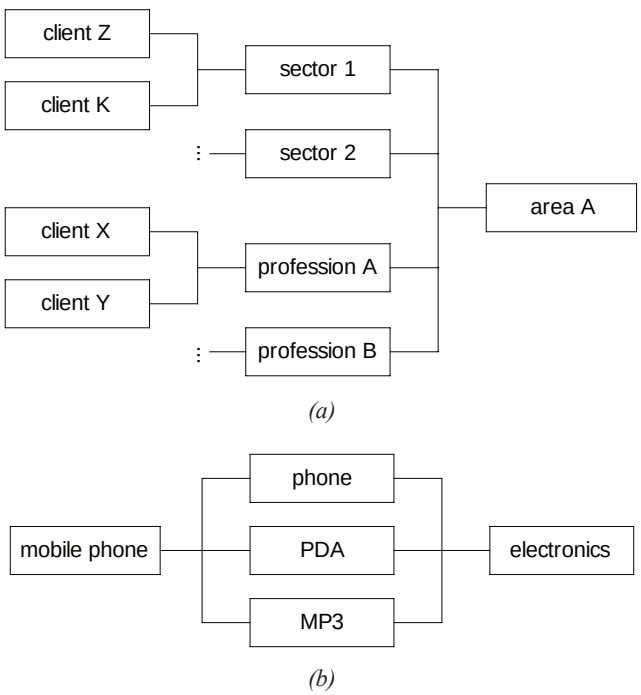
Classification of Hierarchies

We propose next a classification of hierarchies considering their differences at the schema and at the instance levels. Figure 4 shows examples of members for the Customer and Product dimensions from Figure 3. The distinction at the instance level is important since different aggregation procedures are required depending on whether the hierarchy members form a tree or an acyclic graph. This may be deduced from the cardinalities included in the schema.

We distinguish the following types of hierarchies.

- **Simple:** In these hierarchies the relationship between their members can be represented as a tree. They can be of different types.
  - **Balanced:** An example of this hierarchy is the Store location in Figure 3. At the schema level there is only one path where all levels are mandatory. At the instance level the members form a tree where all the branches have the same length. A parent member has one or several child members (at least one)

Figure 4. Examples of members for a) the Customer and b) the Product dimensions



and a child member belongs to only one parent member: the cardinality of child roles is (1,1) and that of parent roles is (1,n).

- **Unbalanced:** This type of hierarchy is not included in Figure 3; however, they are present in many data warehouse applications. For example, a bank may include a hierarchy composed by the levels ATM, Agency, and Branch. However, some agencies may not have ATMs and small branches may not have any organizational division. This kind of hierarchy has only one path at the schema level. However, since at the instance level, some parent members may not have associated child members, the cardinality of the parent role is (0,n).
- **Generalized:** The Client type hierarchy in Figure 3 with instances in Figure 4 a) belongs to this type. In this hierarchy a client can be a person or a company having in common the Client and Area levels. However, the buying behavior of clients can be analyzed according to the specific level Profession for a person type, and Sector for a company type. This kind of hierarchy has at the schema level multiple exclusive paths sharing some levels. All these paths represent one hierarchy and account for the same analysis criterion. At the instance level each member of the hierarchy only belongs to one path. We use the symbol ⊗ for indicating that the paths are exclusive. **Non-covering** hierarchies (the Sales organization hierarchy in Figure 3) are generalized hierarchies with the additional restriction that the alternative paths are obtained by skipping one or several intermediate levels. At the instance level every child member has only one parent member.

- **Non-strict:** An example is the Product groups hierarchy in Figure 3 with members in Figure 4 b). This hierarchy models the situation when mobile phones can be classified in different products categories, e.g., phone, PDA, and MP3 player. Non-strict hierarchies have at the schema level at least one many-to-many cardinality, e.g., between the Product and Category levels in Figure 3. A hierarchy is called *strict* if all cardinalities are many-to-one. Since at the instance level, a child member may have more than one parent member, the members form an acyclic graph. To indicate how the measures are distributed between several parent members, we include a distributing factor symbol ⊜. The different kinds of hierarchies previously presented can be either strict or non-strict.
- **Alternative:** The Time hierarchy in the Date dimension is a alternative hierarchy. At the schema level there are several non-exclusive simple hierarchies sharing at least the leaf level, all these hierarchies accounting for the same analysis criterion. At the instance level such hierarchies form a graph since a child member can be associated with more than one parent member belonging to different levels. In such hierarchies it is not semantically correct to simultaneously traverse the different composing hierarchies. Users must choose one of the alternative hierarchies for analysis, e.g., either the hierarchy composed by Date, Fiscal quarter, and Fiscal year or the one composed by Date, Calendar quarter, and Calendar year.
- **Parallel:** A dimension has associated several hierarchies accounting for different analysis criteria. Parallel hierarchies can be of two types. They are *independent,* if the composing hierarchies do not share levels; otherwise, they are *dependent*. The Store dimension includes two parallel independent hierarchies: Sales organization and Store location. They allow analyzing measures according to different criteria.

The schema in Figure 3 clearly indicates users' requirements concerning the focus of analysis and the aggregation levels represented by the hierarchies. It also preserves the characteristics of star or snowflake schemas providing at the same time a more abstract conceptual representation. Notice that even though the schemas in Figures 1 and 3 include the same hierarchies, they can be easily distinguished in the Figure 3 while this distinction cannot be made in Figure 1.

Existing multidimensional models do not consider all types of hierarchies described above. Some models give only a description and/or a definition of some of the hierarchies, without a graphical representation. Further, for the same type of hierarchy different names are used in different models. Strict hierarchies are included explicitly or implicitly in all proposed models.

Since none of the models takes into account different analysis criteria, alternative and parallel hierarchies cannot be distinguished. Further, very few models propose a graphical representation for the different hierarchies that facilitate their distinction at the schema and instance levels.

To show the feasibility of implementing the different types of hierarchies, we present in Malinowski and Zimányi, (2006, 2008) their mappings to the relational model and give examples of their implementation in Analysis Services and Oracle OLAP.

FUTURE TRENDS

Even though some of the presented hierarchies are considered as an advanced feature of multidimensional models (Torlone, 2003), there is a growing interest in having them in the research community and in commercial products.

Nevertheless, several issues have yet to be addressed. It is necessary to develop aggregation procedures for all types of hierarchies defined in this paper. Some proposals for managing them exist (e.g., Pedersen *et al.*, 2001; Abelló *et al.*, 2006; Hurtado & Gutierrez, 2007). However, not all hierarchies are considered and some of the proposed solutions may not be satisfactory for users since they transform complex hierarchies into simpler ones to facilitate their manipulation.

Another issue is to consider the inclusion of other ER constructs in the multidimensional model, such as weak entity types, multivalued or composite attributes. The inclusion of these features is not straightforward and requires analysis of their usefulness in multidimensional modeling.

CONCLUSION

Data warehouse and OLAP applications use a multidimensional view of data including dimensions, hierarchies, facts, and measures. In particular, hierarchies are important in order to automatically aggregate the measures for analysis purposes.

We advocated that it is necessary to represent data requirements for data warehouse and OLAP applications at a conceptual level. We proposed the MultiDim model, which includes graphical notations for the different elements of a multidimensional model. These notations allow a clear distinction of each hierarchy type taking into account their differences at the schema and at the instance levels.

We also provided a classification of hierarchies. This classification will help designers to build conceptual models of multidimensional databases. It will also give users a better understanding of the data to be analyzed, and provide a better vehicle for studying how to implement such hierarchies using current OLAP tools. Further, the proposed hierarchy classification provides OLAP tool implementers the requirements needed by business users for extending the functionality offered by current tools.

KEY TERMS

Conceptual Model: A model for representing schemas that are designed to be as close as possible to users' perception, not taking into account any implementation considerations.

MultiDim Model: A conceptual multidimensional model used for specifying data requirements for data warehouse and OLAP applications. It allows one to represent dimensions, different types of hierarchies, and facts with associated measures.

Dimension: An abstract concept for grouping data sharing a common semantic meaning within the domain being modeled.

Hierarchy: A sequence of levels required for establishing meaningful paths for roll-up and drill-down operations.

Level: A type belonging to a dimension. A level defines a set of attributes and is typically related to other levels for defining hierarchies.

Multidimensional Model: A model for representing the information requirements of analytical applications. A multidimensional model comprises facts, measures, dimensions, and hierarchies.

Star Schema: A relational schema representing multidimensional data using de-normalized relations.

Snowflake Schema: A relational schema representing multidimensional data using normalized relations.

ENDNOTE

1 A detailed description of proposals for multidimensional modeling can be found in Torlone (2003).

Constrained Data Mining

Brad Morantz
Science Applications International Corporation, USA

INTRODUCTION

Mining a large data set can be time consuming, and without constraints, the process could generate sets or rules that are invalid or redundant. Some methods, for example clustering, are effective, but can be extremely time consuming for large data sets. As the set grows in size, the processing time grows exponentially.

In other situations, without guidance via constraints, the data mining process might find morsels that have no relevance to the topic or are trivial and hence worthless. The knowledge extracted must be comprehensible to experts in the field. (Pazzani, 1997) With time-ordered data, finding things that are in reverse chronological order might produce an impossible rule. Certain actions always precede others. Some things happen together while others are mutually exclusive. Sometimes there are maximum or minimum values that can not be violated. Must the observation fit all of the requirements or just most. And how many is "most?"

Constraints attenuate the amount of output (Hipp & Guntzer, 2002). By doing a first-stage constrained mining, that is, going through the data and finding records that fulfill certain requirements before the next processing stage, time can be saved and the quality of the results improved. The second stage also might contain constraints to further refine the output. Constraints help to focus the search or mining process and attenuate the computational time. This has been empirically proven to improve cluster purity. (Wagstaff & Cardie, 2000)(Hipp & Guntzer, 2002)

The theory behind these results is that the constraints help guide the clustering, showing where to connect, and which ones to avoid. The application of user-provided knowledge, in the form of constraints, reduces the hypothesis space and can reduce the processing time and improve the learning quality.

BACKGROUND

Data mining has been defined as the process of using historical data to discover regular patterns in order to improve future decisions. (Mitchell, 1999) The goal is to extract usable knowledge from data. (Pazzani, 1997) It is sometimes called knowledge discovery from databases (KDD), machine learning, or advanced data analysis. (Mitchell, 1999)

Due to improvements in technology, the amount of data collected has grown substantially. The quantities are so large that proper mining of a database can be extremely time consuming, if not impossible, or it can generate poor quality answers or muddy or meaningless patterns. Without some guidance, it is similar to the example of a monkey on a typewriter: Every now and then, a real word is created, but the vast majority of the results is totally worthless. Some things just happen at the same time, yet there exists no theory to correlate the two, as in the proverbial case of skirt length and stock prices.

Some of the methods of deriving knowledge from a set of examples are: association rules, decision trees, inductive logic programming, ratio rules, and clustering, as well as the standard statistical procedures. Some also use neural networks for pattern recognition or genetic algorithms (evolutionary computing). Semi-supervised learning, a similar field, combines supervised learning with self-organizing or unsupervised training to gain knowledge (Zhu, 2006) (Chappelle et al., 2006). The similarity is that both constrained data mining and semi-supervised learning utilize the a-priori knowledge to help the overall learning process.

Unsupervised and unrestricted mining can present problems. Most clustering, rule generation, and decision tree methods have order O much greater than N, so as the amount of data increases, the time required to generate clusters increases at an even faster rate. Additionally, the size of the clusters could increase, making it harder to find valuable patterns. Without

constraints, the clustering might generate rules or patterns that have no significance or correlation to the problem at hand. As the number of attributes grows, the complexity and the number of patterns, rules, or clusters grows exponentially, becoming unmanageable and overly complex. (Perng et al,2002)

A constraint is a restriction; a limitation. By adding constraints, one guides the search and limits the results by applying boundaries of acceptability. This is done when retrieving the data to search (i.e. using SQL) and/or during the data mining process. The former reduces the amount of data that will be organized and processed in the mining by removing extraneous and unacceptable regions. The latter is what directly focuses the process to the desired results.

MAIN FOCUS

Constrained Data Mining Applications

Constrained data mining has been said to be the "best division of labor," where the computer does the number crunching and the human provides the focus of attention and direction of the search by providing search constraints. (Han et al, 1999) Constraints do two things: 1) They limit where the algorithm can look; and 2) they give hints about where to look. (Davidson & Ravi, 2005) As a constraint is a guide to direct the search, combining knowledge with inductive logic programming is a type of constraint, and that knowledge directs the search and limits the results. This combination is extremely effective. (Muggleton, 1999)

If every possible pattern is selected and the constraints tested afterwards, then the search space becomes large and the time required to perform this becomes excessive. (Boulicaut & Jeudy, 2005) The constraints must be in place during the search. They can be as simple as thresholds on rule quality measure support or confidence, or more complicated logic to formulate various conditions. (Hipp & Guntzer, 2002)

In mining with a structured query language (SQL), the constraint can be a predicate for association rules. (Ng et al, 1998) In this case, the rule has a constraint limiting which records to select. This can either be the total job or produce data for a next stage of refinement. For example, in a large database of bank transactions, one could specify only records of ACH transactions that occurred during the first half of this year. This reduces the search space for the next process.

A typical search would be:

```
select * where year = 2006 and where month < 7
```

It might be necessary that two certain types always cluster together (must-link), or the opposite, that they may never be in the same cluster (cannot-link). (Ravi & Davidson, 2005) In clustering (except fuzzy clustering), elements either are or are not in the same cluster. (Boulicaut & Jeudy, 2005) Application of this to the above example could further require that the transactions must have occurred on the first business day of the week (must-link), even further attenuating the dataset. It could be even further restricted by adding a cannot-link rule such as not including a national holiday. In the U.S.A., this rule would reduce the search space by a little over 10 percent. The rule would be similar to:

```
select * where day = monday and day <8 and where
day \=holiday
```

If mining with a decision tree, pruning is an effective way of applying constraints. This has the effect of pruning the clustering dendogram (clustering tree). If none of the elements on the branch meet the constraints, then the entire branch can be pruned. (Boulicaut & Jeudy, 2005) In Ravi and Davidson's study of image location for a robot, the savings from pruning were between 50 percent and 80 percent. There was also a typical improvement of a 15 percent reduction in distortion in the clusters, and the class label purity improved. Applying this to the banking example, any branch that had a Monday national holiday could be deleted. This would save about five weeks a year, or about 10 percent.

The Constraints

Types of constraints:

1. **Knowledge-based:** what type of relationships are desired, association between records, classification, prediction, or unusual repetitive patterns
2. **Data-based:** range of values, dates or times, relative values
3. **Rules:** time order, relationships, acceptable patterns

4. **Statistical:** at what levels are the results interesting (Han et al, 1999)
5. **Linking:** must-link and cannot-link (Davidson & Ravi, 2005)

Examples of constraints:

1. Borders
2. Relationships
3. Syntax
4. Chronology
5. Magnitude
6. Phase
7. Frequency

Sources of constraints:

1. A priori knowledge
2. Goals
3. Previous mining of the data set
4. The analyst
5. Insight into the data, problem, or situation
6. Time
7. User needs
8. Customer information or instruction
9. Domain knowledge

Attribute relationships and dependencies can provide needed constraints. Expert and/or domain knowledge, along with user preferences, can provide additional rules. (Perng et al., 2002)

Common or domain knowledge as well as item taxonomies can add insight and direct which attributes should be included or excluded, how they should be used in the grouping, and the relationships between the two. (Perng et al., 2002)

When observations occur over time, some data occurs at a time when it could not be clustered with another item. For example, if A always occurs before B, then one should only look at records where this is the case. Furthermore, there can also be a maximum time between the two observations; if too much time occurs between A and B, then they are not related. This is a mathematical relationship, setting a window of allowable time. The max-gap strategy sets a limit for the maximum time that can be between two elements. (Boulicaut & Jeudy, 2005) An example is:

IF ((time(A) < time(B)) AND (time(B) – time(A) < limit))

Domain knowledge can also cause groupings. Some examples are: knowing that only one gender uses a certain item, most cars have four tires, or that something is only sold in pairs. These domain knowledge rules help to further divide the search space. They produce limitations on the data.

Another source of constraints is the threshold of how many times or what percentage the discovered pattern has occurred in the data set. (Wojciechowski & Zakrewicz, 2002) Confidence and support can create statistical rules that reduce the search space and apply probabilities to found rules. Using ratio rules is a further refinement to this approach, as it predicts what will be found based upon past experience. (Korn et al., 2000)

Using the Constraints

User interactive constraints can be implemented by using a data mining query language generating a class of conditions that will extract a subset of the original database. (Goethals & van der Bussche, 2003) Some miners push the constraints into the mining process to attenuate the number of candidates at each level of the search. (Perng et al., 2002) This might suffice or further processing might be done to refine the data down to the desired results. Our research has shown that if properly done, constraints in the initial phase not only reduce computation time, but also produce clearer and more concise rules, with clusters that are statistically well defined. Setting the constraints also reduces computation time in clustering by reducing the number of distance calculations required. Using constraints in clustering increases accuracy while it reduces the number of iterations, which translates to faster processing times. (Davidson & Ravi, 2005)

Some researchers claim that sometimes it is more effective to apply the constraints after the querying process, rather than within the initial mining phase. (Goethals & van der Bussche, 2003) Using constraints too early in the process can have shortcomings or loss of information, and therefore, some recommend applying constraints later. (Hipp & Guntzer, 2002) The theory is that something might be excluded that should not have been.

Ratio rules (Korn et al, 2000) allow sorting the data into ranges of ratios, learning ratio patterns, or finding anomalies and outliers. Ratio rules allow a better understanding of the relationships within the data. These ratios are naturally occurring, in everyday life. A person wears, one skirt, one blouse, and zero or one hat. The numbers do not vary from that. In many things in life, ratios exist, and employing them in data mining will improve the results.

Ratio rules offer the analyst many opportunities to craft additional constraints that will improve the mining process. These rules can be used to look at anomalies and see why they are different, to eliminate the anomalies and only consider average or expected performances, split the database into ratio ranges, or only look within certain specified ranges. Generating ratio rules requires a variance-covariance matrix, which can be time- and resource-consuming.

In a time-ordered database, it is possible to relate the changes and put them into chronological order. The changes then become the first derivative over time and can present new information. This new database is typically smaller than the original one. Mining the changes database can reveal even more information.

In looking for relationships, one can look in both directions, both to see A occur and then look for B, or after finding B, look for the A that could have been the cause. After finding an A, the search is now only for the mating B, and nothing else, reducing even more the search space and processing time. A maximum time interval makes this a more powerful search criteria. This further reduces the search space.

User desires, a guide from the user, person, or group commissioning the data mining, is an important source. Why spend time and energy getting something that is not wanted. This kind of constraint is often overlooked but is very important. The project description will indicate which items or relationships are not of interest, are not novel, or are not of concern. The user, with this domain knowledge, can direct the search.

Domain knowledge, with possible linking to other databases, will allow formulating a maximum or minimum value of interrelation that can serve as a limit and indicate a possibility. For example, if a person takes the bus home, and we have in our database the bus schedule, then we have some expected times and limits for the arrival time at home. Furthermore, if we knew how far the person lived from the bus stop, and how fast the person walked, we could calculate a window of acceptable times.

Calculations can be done on the data to generate the level of constraint. Some of this can be done in the query, and more complex mathematics can be implemented in post processing. Our research has used IDL for exploratory work and then implemented in Fortran 95 for automated processing. Fortran 95, with its matrix manipulations and built-in array functions, allowed fast programming. The question is not which constraints to use, but rather what is available. In applying what knowledge is in hand, the process is more focused and produces more useful information.

FUTURE TRENDS

An automated way to implement the constraints simply into the system without having to hard code them into the actual algorithm (as the author did in his research) would simplify the process and facilitate acceptance into the data mining community. Maybe a table where rules can be entered, or possibly a specialized programming language, would facilitate this process. The closer that it can approach natural language, the more likely it is to be accepted. The entire process is in its infancy and, over time, will increase performance both in speed and accuracy. One of the most important aspects will be the ability to uncover the hidden nuggets of information or relatioships that are both important and unexpected.

With the advent of multi-core processors, the algorithms for searching and clustering the data will change in a way to fully (or at least somewhat) utilize this increased computing power. More calculations and comparisons will be done on the fly as the data is being processed. This increased computing power will not only process faster, but will allow for more intelligent and computationally intensive constraints and directed searches.

CONCLUSION

Large attenuation in processing times has been proven by applying constraints that have been derived from user or domain knowledge, attribute relationships and dependencies, customer goals, and insights into given problems or situations (Perng et al., 2002). In applying these rules, the quality of the results improves, and the results are quite often more meaningful.

KEY TERMS

Anomaly: An irregular value, or one that is beyond the limits of acceptability; in statistics, a value further from the mean than a specified distance, typically 2 or 3 sigma.

Association Rule: A data mining term for a rule that describes items in a basket that are dependent on other items also in the basket.

Cluster: A collection of like items, similar along specified dimensions. Cluster analysis is a process where items or data points are sorted by their similarities and separated by their differences.

Constraint: A restriction, a forced guideline, a specific confining rule; in data mining, it is an exacting, specific rule defining specific intents and areas.

Fortran 95: A mathematical programming language, one of the first computer languages ever developed; the latest versions are optimized for matrix operations and multiprocessing.

Ratio Rule: A data mining term for a quantity relationship between attributes.

Tree building: A mathematical process if generating a decision tree that is data-driven and can be used for classification.

Constraint-Based Association Rule Mining

Carson Kai-Sang Leung
The University of Manitoba, Canada

INTRODUCTION

The problem of association rule mining was introduced in 1993 (Agrawal et al., 1993). Since then, it has been the subject of numerous studies. Most of these studies focused on either performance issues or functionality issues. The former considered *how* to compute association rules efficiently, whereas the latter considered *what* kinds of rules to compute. Examples of the former include the Apriori-based mining framework (Agrawal & Srikant, 1994), its performance enhancements (Park et al., 1997; Leung et al., 2002), and the tree-based mining framework (Han et al., 2000); examples of the latter include extensions of the initial notion of association rules to other rules such as dependence rules (Silverstein et al., 1998) and ratio rules (Korn et al., 1998). In general, most of these studies basically considered the data mining exercise in isolation. They did not explore how data mining can interact with the human user, which is a key component in the broader picture of knowledge discovery in databases. Hence, they provided little or no support for user focus. Consequently, the user usually needs to wait for a long period of time to get numerous association rules, out of which only a small fraction may be interesting to the user. In other words, the user often incurs a high computational cost that is disproportionate to what he wants to get. This calls for *constraint-based association rule mining*.

BACKGROUND

Intuitively, *constraint-based association rule mining* aims to develop a systematic method by which the user can find important association among items in a database of transactions. By doing so, the user can then figure out how the presence of some *interesting* items (i.e., items that are interesting to the user) implies the presence of other interesting items in a transaction. To elaborate, many retailers, such as supermarkets, carry a large number of items. Progress in bar-code technology has made it possible to record items purchased on a per-transaction basis. Each customer purchases one or more items in a given transaction. Types and quantities of different items can vary significantly among transactions and/or customers. Given a database of sales transactions, constraint-based association rule mining helps discover important relationships between the different interesting items so that retailers can learn how the presence of some interesting items in a transaction relates to the presence of other interesting items in the same transaction. The discovered rules reveal the buying patterns in consumer behaviour. These rules are useful in making decisions in applications such as customer targeting, shelving, and sales promotions. Although we describe this problem in the context of the shoppers' market basket application, constraint-based association rule mining is also useful in many other applications such as finding important relationships from financial time series, Web click streams, and biomedical records. When compared with its traditional unconstrained counterpart, constraint-based association rule mining allows the user to express his interest via the use of constraints. By exploiting some nice properties of these constraints, the user can efficiently find association rules that are interesting to him.

More formally, the problem of *constraint-based association rule mining* can be described as follows. Given a database of transactions, each transaction corresponds to a set of items (also known as an *itemset*) that appear together (say, merchandise items that are purchased together by a customer in a single visit to a checkout counter). Constraint-based association rule mining generally consists of two key steps. First, it finds interesting frequent itemsets (i.e., frequent itemsets that satisfy user-specified constraints) from the database of transactions. An itemset is frequent if its frequency exceeds or equals the user-specified minimum frequency threshold. Then, it uses these interesting frequent itemsets to form association rules that satisfy user-specified constraints. Typically, rules are of the form "A➔C" such that both A (which represents the antecedent of the rule) and C (which represents the consequent of the rule) are interesting frequent itemsets.

MAIN FOCUS

Constraint-based association rule mining generally aims to mine association rules that satisfy user-specified constraints, where the antecedent and the consequent of the rules are frequent itemsets that satisfy user-specified constraints. It has several advantages over its traditional unconstrained counterpart. First, it provides *user flexibility* so that the user is able to express his interest by specifying various types of constraints. Second, it leads to *system optimization* so that the computational cost for rules is proportionate to what the user wants to get. Note that, on the surface, it may appear that constraint checking would incur extra computation. However, the constraints can be pushed deep inside the mining process through the exploitation of their nice properties, and thus reducing computation. In the following, we describe *what* types of constraints have been proposed and we also discuss *how* the properties of constraints can be exploited to efficiently find association rules that satisfy the constraints.

Types of Constraints

The user-specified constraints can be categorized according to their types or according to their properties. For constraint-based association rule mining, the user can specify various types of constraints—which include knowledge-type constraints, data constraints, dimension constraints, level constraints, interestingness constraints, and rule constraints (Han & Kamber, 2006). Let us give a brief overview of these types of user-specified constraints as follows:

- **Knowledge-type constraints** allow the user to specify what type of knowledge (e.g., association, correlation, causality) to be discovered.
- **Data constraints** allow the user to specify what set of data (e.g., sales transactions, financial time series, Web click streams, biomedical records) to be used in the mining process.
- **Dimension constraints** allow the user to specify how many dimensions of data to be used when forming rules. By specifying dimension constraints, the user could express his interest of finding one-dimensional rules (e.g., "buy(milk) ➔ buy(bread)" that involves only one dimension "buy"), two-dimensional rules (e.g., "occupation(student) ➔ buy(textbook)" that relates two dimensions "occupation" and "buy"), or multi-dimensional rules.
- **Level constraints** allow the user to specify how many levels of the concept hierarchy to be used in the mining process. By specifying level constraints, the user could express his interest of finding single-level rules (e.g., "milk➔bread" that involves only a single level of the concept hierarchy) or multi-level rules (e.g., "dairy product ➔ Brand-X white bread" that involves multiple levels as (1) milk is a dairy product and (2) the consequent of this rule is a brand of white bread, which in turn is a kind of bread).
- **Interestingness constraints** allow the user to specify what statistical measure (e.g., support, confidence, lift) or thresholds to be applied when computing the interestingness of rules.
- **Rule constraints** allow the user to specify what forms of rules (e.g., what items to be included in or excluded from the rules) to be mined.

Over the past decade, several specific constraints have been proposed for constraint-based association rule mining. The following are some notable examples of rule constraints. For instance, Srikant et al. (1997) considered *item constraints*, which allow the user to impose a Boolean expression over the presence or absence of items in the association rules. The item constraint "(jackets AND shoes) OR (shirts AND (NOT hiking boots))" expresses the user interest of finding rules that either contain jackets and shoes or contain shirts but not hiking boots.

Lakshmanan, Ng, and their colleagues (Ng et al., 1998; Lakshmanan et al., 1999, 2003) proposed a constraint-based association rule mining framework, within which the user can specify a rich set of rule constraints. These constraints include SQL-style aggregate constraints and non-aggregate constraints like domain constraints. *SQL-style aggregate constraints* are of the form "*agg*(S.*attribute*) θ *constant*", where *agg* is an SQL-style aggregate function (e.g., min, max, sum, avg) and θ is a Boolean comparison operator (e.g., =, ≠, <, ≤, ≥, >). For example, the aggregate constraint "min(S.Price) ≥ 20" expresses that the minimum price of all items in an itemset S is at least $20. *Domain constraints* are non-aggregate constraints, and they can be of the following forms: (1) "S.*attribute* θ *constant*", where θ is a Boolean comparison operator; (2) "*constant* ∈ S.*attribute*"; (3) "*constant* ∉ S.*attribute*";

or (4) "S.*attribute* φ *set of constants*", where φ is a set comparison operator (e.g., $=, \neq, \subset, \not\subset, \subseteq, \supseteq, \supset$). For example, the domain constraint "S.Type = snack" expresses that each item in an itemset S is snack. Other examples include domain constraints "10 $\in$ S.Price" (which expresses that a $10-item must be in an itemset S), "300 $\notin$ S.Price" (which expresses that an itemset S does not contain any $300-item), and "S.Type $\supseteq$ {snack, soda}" (which expresses that an itemset S must contain some snacks and soda).

In addition to allowing the user to impose these aggregate and non-aggregate constraints on the antecedent as well as the consequent of the rules, Lakshmanan et al. (1999) also allowed the user to impose *two-variable constraints* (i.e., constraints that connect two variables representing itemsets). For example, the two-variable constraint "max(A.Price) $\leq$ min(C.Price)" expresses that the maximum price of all items in an itemset A is no more than the minimum price of all items in an itemset C, where A and C are itemsets in the antecedent and the consequent of a rule respectively.

Gade et al. (2004) mined closed itemsets that satisfy the *block constraint*. This constraint determines the significance of an itemset S by considering the dense block formed by items within S and by transactions associating with S.

Properties of Constraints

A simple way to find association rules satisfying the aforementioned user-specified constraints is to perform a post-processing step (i.e., test to see if each association rule satisfies the constraints). However, a better way is to exploit properties of constraints so that the constraints can be pushed inside the mining process, which in turn make the computation for association rules satisfying the constraints be proportionate to what the user wants to get. Hence, besides categorizing the constraints according to their types, constraints can also be categorized according to their properties—which include anti-monotonic constraints, succinct constraints, monotonic constraints, and convertible constraints.

Lakshmanan, Ng, and their colleagues (Ng et al., 1998; Lakshmanan et al., 2003) developed the CAP and the DCF algorithms in the constraint-based association rule mining framework mentioned above. Their algorithms exploit properties of anti-monotonic constraints to give as much pruning as possible. A constraint such as "min(S.Price) $\geq$ 20" (which expresses that the minimum price of all items in an itemset S is at least $20) is *anti-monotonic* because any itemset S violating this constraint implies that all its supersets also violate the constraint. Note that, for any itemsets S & Sup such that S $\subseteq$ Sup, it is always the case that min(Sup.Price) $\leq$ min(S.Price). So, if the minimum price of all items in S is less than $20, then the minimum price of all items in Sup (which is a superset of S) is also less than $20. By exploiting the property of anti-monotonic constraints, both CAP and DCF algorithms can safely remove all the itemsets that violate anti-monotonic constraints and do not need to compute any superset of these itemsets.

Note that the constraint "support(S) $\geq$ minsup" commonly used in association rule mining (regardless whether it is constraint-based or not) is also *anti-monotonic*. The Apriori, CAP and DCF algorithms all exploit the property of such an anti-monotonic constraint in a sense that they do not consider supersets of any infrequent itemset (because these supersets are guaranteed to be infrequent).

In addition to anti-monotonic constraints, both CAP and DCF algorithms (in the Apriori-based framework) also exploit succinct constraints. Moreover, Leung et al. (2002) proposed a constraint-based mining algorithm—called FPS—to find frequent itemsets that satisfy succinct constraints in a tree-based framework. A constraint "10 $\in$ S.Price" (which expresses that a $10-item must be in an itemset S) is *succinct* because one can directly generate precisely *all* and *only* those itemsets satisfying this constraint by using a precise "formula". To elaborate, all itemsets satisfying "10 $\in$ S.Price" can be precisely generated by combining a $10-item with some other (optional) items of any prices. Similarly, the constraint "min(S.Price) $\geq$ 20" is also succinct because all itemsets satisfying this constraint can be precisely generated by combining items of price at least $20. By exploiting the property of succinct constraints, the CAP, DCF and FPS algorithms use the "formula" to directly generate precisely *all* and *only* those itemsets satisfying the succinct constraints. Consequently, there is no need to generate and then exclude itemsets not satisfying the constraints. Note that a succinct constraint can also be anti-monotonic (e.g., "min(S.Price) $\geq$ 20").

Grahne et al. (2000) exploited monotonic constraints when finding correlated itemsets. A constraint such as "10 $\in$ S.Price" is *monotonic* because any itemset S

satisfying this constraint implies that all supersets of S also satisfy the constraint. By exploiting the property of monotonic constraints, one does not need to perform further constraint checking on any superset of an itemset S once S is found to be satisfying the monotonic constraints. Note that this property deals with satisfaction of constraints, whereas the property of anti-monotonic constraints deals with violation of constraints (i.e., any superset of an itemset violating anti-monotonic constraints must also violate the constraints).

Bonchi and Lucchese (2006) also exploited monotonic constraints, but they did so when mining closed itemsets. Bucila et al. (2003) proposed a dual mining algorithm—called DualMiner—that exploits both anti-monotonic and monotonic constraints simultaneously to find itemsets satisfying the constraints.

Knowing that some tough constraints such as "sum(S.Price) $\leq$ 70" (which expresses that the total price of all items in an itemset S is at most \$70) are not anti-monotonic or monotonic in general, Pei et al. (2004) converted these constraints into ones that possess anti-monotonic or monotonic properties. For example, when items within each itemset are arranged in ascending order of prices, for any *ordered* itemsets S & Sup, if S is a prefix of Sup, then Sup is formed by adding to S those items that are more expensive than any item in S (due to the ascending price order). So, if S violates the constraint (i.e., the total price of all items in S exceeds \$70), then so does Sup (i.e., the total price of all items in Sup also exceeds \$70). Such a constraint is called *convertible anti-monotonic constraint*.

Similarly, by arranging items in ascending order of prices, the constraint "sum(S.Price) $\geq$ 60" possesses monotonic properties (i.e., if an itemset S satisfies this constraint, then so does any *ordered* itemset having S as its prefix). Such a constraint is called *convertible monotonic constraint.* To a further extent, Bonchi and Lucchese (2007) exploited other tough constraints involving aggregate functions variance and standard deviation.

FUTURE TRENDS

A future trend is to integrate constraint-based association rule mining with other data mining techniques. For example, Lakshmanan et al. (2003) and Leung (2004b) integrated *interactive mining* with constraint-based association rule mining so that the user can interactively monitor the mining process and change the mining parameters. As another example, Leung (2004a) proposed a *parallel mining* algorithm for finding constraint-based association rules.

Another future trend is to conduct constraint-based mining on different kinds of data. For example, Leung and Khan (2006) applied constraint-based mining on *data streams*. Pei et al. (2007) and Zhu et al. (2007) applied constraint-based mining on *time sequences* and on *graphs*, respectively.

CONCULSION

Constraint-based association rule mining allows the user to get association rules that satisfy user-specified constraints. There are various types of constraints such as rule constraints. To efficiently find association rules that satisfy these constraints, many mining algorithms exploited properties of constraints such as anti-monotonic, succinct, and monotonic properties of constraints. In general, constraint-based association rule mining is not confined to finding interesting association from market basket data. It can also be useful in many other real-life applications. Moreover, it can be applied on various kinds of data and/or integrated with different data mining techniques.

KEY TERMS

Anti-Monotonic Constraint: A constraint C is *anti-monotonic* if and only if an itemset S satisfying C implies that any subset of S also satisfies C.

Closed Itemset: An itemset S is *closed* if there does not exist any proper superset of S that shares the same frequency with S.

Convertible Anti-Monotonic Constraint: A constraint C is *convertible anti-monotonic* provided there is an order R on items such that an ordered itemset S satisfying C implies that any prefix of S also satisfies C.

Convertible Constraint: A constraint C is *convertible* if and only if C is a convertible anti-monotonic constraint or a convertible monotonic constraint.

Convertible Monotonic Constraint: A constraint C is *convertible monotonic* provided there is an order R on items such that an ordered itemset S violating C implies that any prefix of S also violates C.

Correlated Itemset: An itemset S consisting of k items is *correlated* if any of the 2^k combinations of the items in S and their complements is not independent.

Frequent Itemset: An itemset is *frequent* if its frequency exceeds or equals the user-specified minimum threshold.

Itemset: An *itemset* is a set of items.

Monotonic Constraint: A constraint C is *monotonic* if and only if an itemset S violating C implies that any subset of S also violates C.

Succinct Constraint: A constraint C is *succinct* provided that all itemsets satisfying C can be expressed in terms of powersets of a fixed number of succinct sets using the set union and/or set difference operators. A succinct set is an itemset, in which items are selected from the domain using the usual SQL selection operator. In simple terms, a constraint C is *succinct* meaning that all and only those itemsets satisfying C can be explicitly and precisely generated using some precise "formula".

Constraint-Based Pattern Discovery

INTRODUCTION

Devising fast and scalable algorithms, able to crunch huge amount of data, was for many years one of the main goals of data mining research. But then we realized that this was not enough. It does not matter how efficient such algorithms can be, the results we obtain are often of limited use in practice. Typically, the knowledge we seek is in a small pool of local patterns hidden within an ocean of irrelevant patterns generated from a sea of data. Therefore, it is the volume of the results itself that creates a second order mining problem for the human expert. This is, typically, the case of association rules and frequent itemset mining (Agrawal & Srikant, 1994), to which, during the last decade a lot of researchers have dedicated their (mainly algorithmic) investigations. The computational problem is that of efficiently mining from a database of transactions, those itemsets which satisfy a user-defined constraint of minimum frequency.

Recently the research community has turned its attention to more complex kinds of frequent patterns extracted from more structured data: *sequences*, *trees*, and *graphs*. All these different kinds of pattern have different peculiarities and application fields, but they all share the same computational aspects: a usually very large input, an exponential search space, and a too large solution set. This situation—too many data yielding too many patterns—is harmful for two reasons. First, performance degrades: mining generally becomes inefficient or, often, simply unfeasible. Second, the identification of the fragments of interesting knowledge, blurred within a huge quantity of mostly useless patterns, is difficult. The paradigm of *constraint-based pattern mining* was introduced as a solution to both these problems. In such paradigm, it is the user who specifies to the system what is *interesting* for the current application: constraints are a tool to drive the mining process towards potentially interesting patterns, moreover they can be pushed deep inside the mining algorithm in order to fight the exponential search space curse, and to achieve better performance (Srikant et al., 1997; Ng et al. 1998; Han et al., 1999; Grahne et al., 2000).

BACKGROUND

Intuitively the constraint-based pattern mining problem requires to extract from a database the patterns which satisfy a conjunction of constraints. Such conjunction usually contains the minimum frequency constraint, plus other constraints which can be defined on the structure of the patterns (e.g., on the size of the patterns, or on the singletons that the patterns may or may not contain), or on some aggregated properties of the patterns (e.g., the sum of "prices", or the average of "weights").

The following is an example of constraint-based mining query:

$$Q : supp_D(X) \geq 1500 \wedge |X| \geq 5 \wedge avg(X.weight) \leq 15 \wedge sum(X.price) \geq 22$$

it requires to mine, from database D, all patterns which are frequent (have a support at least 1500), have cardinality at least 5, have average weight at most 15 and a sum of prices at least 22.

The constraint-based mining paradigm has been successfully applied in medical domain (Ordonez et al., 2001), and in biological domain (Besson et al., 2005). According to the constraint-based mining paradigm, the data analyst must have a high-level vision of the pattern discovery system, without worrying about the details of the computational engine, in the very same way a database designer has not to worry about query optimization: she must be provided with a set of primitives to declaratively specify to the pattern discovery system how the interesting patterns should look like, i.e., which conditions they should obey. Indeed, the task of composing all constraints and producing the most efficient mining strategy (execution plan) for the given data mining query, should be left to an underlying *query optimizer*. Therefore, constraint-based frequent pattern mining has been seen as a query optimization problem

(Ng et al., 1998), i.e., developing efficient, sound and complete evaluation strategies for constraint-based mining queries.

Among all the constraints, the frequency constraint is computationally the most expensive to check, and many algorithms, starting from Apriori, have been developed in the years for computing patterns which satisfy a given threshold of minimum frequency (see the FIMI repository http://fimi.cs.helsinki.fi for the state-of-the-art of algorithms and softwares). Therefore, a naïve solution to the constraint-based frequent pattern problem could be to first mine all frequent patterns and then test them for the other constraints satisfaction. However more efficient solutions can be found by analyzing the properties of constraints comprehensively, and exploiting such properties in order to push constraints in the frequent pattern computation. Following this methodology, some classes of constraints which exhibit nice properties (e.g., monotonicity, anti-monotonicity, succinctness, etc) have been individuated in the last years, and on the basis of these properties efficient algorithms have been developed.

MAIN RESULTS

A first work defining classes of constraints which exhibit nice properties is Ng et al. (1998). In that work is introduced an Apriori-like algorithm, named CAP, which exploits two properties of constraints, namely *anti-monotonicity* and *succinctness*, in order to reduce the frequent itemsets computation. Four classes of constraints, each one with its own associated computational strategy, are identified:

1. constraints that are anti-monotone but not succinct;
2. constraints that are both anti-monotone and succinct;
3. constraints that are succinct but not anti-monotone;
4. constraints that are neither.

Anti-Monotone and Succinct Constraints

An anti-monotone constraint is such that, if satisfied by a pattern, it is also satisfied by all its subpatterns. The frequency constraint is the most known example of a anti-monotone constraint. This property, *the anti-monotonicity of frequency*, is used by the Apriori (Agrawal & Srikant, 1994) algorithm with the following heuristic: if a pattern X does not satisfy the frequency constraint , then no super-pattern of X can satisfy the frequency constraint, and hence they can be pruned. This pruning can affect a large part of the search space, since itemsets form a lattice. Therefore the Apriori algorithm operates in a level-wise fashion moving bottom-up, level-wise, on the patterns lattice, from small to large itemsets, generating the set of *candidate patterns* at iteration k from the set of frequent patterns at the previous iteration. This way, each time it finds an infrequent pattern it implicitly prunes away all its supersets, since they will not be generated as candidate itemsets. Other anti-monotone constraints can easily be pushed deeply down into the frequent patterns mining computation since they behave exactly as the frequency constraint: if they are not satisfiable at an early level (small patterns), they have no hope of becoming satisfiable later (larger patterns). Conjoining other anti-monotone constraints to the frequency one we just obtain a more selective anti-monotone constraint. As an example, if "price" has positive values, then the constraint $sum(X.price) \leq 50$ is anti-monotone. Trivially, let the pattern X be *{olive_oil, tomato_can, pasta, red_wine}* and suppose that it satisfies such constraints, then any of its sub-patterns will satisfy the constraint as well: for instance the set *{olive_oil, red_wine}* for sure will have a sum of prices less than 50. On the other hand, if X does not satisfy the constraint, then it can be pruned since none of its supersets will satisfy the constraint.

Informally, a succinct constraint is such that, whether a pattern X satisfies it or not, can be determined based on the basic elements of X. Succinct constraints are said to be *pre-counting pushable*, i.e., they can be satisfied at candidate-generation time just taking into account the pattern and the single items satisfying the constraint. These constraints are pushed in the level-wise computation by adapting the usual *candidate-generation* procedure of the Apriori algorithm, w.r.t. the given succinct constrain, in such a way that it prunes every pattern which does not satisfy the constraint and that it is not a sub-pattern of any further valid pattern.

Constraints that are both anti-monotone and succinct can be pushed completely in the level-wise computation before it starts (at pre-processing time). For instance, consider the constraint $min(X.price) \geq v$. It is straightforward to see that it is both anti-monotone and succinct. Thus, if we start with the first set of candidates

formed by all singleton items having price greater than *v*, during the computation we will generate all and only those patterns satisfying the given constraint. Constraints that are neither succinct nor anti-monotone are pushed in the CAP computation by inducing weaker constraints which are either anti-monotone and/or succinct. Consider the constraint $avg(X.price) \leq v$ which is neither succinct nor anti-monotone. We can push the weaker constraint $min(X.price) \leq v$ with the advantage of reducing the search space and the guarantee that at least all the valid patterns will be generated.

Monotone Constraints

Monotone constraints work the opposite way of anti-monotone constraints. Whenever a pattern satisfies a monotone constraint, so will do all its super-patterns (or the other way around: if a pattern does not satisfy a monotone constraint, none of its sub-pattern will satisfy the constraint as well). The constraint $sum(X.price) \geq 500$ is monotone, since all prices are not negative. Trivially, if a pattern X satisfies such constraint, then any of its super-patterns will satisfy the constraint as well. Since the frequency computation moves from small to large patterns, we can not push such constraints in it straightforwardly. At an early stage, if a pattern is too small or too cheap to satisfy a monotone constraint, we can not yet say nothing about its supersets. Perhaps, just adding a very expensive single item to the pattern could raise the total sum of prices over the given threshold, thus making the resulting pattern satisfy the monotone constraint. Many studies (De Raedt & Kramer, 2001; Bucila et al., 2002; Boulicaut & Jeudy, 2002; Bonchi et al., 2003a) have attacked this computational problem focussing on its search space, and trying some smart exploration of it. For example, Bucila et al. (2002) try to explore the search space from the top and from the bottom of the lattice in order to exploit at the same time the symmetric behavior of monotone and anti-monotone constraints. Anyway, all of these approaches face the inherent difficulty of the computational problem: the *tradeoff* existing between anti-monotone and monotone constraints, that can be described as follows. Suppose that a pattern has been removed from the search space because it does not satisfy a monotone constraint. This pruning avoids the expensive frequency check for this pattern, but on the other hand, if we check its frequency and find it smaller than the frequency threshold, we may prune away all its super-patterns, thus saving the frequency check for all of them. In other words, by monotone pruning we risk to lose anti-monotone pruning opportunities given by the pruned patterns. The tradeoff is clear: pushing monotone constraints can save frequency tests, however the results of these tests could have lead to more effective anti-monotone pruning. In Bonchi et al. (2003b) a completely new approach to exploit monotone constraints by means of data-reduction is introduced. The *ExAnte Property* is obtained by shifting attention from the pattern search space to the input data. Indeed, the *tradeoff* exists only if we focus exclusively on the search space of the problem, while if exploited properly, monotone constraints can reduce dramatically the data in input, in turn strengthening the anti-monotonicity pruning power. The ExAnte property states that a transaction which does not satisfy the given monotone constraint can be deleted from the input database since it will never contribute to the support of any pattern satisfying the constraint. A major consequence of removing transactions from input database in this way, is that it implicitly reduces the support of a large amount of patterns that do not satisfy the monotone constraint as well, resulting in a reduced number of candidate patterns generated during the mining algorithm. Even a small reduction in the database can cause a huge cut in the search space, because all super-patterns of infrequent patterns are pruned from the search space as well. In other words, monotonicity-based data-reduction of transactions strengthens the anti-monotonicity-based pruning of the search space. This is not the whole story, in fact, singleton items may happen to be infrequent after the pruning and they can not only be removed from the search space together with all their supersets, but for the same anti-monotonicity property they can be deleted also from all transactions in the input database. Removing items from transactions brings another positive effect: reducing the size of a transaction which satisfies the monotone constraint can make the transaction violate it. Therefore a growing number of transactions which do not satisfy the monotone constraint can be found and deleted. Obviously, we are inside a loop where two different kinds of pruning cooperate to reduce the search space and the input dataset, strengthening each other step by step until no more pruning is possible (a fix-point has been reached). This is the key idea of the ExAnte pre-processing method. In the end, the reduced dataset resulting from this fix-point computation is usually much smaller than the initial dataset, and it can

feed any frequent itemset mining algorithm for a much smaller (but complete) computation. This simple yet very effective idea has been generalized from pre-processing to effective mining in two main directions: in an Apriori-like breadth-first computation in *ExAMiner* (Bonchi et al., 2003c), and in a depth-first computation in *FP-Bonsai* (Bonchi & Goethals, 2004).

Convertible Constraints

In Pei and Han (2000); Pei et al. (2001) the class of convertible constraints is introduced, and depth-first strategy, based on a prefix-tree data structure, able to push such constraints is proposed. Consider the constraint defined on the average aggregate (e.g., *avg(X: price)* $\geq$ *15*): it is quite straightforward to show that it is not anti-monotone, nor monotone, nor succinct. Subsets (or supersets) of a valid pattern could well be invalid and vice versa. For this reason, the authors state that within the level-wise Apriori framework, no direct pruning based on such constraints can be made. But, if we change the focus from the subset to the prefix concept we can find interesting properties. Consider the constraint *avg(X:price)* $\geq$ *15*, if we arrange the items in price-descending-order we can observe an interesting property: the average of a pattern is no more than the average of its prefix, according to this order.

As an example consider the following items sorted in price-descending-order (we use the notation *[item : price]*): *[a : 20], [b : 15], [c : 8], [d : 8], [e : 4]*. We got that the pattern *{a,b,c}* violates the constraint, thus we can conclude that any other pattern having *{a,b,c}* as prefix will violate the constraint as well: the constraint has been converted to an anti-monotone one!

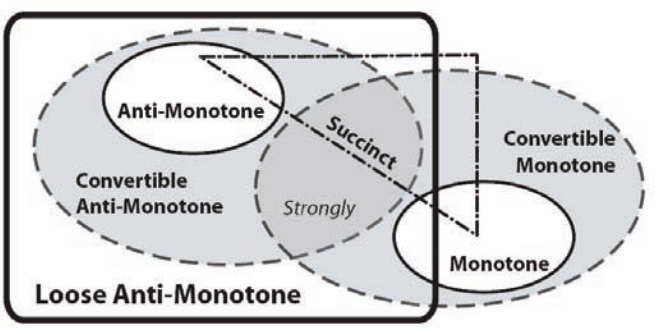
Therefore if we adopt a depth-first visit of the search space, based on the prefix, we can exploit this kind of constraints. More formally, a constraint is said to be convertible anti-monotone provided there is an order on items such that whenever an itemset X satisfies the constraint , so does any prefix of X. A constraint is said to be convertible monotone provided there is an order R on items such that whenever an itemset X violates the constraint, so does any prefix of X.

A major limitation of this approach is that the initial database (internally compressed in the prefix-tree) and all intermediate projected databases must fit into main memory. If this requirement cannot be met, this approach can simply not be applied anymore. This problem is very hard when using an order on items different from the frequency-based one, since it makes the prefix-tree lose its compressing power. Thus we have to manage much greater data structures, requiring a lot more main memory which might not be available. Another important drawback of this approach is that it is not possible to take full advantage of a conjunction of different constraints, since each constraint could require a different ordering of items.

Non-Convertible Constraints

A first work, trying to address the problem of how to push constraints which are not convertible, is Kifer et al. (2003). The framework proposed in that paper is based on the concept of finding a *witness*, i.e., a pattern such that, by testing whether it satisfies the constraint we can deduce information about properties of other patterns, that can be exploited to prune the search space. This idea is embedded in a depth-first visit of the patterns

Figure 1.



search space. The authors instantiate their framework to the constraint based on the *variance* aggregate. Another work going beyond convertibility is Bonchi & Lucchese (2005), where a new class of constraints sharing a nice property named *"loose anti-monotonicity"*, is individuated. This class is a proper superclass of convertible anti-monotone constraints, and it can also deal with other tougher constraints. Based on loose anti-monotonicity the authors define a data reduction strategy, which makes the mining task feasible and efficient. Recall that an anti-monotone constraint is such that, if satisfied by a pattern then it is satisfied by *all* its sub-patterns. Intuitively a loose anti-monotone constraint is such that, if it is satisfied by an itemset of cardinality k then it is satisfied by *at least one* of its subsets of cardinality k-1. It is quite straightforward to show that the constraints defined over variance, standard deviation or similar aggregated measures, are not convertible but are loose anti-monotone. This property can be exploited within a levelwise Apriori framework in the following way: at the k_{th} iteration a transaction is not superset of at least one pattern of size k which satisfies both the frequency and the loose anti-monotone constraint, then the transaction can be deleted from the database. As in ExAMiner (Bonchi et al., 2003c) the anti-monotonicity based data reduction was coupled with the monotonicity based data reduction, similarly we can embedd the loose anti-monotonicity based data reduction described above within the general Apriori framework. The more data-reduction techniques the better: we can exploit them all together, as they strengthen each other and strengthen search space pruning as well; i.e. and the total benefit is always greater than the sum of the individual benefits.

FUTURE TRENDS

So far the research on constraint-based pattern discovery has mainly focused on developing efficient mining techniques. There are still many aspects which deserve further investigations, especially going towards practical systems and methodologies of use for the paradigm of pattern discovery based on constraints. One important aspect is the *incremental mining* of constraint-based queries; i.e., the reusing of already mined solution sets for new queries computation. Altough few studies (Cong & Liu, 2002; Cong et al., 2004) have started investigating this direction there is still room for improvement. Another important aspect is to study and define the relationships between constraint-based mining queries and *condensed representations*: once again, little work already exists (Boulicaut & Jeudy, 2002; Bonchi & Lucchese, 2004), but the topic is worth of further investigation. Finally we must design and develop *practical systems* able to use the constraint-based techniques on real-world problems.

CONCLUSION

In this chapter we have introduced the paradigm of pattern discovery based on user-defined constraints. Constraints are a tool in the user's hands to drive the discovery process toward interesting knowledge, while at the same time reducing the search space and thus the computation time. We have reviewed the state-of-the-art of constraints that can be pushed in the frequent pattern mining process and their associated computational startegies. Finally we have indicated few path of future research and development.

KEY TERMS

Anti-Monotone Constraint: A constraint such that, if satisfied by a pattern, it is also satisfied by all its subpatterns.

Constraint-Based Pattern Discovery: When the Pattern Discovery task is driven by a conjunction of user-defined constraints, which provides a description of the interesting patterns the user is looking for.

Constraint-Pushing Techniques: Algorithmic techniques developed to "push" some classes of constraints within the Frequent Pattern Discovery process. These techniques usually exploit constraints to prune the search space or to reduce the data of the frequent pattern computation, achieving better performances.

Convertible Constraint: A constraint that is neither monotone, nor anti-monotone, nor succinct; but that can be *converted* to a monotone or to an anti-monotone one, by imposing an order on the basic elements of patterns.

Frequent Pattern Discovery: The discovery of structures of information frequently (i.e., a number of times larger than a given threshold) occurring within a database. For instance, given a database of sets, the discovery of frequent subsets; given a database of graphs, the discovery of frequent subgraphs.

Loose Anti-Monotone Constraint: A constraint such that, if it is satisfied by a pattern of size k then it is satisfied by *at least one* of its subpatterns of size k-1.

Monotone Constraint: A constraint such that, if satisfied by a pattern, it is also satisfied by all its super-patterns.

Succinct Constraint: A constraint such that, whether a pattern X satisfies it or not, can be determined based on the basic components of X.

INTRODUCTION

Decisions in the modern world are often made in rapidly changing, sometimes unexpected, situations. Such situations require availability of systems / tools allowing fast and clear description of situation, generation of new and reuse of previously made effective solutions for situation reformation, selection of a right decision maker and supplying him/her with necessary data. Such tools include components for actual situation description, user modeling, finding appropriate methods for problem solving, integration of data from heterogeneous sources, finding / generation of insufficient data, removing uncertainties, estimating solutions, etc. During decision making process a large amount of auxiliary raw data are accumulated in repositories. Methods of data mining are used in such systems for different purposes: finding associative rules between decisions and factors affecting them, user clustering using decision trees and neural networks, recognition of common users' features / interests and others (Chiang et al., 2006; Li, 2005; Thomassey and Fiordaliso, 2006). Validation of the obtained results can be performed using simulation software modules.

BACKGROUND

The chapter presents a developed approach that assumes usage of (i) ontologies for application domain description (notions, relations between notions, data sources and methods), (ii) user profiles to accumulate raw data and build the system's vision of the user, and (iii) context for actual situation description. The developed approach is oriented to producing an ontology-driven context model so that the decision makers would be provided with the information and knowledge required in the situation they are interested in and according to the roles they play.

Within the presented approach the context is a weakly-structured information containing three constituents: (i) ontology elements describing the actual situation; (ii) user data representing user's role, preferences, competences, etc.; and (iii) data / information / knowledge extracted from available sources and relevant the actual situation. Context is built when a situation occurs and used for processing requests related to this situation. The context is a basis for generation and estimation of alternative solutions and presenting them to the decision maker for selecting the best one from his/her point of view. Each situation is described by the following components: context, solutions generated using the context and the final decision (selected solution / solutions). These components are stored in the user profile.

Finding influence of the context on the final decision made by the decision maker playing a certain role is an important task because it helps to (i) find and model typical scenarios of interaction between users; (ii) reveal typical situations within large amount of raw data; and (iii) cluster existing decision makers into groups, thus, allowing reducing the number of supported user

models and increasing the data presentation quality. Finally, these results lead to increasing the decision quality, what is important when decisions have to be made under time pressure. To find the above inference the described here approach applies decision mining techniques as a subarea of data mining.

Analysis of different decisions' kinds is one of the areas of data mining for business processes. The goal of decision mining is to find "rules" explaining under what circumstances certain activity is to be selected rather than the other one. For instance, decision mining aims at detecting data dependencies that affect the routing of a case in the event log of the business process executions (Rozinat and van der Aalst, 2006). There is a set of tools implementing different tasks of decision mining: "Decision Miner" (Rozinat and van der Aalst, 2006), Decision mining software "Risky Business" and "GoldPan" (Decision Mining software, 2007) and other.

Decision mining covers a wide range of problems. Estimation of data quality and interpretation of their semantics is one of the major tasks of decision mining. It requires the following interpretation of data: whether it is relevant, what it actually means, in what units it is measured, etc. Classification of decisions is also one of important tasks for decision mining. These tasks solving requires development of decision models and (semi)automatic decision analysis techniques. For instance, in the approach the concept of decision trees has been adapted to carry out a decision point analysis (Rozinat and van der Aalst, 2006), spatial analysis has been adapted for criminal event prediction (Brown et al., 2006).

The developed approach proposes an application of decision mining techniques to the area of intelligent decision support. Classification of decisions allows discovering correspondence between decision makers and their roles. Revealing preferences of decision makers helps to build decision trees that allow making right decisions in critical situations (semi)automatically.

Main Focus: Context-Sensitive Decision Support

The idea of using ontology-driven context model for decision support arose from the definition. Context is defined as any information that can be used to characterize the situation of an entity where an entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves (Dey et al., 2001).

In modern information systems ontologies are widely used as a basis for domain knowledge description. In the presented approach the formalism of Object-Oriented Constraint Networks (OOCN) is used for a formal ontology representation. Summary of the possibility to convert knowledge elements from OWL (W3C, 2007) as one of the most widespread standards of knowledge representation into the OOCN formalism is presented in Table 1.

The developed approach proposes integration of environmental information and knowledge in context (Smirnov et al., 2005). The context is purposed to represent only relevant information and knowledge from the large amount of those. Relevance of the information and knowledge is evaluated based on what is their relation to an ad hoc problem modeling. The methodology proposes integration of environmental information and domain knowledge in a context of the current situation. It is done through linkage of representation of this knowledge with semantic models of information sources providing information about the environment. The methodology (Figure 1) considers context as a problem model built using knowledge extracted from the application domain and formalized within an ontology by a set of constraints. The set of constraints, additionally to the constraints describing domain knowledge, includes information about the environment and various preferences of the user concerning the problem solving (user defined constraints). Two types of context are used: 1) *abstract context* that is an ontology-based model integrating information and knowledge relevant to the problem, and 2) *operational context* that is an instantiation of the abstract context with data provided by the information sources or calculated based on functions specified in the abstract context.

The approach relies on a three-phase model of decision making process (Simon, 1965). The model describes decision making consisting of "intelligence", "design", and "choice" phases. The proposed approach expands the "intelligence phase" that addresses problem recognition and goal settings into steps reiterating all three phases of this model. Using the constraint satisfaction technology the proposed approach covers the last two phases focusing on a generation of alternative solutions and choice of a decision (Table 2).

The conceptual framework of the developed approach is as follows.

Table 2. Decision making stage related to the three-phase model

Phase	Phase content	Steps	Proposed approach steps
Intelligence	Problem recognition	- fixing goals - setting goals	- abstract context composition - operational context producing
Design	Alternatives generation	- designing alternatives	- constraint-based generating efficient alternatives
Choice	Efficient alternatives selection	- evaluation & choosing alternatives	

Before a problem can be solved an ontology describing relevant areas has to be built. The ontology combines the domain knowledge and problem solving knowledge. Decision making in dynamic domains is characterized by a necessity to dynamically process and integrate information from heterogeneous sources and to provide the user with context-driven assistance for the analysis of the current situation. Systems of context-driven decision making support are based on usage of information / data, documents, knowledge and models for problem identification and solving.

Another necessary prerequisite for the system operation is its connection to information sources. The connection is based on three operations: finding information sources, connection of the found sources to the system using Web-services, and assigning information source references to attributes of the ontology, in other words, defining what sources the ontology attributes take values from.

Once the above operations are completed the decision support system is considered to be ready for problem processing. Personalization is one of important features of decision support. For this reason users are described in the system via user profiles and associated with different roles that set certain limitations to provide only information that is useful for a particular user.

When the user passes the registration in the system the user profile is updated or created if it did not exist before. Then, depending on the user role and available information the user either describes the problem or selects a situation. In the latter case the abstract context is assumed to exist and it is activated. In order to ensure usability of the previously created abstract context the context versioning technique described in the following section is used. In the former case few more steps are required. The problem description stored in the profile for its further analysis is recognized by the system, and recognized meaningful terms are mapped to the vocabulary of the ontology; the vocabulary includes class names, attribute names, string domains, etc. Based on the identified ontology elements and the developed algorithm a set of ontology slices relevant to the problem is built. Based on these slices a set of abstract contexts is generated. Since some of the problem solving methods can be alternative, integration of such slices leads to a set of alternative abstract contexts. The generated abstract contexts are checked for consistency, their attributes are assigned information sources based on the information from the ontology, and it is saved in the context archive. Role constraints are applied to the generated abstract context to remove information that is not interesting for or not supposed to be seen by the user.

The abstract contexts are checked if they are sufficient enough for solving the current problem. Then the required information is acquired from the appropriate information sources and calculations are performed. Due to the chosen OOCN notation a compatible constraint solver can be used for this purpose. The constraint solver analyses information acquired from the sources and produces a set of feasible solutions eliminating contradictory information.

The above operations result in forming operational contexts for each abstract context. Among the operational contexts one with values for all attributes is selected. This operational context is used at the later problem solving stages. All the operational contexts are stored in the context archive, and references to the operational contexts are stored in the user profile.

Based on the identified operational context the set of solutions is generated. Among the generated solutions the user selects the most appropriate one and makes a decision. The solutions and the final decision are stored in the user profile for further analysis. Stored in the profile information can be used for various purposes including audit of user activities, estimation of user skills in certain areas, etc. In the presented research this information is used for decision mining.

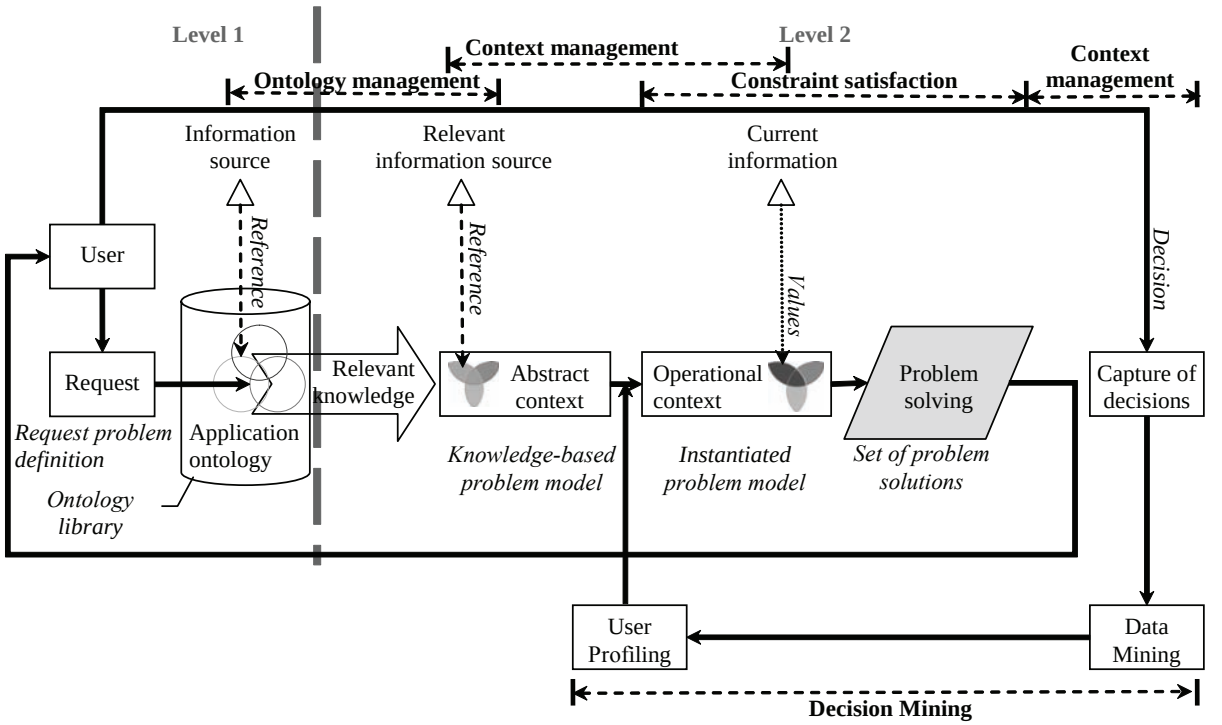
The described above conceptual framework is presented in Figure 2.

Three main forms of constraint satisfaction problems (CSP) are distinguished (Bowen, 2002):

- **The Decision CSP.** Given a network, decide whether the solution set of the network is nonempty;
- **The Exemplification CSP.** Given a network, return some tuple from the solution set if the solution set is nonempty, or return an empty solution otherwise;
- **The Enumeration CSP.** Given a network, return the solution set.

If all the domains in an operational context have been redefined the operational context is considered as a situation description. This case corresponds to CSP of the 1st type. If an operational context contains not

Figure 2. Conceptual framework of context-driven decision making support



redefined domains, it means that a solution is expected. In this case CSP falls under the 2nd or the 3rd form.

The approach proposes usage of a profile model that supports user clustering using text mining techniques (Smirnov et al., 2005b). The result of user clustering is identification of roles for decision maker grouping. Grouping shows similarities between different users and allows finding alternative decision makers with similar competence, knowledge, etc. Inputs for clustering algorithm are user requests and the ontology.

In the implemented prototype only specific action of users are considered for clustering. The list of action types can be extended. In this case different actions can be assigned different weights for similarity measurement or several classifications based on different actions can be performed. Initially a new user has an empty profile and cannot be classified. Later, when the profile is filled up with some accumulated information the user can be clustered.

To take into account other data stored in user profiles a method based on the analysis of alternatives has been developed. Unlike the mentioned above method searching for similarities of the decisions selected by the user, this method assumes an analysis of differences between decisions from the remaining solutions. These differences are stored and appropriate statistics is accumulated. Based on the statistics the user preferences can be identified as most common differences of his/her decisions from the remaining solutions taking into account information from the operational context.

Let $DM = \{Sol_{1, \ldots, n}, Dec\}$, where Sol_i is a solution and *Dec* is a decision selected by the user. The decision *Dec* is considered to be excluded from the set of solutions $Sol_{1, \ldots, n}$.

Each decision as well as the solution consists of objects (class instances) *I* with instantiated attributes *P* (attribute values *V*): $Sol_i = \{<I, P, V>\}$.

Comparison of the decision with each solution results in sets:

$Diff_i^+ = \{<I, P, V>\}$, $i = 1, \ldots, n$, containing objects from the decision and object attributes that differ from those of the solution ($\forall <I, P, V> \subset Diff_i^+$: $<I, P, V> \subset Dec$, $<I, P, V> \not\subset Sol_i$).

$Diff_i^- = \{<I, P, V>\}$, $i = 1, \ldots, n$, containing objects from the solution and object attributes that differ from

those of the decision ($\forall$ <*I, P, V*> $\subset Diff_i^-$: <*I, P, V*> $\not\subset$ *Dec*, <*I, P, V*> $\subset Sol_i$).

Then, these sets are united and number of occurrences (*k*) of each tuple <*I, P, V*> is calculated:

$Diff^+ = \{<I, P, V>, k_l\}$ – objects and their values preferred by the user.

$Diff^- = \{<I, P, V>, k_m\}$ – objects and their values avoided by the user.

When the volume of the accumulated statistics is enough (it depends on the problem complexity and is defined by the system administrator) a conclusion can be made about usually preferred and/or avoided objects and their parameters from the problem domain by the user. This conclusion is considered as the user preference.

The resulting preferences can be described via rules, e.g.:

if Weather.WindSpeed > 10 **then** EXCLUDE HELICOPTERS

if Disaster.Type = "Fire" **then** INCLUDE FIREFIGHTERS

if Disaster.Number_Of_Victims > 0 **then** Solution. Time -> min

When users are clustered into roles and their preferences are revealed it is possible to compare preferred objects in each cluster and build hypothesis what decision trees have to look like. The extracted preferences are used for building decision trees allowing making a right decision in a critical situation (semi)automatically. Also such decision trees could be useful for supporting decision maker in solution estimation and ranking. Today, there are a lot of algorithms and tools implementing them to solve this task (e.g., CART – Classification and Regression Tree algorithm (Breiman et al., 1984), C4.5 (Ross Quinlan, 1993) and others).

A detailed description of the approach and some comparisons can be found in (Smirnov et al., 2007)

Future Trends

Usually, complex situations involve a great number of different heterogeneous teams (sometimes multinational), which have to collaborate in order to succeed. Besides, it might be often necessary to use external sources to get required information. Such actions require intensive information exchange in order to achieve necessary level of the situational awareness, creation of ad-hoc action plans, and continuously updated information.

Centralized control is not always possible due to probable damages in local infrastructure, different subordination of participating teams, etc. Another disadvantage of the centralized control is its possible failure that would cause failure the entire operation. Possible solution for this is organization of a decentralized self-organizing coalitions consisting of the operation participants. However, in order keep this coalition-based network operating it is necessary to solve a number of problems that can be divided into technical (hardware-related) and methodological constituents. Some of the problems that are currently under study include providing for semantic interoperability between the participants and definition of the standards and protocols to be used. For this purpose such technologies as situation management, ontology management, profiling and intelligent agents can be used. Standards of information exchange (e.g., Web-service standards), negotiation protocols, decision making rules, etc. can be used for information / knowledge exchange and rapid establishing of ad-hoc partnerships and agreements between the participating parties.

CONCLUSION

The article presents results of a research related to the area of data mining in the context-sensitive intelligent decision support. In the proposed approach auxiliary data are saved in the user profile after each decision making process. These data are ontology elements describing actual situation, preferences of the user (decision maker), set of alternative solutions and the final decision. A method for role-based decision mining for revealing the user preferences influencing upon the final user decision has been proposed.

In the future other methods from the area of data mining can be developed or adapted to extract new results from the accumulated data.

KEY TERMS

Abstract Context: An ontology-based model integrating information and knowledge relevant to the problem at hand.

Context: Any information that can be used to characterize the situation of an entity where an entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves (Dey et al., 2001).

Decision Mining: A data mining area aimed at finding "rules" explaining under what circumstances one activity is to be selected rather than the other one.

Object-Oriented Constraint Network Formalism (OOCN): An ontology representation formalism, according to which an ontology (*A*) is defined as: *A* = (*O, Q, D, C*) where: *O* is a set of *object classes* ("*classes*"), *Q* is a set of class attributes ("*attributes*"), *D* is a set of attribute domains ("*domains*"), and *C* is a set of *constraints*.

Ontology: An *explicit specification* of the structure of the certain *domain* that includes *a vocabulary* (i.e. a list of logical constants and predicate symbols) for referring to the subject area, and *a set of* logical state-

ments expressing the *constraints* existing *in the domain* and restricting the interpretation of the vocabulary; it provides a vocabulary for representing and communicating *knowledge* about some topic and *a set of relationships and properties* that hold for the *entities* denoted by that vocabulary (FIPA, 1998).

Operational Context: An instantiation of the abstract context with data provided by the information sources or calculated based on functions specified in the abstract context.

Web Ontology Language (OWL): The OWL Web Ontology Language is designed to be used by applications that need to process the content of information instead of just presenting information to humans. OWL facilitates greater machine interpretability of Web content than that supported by XML, RDF, and RDF Schema (RDF-S) by providing additional vocabulary along with a formal semantics. OWL has three increasingly-expressive sublanguages: OWL Lite, OWL DL, and OWL Full (W3C, 2007).

Context-Sensitive Attribute Evaluation

Marko Robnik-Šikonja
University of Ljubljana, FRI

INTRODUCTION

The research in machine learning, data mining, and statistics has provided a number of methods that estimate the usefulness of an attribute (feature) for prediction of the target variable. The estimates of attributes' utility are subsequently used in various important tasks, e.g., feature subset selection, feature weighting, feature ranking, feature construction, data transformation, decision and regression tree building, data discretization, visualization, and comprehension. These tasks frequently occur in data mining, robotics, and in the construction of intelligent systems in general.

A majority of attribute evaluation measures used are myopic in a sense that they estimate the quality of one feature independently of the context of other features. In problems which possibly involve much feature interactions these measures are not appropriate. The measures which are historically based on the Relief algorithm (Kira & Rendell, 1992) take context into account through distance between the instances and are efficient in problems with strong dependencies between attributes.

BACKGROUND

The majority of feature evaluation measures are impurity based, meaning that they measure impurity of the class value distribution. These measures evaluate each feature separately by measuring impurity of the splits resulting from partition of the learning instances according to the values of the evaluated feature. Assuming the conditional independence of the features upon the class, these measures are myopic, as they do not take the context of other features into account. If the target concept is a discrete variable (the classification problem) well-known and used measures of these kind are information gain (Hunt et al., 1966), Gini index (Breiman et al., 1984), j-measure (Smyth & Goodman, 1990), Gain ration (Quinlan, 1993) and MDL (Kononenko, 1995). Large differences in the impurity of class values before the split, and after the split on a given feature, imply purer splits and therefore more useful features. We cannot directly apply these measures to numerical features, but we can use discretization techniques and then evaluate discretized features. If the target concept is presented as a real valued function (regression problem), the impurity based evaluation heuristics used are e.g., the mean squared and the mean absolute error (Breiman et al., 1984).

The term context here represents related features, which interact and only together contain sufficient information for classification of instances. Note that the relevant context may not be the same for all instances in a given problem. The measures which take the context into account through distance between the instances and are efficient in classification problems with strong dependencies between attributes are Relief (Kira & Rendell, 1992), Contextual Merit (Hong, 1997), and ReliefF (Robnik-Sikonja & Kononenko, 2003). RReliefF is a measure proposed to address regression problems (Robnik-Sikonja & Kononenko, 2003).

For a more thorough overview of feature quality evaluation measures see (Kononenko & Kukar, 2007). Breiman (2001) has proposed random forest learning algorithm which, as a byproduct, can output the utility of the attributes. With large enough data sample which ensures sufficiently large and diverse trees in the forest these estimates are also context-sensitive. For an overview of other recent work, especially in the context of feature subset selection see (Guyon & Elisseeff, 2003). Note that this chapter is solely a machine learning view of feature selection and omits methods for model selection in regression that amount to feature selection. A recent work trying to bridge the two worlds is (Zhou et al., 2006).

MAIN FOCUS

The main idea of how to take the context of other features into account was first presented in algorithm Relief (Kira & Rendell, 1992), which is designed for two-class problems without missing values. The idea of the algorithm, when analyzing learning instances, is to take into account not only the difference in feature values and the difference in classes, but also the distance between the instances. Distance is calculated in the feature space, therefore similar instances are close to each other and dissimilar are far apart. By taking the similarity of instances into account, the context of all the features is implicitly considered.

The algorithm Relief illustrated in Box 1 randomly selects an instance and finds the nearest instance from the same class (nearest hit) and the nearest instance from the opposite class (nearest miss). Then it updates the quality of each feature with respect to whether the feature differentiates two instances from the same class (undesired property of the feature) and whether it differentiates two instances from opposite classes (desired property). By doing so, the quality estimate takes into account the local ability of the feature to differentiate between the classes. Repeating the whole procedure for large enough sample these local estimates provide a global picture of the feature utility, but the locality implicitly takes into account the context of other features.

Let's say that a given feature explains the change of the class value of the instance, when the change of its values is one of the minimal changes required for changing the class value. The quality evaluations of Relief algorithms can then be interpreted as the portions of the explained concept i.e., as the ratio between the number of the explained changes in the concept and the number of examined instances.

ReliefF for Classification and RReliefF for Regression

A more realistic and practically useful variant of Relief is its extensions, called ReliefF for classification and RReliefF for regression problems (Robnik-Sikonja & Kononenko, 2003). Unlike original Relief these two algorithms are able to deal with incomplete and noisy data. The most important difference is in searching for the nearest hit and miss. Noise or mistakes in class and/or feature values significantly affects the selection of nearest hits and misses. In order to make this process more reliable in the presence of noise, ReliefF and RReliefF use several nearest hits and misses and average their contributions to features' quality estimates. ReliefF can be used also for evaluating the feature quality in multi-class problems and to do so it searches for nearest instances from each class. The contributions of different classes are weighted with their prior probabilities. In regression problems the target variable is numerical, therefore nearest hits and misses cannot be used in a strict sense. RReliefF (Regressional ReliefF) uses a kind of ``probability'' that two instances belong to two ``different'' classes. This ``probability'' is modeled with the distance between the values of the target variable of two learning instances.

Box 1.

Algorithm Relief
Input: set of instances $<x_i, \tau_i>$
Output: the vector W of attributes' evaluations

```
set all weights W[A] := 0.0;
for i := 1 to #sample_size do begin
  randomly select an instance R;
  find nearest hit H and nearest miss M;
  for A := 1 to #all_attributes do
   W[A] := W[A] - diff(A,R,H)/m + diff(A,R,M)/m;
end;
```

Extensions of ReliefF

The ideas of context-sensitive attribute evaluation introduced in Relief, ReliefF and RReliefF have been adapted for efficient feature evaluation in other areas like inductive logic programming, cost-sensitive learning, and evaluation of ordered features at value level (Kononenko & Robnik-Sikonja, 2007).

In inductive logic programming aka multi-relational data mining (Dzeroski & Lavrac, 2001), the goal of learning is to develop predicate descriptions from examples and background knowledge. The examples, background knowledge and final descriptions are all described as logic programs. The key idea of context-sensitive feature evaluation is to estimate literals according to how well they distinguish between the instances that are logically similar. For that one has to change the notion of a distance between the literals.

In cost-sensitive classification all errors are not equally important (Elkan, 2001). In general, differences in importance of errors are handled through the cost of misclassification. Cost-sensitivity is a desired property of an algorithm which tries to rank or weight features according to their importance. The key idea in cost-sensitive ReliefF is to use the expected cost of misclassifying an instance in weighting the quality updates (Robnik-Sikonja, 2003).

A context sensitive algorithm for evaluation of ordinal features was proposed in (Robnik-Sikonja & Vanhoof, 2007) and used on a customer (dis)satisfaction problem from marketing research. The ordEval algorithm exploits the information hidden in ordering of features' and class values and provides a separate score for each value of the feature. Similarly to ReliefF the contextual information is exploited via selection of nearest instances. The ordEval outputs probabilistic factors corresponding to the effect an increase/decrease of feature's value has on the class value. This algorithm and its visualizations can be used as an exploratory tool for analysis of any survey with graded answers.

Applications

(R)ReliefF has been applied in a variety of different ways in data mining and many studies have reported its good performance in comparison with other feature evaluation methods. Besides the usual application for filter subset selection, (R)ReliefF was used for feature ranking, feature weighing, building tree-based models and associative rules, feature discretization, controlling the search in genetic algorithms, literal ranking in ILP, and constructive induction. It is implemented in many data mining tools, including CORElearn, Weka, Orange and R.

FUTURE TRENDS

The main challenge of context-sensitive feature evaluation is handling ever-increasing number of instances and features. When dealing with data sets with a huge number of instances feature selection methods typically perform a random sampling. Liu & Motoda (2004) introduce the concept of active feature selection, and apply selective sampling based on data variance to ReliefF. They reduced the required number of training instances and achieve considerable time savings without performance deterioration. Context-sensitive algorithms are especially sensitive to large number of features as they blur the distance and the context. In high-dimensional spaces the performance may deteriorate and we need tools for analysis and detection of such behavior. The stability of feature selection algorithms was studied by (Kalousis et al., 2007). One possible solution is to make the feature evaluation procedure iterative. For ReliefF such an attempt was made by (Draper et al., 2003). Relief algorithms are computationally more complex than some other (myopic) feature estimation measures. However, they also have a possible advantage that they can be naturally split into several independent tasks which is a prerequisite for successful parallelization of an algorithm. Iterations in the algorithm are natural candidates for separate processes, which would turn Relief into the fine-grained parallel algorithm. With arrival of microprocessors with multiple cores this will be an easy speedup.

Feature evaluation is a lively research topic in data mining, mostly motivated by the feature subset selection challenges posed by image analysis, web applications, and bioinformatics, in particular gene expression analysis (Gadat & Younes, 2007; Ooi et al., 2007; Nilsson et al., 2007). New approaches and discoveries are also in the basic approach towards feature evaluation. Torkkola (2003) has proposed a feature selection method based on non-parametric mutual information maximization. While this approach is useful for sets of features, its estimates could be adapted to serve for evaluation of individual features without independence assump-

tion. Zhao & Liu (2007) propose a unifying approach to feature evaluation in supervised and unsupervised learning based on pairwise distance similarity graph and show that ReliefF is a special case of the proposed framework.

CONCLUSION

ReliefF in classification and RReliefF in regression exploit the context of other features through distance measures and can detect highly conditionally dependent features. The basic idea of these algorithms is to evaluate features in the local context. These algorithms are able to deal with the incomplete data, with multi-class problems, and are robust with respect to the noise. Various extensions of the ReliefF algorithm, like evaluation of literals in inductive logic programming, cost-sensitive feature evaluation with ReliefF, and the ordEval algorithm for the evaluation of features with ordered values, show the general applicability of the basic idea. (R)ReliefF family of algorithms has been used in many different data mining (sub)problems and applications. The comprehensive interpretability of the (R)ReliefF's estimates makes this approach attractive also in the application areas where the knowledge discovery is more important than predictive performance, which is often case in the medicine and social sciences. In spite of some claims that (R)ReliefF is computationally demanding, this is not an inherent property and efficient implementations and use do exist.

KEY TERMS

Attribute Evaluation: A data mining procedure which estimates the utility of attributes for given task (usually prediction). Attribute evaluation is used in many data mining tasks, for example in feature subset selection, feature weighting, feature ranking, feature construction, decision and regression tree building, data discretization, visualization, and comprehension.

Context of Attributes: In a given problem the related attributes, which interact in the description of the problem. Only together these attributes contain sufficient information for classification of instances. The relevant context may not be the same for all the instances in given problem.

Cost-Sensitive Classification: Classification where all errors are not equally important. Usually differences in importance of errors are handled through the cost of misclassification.

Evaluation of Ordered Attributes: For ordered attributes the evaluation procedure should take into account their double nature: they are nominal, but also behave as numeric attributes. So each value may have its distinct behavior, but values are also ordered and may have increasing impact.

Feature Construction: A data transformation method aimed to increase the expressive power of the models. Basic features are combined with different operators (logical and arithmetical) before or during learning.

Feature Ranking: The ordering imposed on the features to establish their increasing utility for the given data mining task.

Feature Subset Selection: Procedure for reduction of data dimensionality with a goal to select the most relevant set of features for a given task trying not to sacrifice the performance.

Feature Weighting: Under the assumption that not all attributes (dimensions) are equally important feature weighting assigns different weights to them and thereby transforms the problem space. This is used in data mining tasks where the distance between instances is explicitly taken into account.

Impurity Function: A function or procedure for evaluation of the purity of (class) distribution. The majority of these functions are coming from information theory, e.g., entropy. In attribute evaluation the impurity of class values after the partition by the given attribute is an indication of the attribute's utility.

Non-Myopic Attribute Evaluation: An attribute evaluation procedure which does not assume conditional independence of attributes but takes context into account. This allows proper evaluation of attributes which take part in strong interactions.

Ordered Attribute: An attribute with nominal, but ordered values, for example, increasing levels of satisfaction: low, medium, and high.

Control-Based Database Tuning Under Dynamic Workloads

Yi-Cheng Tu
University of South Florida, USA

Gang Ding
Olympus Communication Technology of America, Inc., USA

INTRODUCTION

Database administration (tuning) is the process of adjusting database configurations in order to accomplish desirable performance goals. This job is performed by human operators called database administrators (DBAs) who are generally well-paid, and are becoming more and more expensive with the increasing complexity and scale of modern databases. There has been considerable effort dedicated to reducing such cost (which often dominates the total ownership cost of mission-critical databases) by making database tuning more automated and transparent to users (Chaudhuri *et al*, 2004; Chaudhuri and Weikum, 2006). Research in this area seeks ways to automate the hardware deployment, physical database design, parameter configuration, and resource management in such systems. The goal is to achieve acceptable performance on the whole system level without (or with limited) human intervention.

According to Weikum *et al*. (2002), problems in this category can be stated as:

workload × configuration (?) → performance

which means that, given the features of the incoming workload to the database, we are to find the right settings for all system knobs such that the performance goals are satisfied The following two are representatives of a series of such tuning problems in different databases:

- **Problem 1: Maintenance of multi-class service-level agreements (SLA) in relational databases.** Database service providers usually offer various levels of performance guarantees to requests from different groups of customers. Fulfillment of such guarantees (SLAs) is accomplished by allocating different amounts of system resources to different queries. For example, query response time is negatively related to the amount of memory buffer assigned to that query. We need to dynamically allocate memory to individual queries such that the absolute or relative response times of queries from different users are satisfied.
- **Problem 2: Load shedding in stream databases.** Stream databases are used for processing data generated continuously from sources such as a sensor network. In streaming databases, data processing delay, i.e., the time consumed to process a data point, is the most critical performance metric (Tatbul *et al*., 2003). The ability to remain within a desired level of delay is significantly hampered under situations of overloading (caused by bursty data arrivals and time-varying unit data processing cost). When overloaded, some data is discarded (i.e., load shedding) in order to keep pace with the incoming load. The system needs to continuously adjust the amount of data to be discarded such that 1) delay is maintained under a desirable level; 2) data is not discarded unnecessarily.

Such problems can hardly be solved by using rules of thumbs and simply throwing in more hardware. In the following section, we shall also see that the traditional approach of treating tuning problems as static optimization problems does not work well for dynamic workloads such as those with OLAP queries. In this chapter, we introduce an emerging new approach to attack self-tuning database problems that is based on well-established results in feedback control theory. Specifically, we address the core issues of the approach and identify critical challenges of applying control theory in the area of self-tuning databases.

BACKGROUND

Current research in automatic tuning (or self-tuning) of databases tend to treat the problem as an optimization problem with the performance metrics and workload characteristics as inputs. The main drawback for this strategy is: real-world workloads, especially OLAP workloads, are highly unpredictable in that their parameters and behaviors can change very frequently (Tu *et al*., 2005). Such uncertainties in workloads can bring dramatic variations to system performance and cause the database to run in suboptimal status. In order to maintain consistently good performance, we need to develop means for the database to quickly adapt to the changes in workload.

One way to address the above challenge is to treat the problem as an online optimization (Chaudhuri and Weikum, 2006) and solve it by incremental algorithms. However, there is generally no guarantee on the accuracy and convergence of such algorithms, and some problems have no incremental solutions. Another important question, which is either ignored or answered empirically in current studies, is *how often do we need to rerun the optimization*? Our observation is that people tend to follow *ad hoc* strategies for individual problems in this field. It would be desirable to have a common theoretical framework under which a series of problems can be approached.

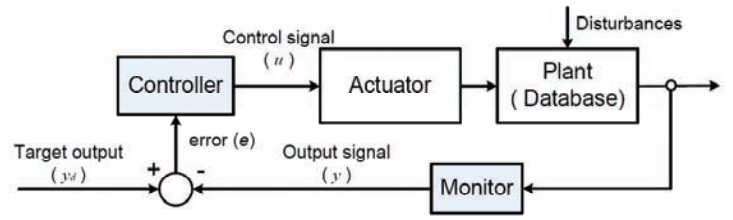
In this chapter, we argue that control theory provides such a foundation to approach the aforementioned problems in self-tuning databases. The reason for this is: designing systems with resistance to internal/external uncertainties is one of the main goals of control theory (Hellerstein *et al*., 2004). Note that control theory is not a single technique. Instead, it is the collection of a rich set of mathematical tools for analyzing system dynamics and designing mechanisms with guaranteed performance. We discuss some of the core issues of using control techniques in self-tuning databases. Currently, we have seen control-theoretical methods in solving database tuning problems and the effectiveness of the method is supported by both analytical and experimental results (Lightstone *et al*., 2007; Storm *et al*., 2006; Tu *et al*., 2005, 2006, 2007; Tu and Prabhakar 2006). For example, a load shedding framework based on feedback control designed by Tu and coworkers (2006, 2007) achieves processing delay violations that are 2 to 3 orders of magnitude lower (with the same amount of data loss), as compared to optimization-based methods. Storm *et al.*, (2006) reported the implementation of the Self-Tuning Memory Manager (STMM) with a control-based design and up to 254% increase in performance (e.g., decrease in query response time) in DB2 Version 9.1.

MAIN FOCUS

In this chapter, the term *control* refers to the manipulation of particular feature(s) (i.e., output signal) of a system (called *plant* in control terminology) by adjusting inputs injected into it (Hellerstein *et al*., 2004). We focus on *feedback control* where output signals are taken into account in making control decisions. The main components of a feedback control system form a *feedback control loop* (Figure 1): a *monitor* measures the output signal y of the plant; the measurements are compared with a desirable output value y_d and the difference between them is called *control error*; a *controller* maps control error e to a control signal u; an *actuator* adjusts the behavior of the plant according to signal u. The goal of the control operations is to overcome the effects of system and environmental uncertainties (named *disturbance*s) such that the output signal tracks the target value.

The above conceptual design can be mapped into a concrete model for our problem: the plant is the database system; the actuator is the existing database mechanisms

Figure 1. Components of a feedback control loop



to implement a tuning decision; output signal is the performance metric(s) we consider; and the control signal is the database configurations we need to tune to. For example, in Problem 1, we have the query response time as output and resource allocation to multiples queries as input. Clearly, the most critical part of the control loop is the controller. Control theory is the mathematical foundation to the design of controllers based on the dynamic features of the plant. Carefully designed controllers can overcome unpredictable disturbances with guaranteed runtime performance such as *stability* and *convergence time*. However, due to the inherent differences between database systems and traditional control systems (i.e., mechanical, electrical, chemical systems), the application of control theory in database systems is by no means straightforward.

Modeling Database Systems

Rigorous control theory is built upon the understanding of the dynamics of the system to be controlled. Derivation of models that describe such dynamics is thus a critical step in control engineering. Therefore, the first challenge of control-based tuning is to *generate dynamic models of various database systems*. Linear systems have been well-studied in the control community. Generally, the dynamic behavior of a single-input-single-output (SISO) linear time-invariant (LTI) system can be modeled by a transfer function between the input u and output y in the frequency domain:

$$G(s) = \frac{a_n s^{n-1} + a_{n-1} s^{n-2} + ... + a_1}{s^n + b_n s^{n-1} + b_{n-1} s^{n-2} + ... + b_1}$$

where n is called the *order* of the model. The above transfer function only gives the relationship between the input and output. All the underlying n system dynamics x can be represented by a state-space model in time domain:

$$\begin{cases} x = Ax + Bu \\ y = Cx + Du \end{cases}$$

where A, B, C, and D are model parameters. Given an accurate model, all dynamics of the object can be analytically obtained, based on which we can analyze important characteristics of the output and states such as stability of the output, the observability, and controllability of each state.

Depending on the available information about the system, there are different ways to obtain the model. When the physical mechanism that drives the system is clearly known, the structure and all parameters of the model can be accurately derived. However, for complex systems such as a database, the analytical model may be difficult to derive. Fortunately, various *system identification* techniques (Franklin *et al*., 2002; Tu *et al*., 2005) can be used to generate approximate models for databases. The idea is to feed the database system with inputs with various patterns. By comparing the actual outputs measured with the derivation of the output as a function of unknown parameters and input frequency, the model order n and parameters a_i, $b_i (1 \le i \le n)$ can be calculated.

Control System Design

The dynamic model of a system only shows the relationship between system input and output. The second challenge of control-based tuning is to *design feedback control loops that guide us how to change the input* (*database configuration*) *in order to achieve desirable output* (*performance*). We need to test various design techniques and identify the ones that are appropriate for solving specific database tuning problems. When the linear system model is known, the proportional-integral-derivative (PID) controller is commonly used. It has three components and we can use mathematical tools such as *root locus* and *bode plot* to find controller parameters that meet our runtime performance requirements (Franklin *et al*., 2002). When model is partly known, more complicated design methods should be involved. For example, when some parameters of the model are unknown or time-variant, the controller can only be designed for an estimated model by online system identification (i.e., adaptive control). For systems with unstructured noises which vary fast, robust control has been actively studied (Ioannou and Datta, 1991).

Database-Specific Issues

Although control theory provides a sound theoretical background for the aforementioned problems, its application in self-tuning databases is non-trivial. The inherent differences between database/information systems and traditional control systems (i.e., mechanical, electrical, chemical systems) bring additional chal-

lenges to the design of the control loop. In this section, we discuss some of the challenges we identified:

1. **Lack of real-time output measurement:** Response time and processing delay are important performance metrics in database systems. Accurate measurements of system output in real-time is essential in traditional control system design. Unfortunately, this requirement is not met in self-tuning database problems where response time and processing delays are the output signals. Under this situation, the output measurement is not only delayed, but also delayed by an unknown amount (the amount is the output itself!). A solution to this is to estimate the output from measurable signals such as queue length.
2. **Actuator design:** In traditional control systems, the actuator can precisely apply the control signal to the plant. For example, in the cruise control system of automobiles, the amount of gasoline injected into the engine can be made very close to the value given by the controller. However, in database systems, we are not always sure that the control signal given by the controller can be correctly generated by our actuator. Two scenarios that cause the above difficulties in actuator design are: 1) Sometimes the control signal is implemented as a modification of the original (uncontrolled) system input signal that is unpredictable beforehand; 2) Another source of errors for the control signal is caused by the fact that the actuator is implemented as a combination of multiple knobs.
3. **Determination of the control period:** The control (sampling) period is an important parameter in digital control systems. An improperly selected sampling period can deteriorate the performance of the feedback control loop. As we mentioned earlier, current work in self-tuning databases consider the choice of control period as an empirical practice. Although the right choice of control period should always be reasoned case by case, there are certain theoretical rules we can follow. For controlling database systems, we consider the following issues in selecting the control period: 1) *Nature of disturbances*. In order to deal with disturbances, the control loop should be able to capture the moving trends of these disturbances. The basic guiding rule for this is the Nyquist-Shannon sampling theorem; 2) *Uncertainties in system signals*. Computing systems are inherently discrete. In database problems, we often use some statistical measurements of continuous events occurring within a control period as output signal and/or system parameter. This requires special consideration in choosing the control period; and 3) *Processing (CPU) overhead*. High sampling frequency would interfere with the normal processing of the database and causes extra delays that are not included in the model. In practice, the final choice of control period is the result of a tradeoff among all the above factors.
4. **Nonlinear system control:** Non-linear characteristics are common in database systems. When the model is nonlinear, there is no generic approach to analyze or identify the model. The most common approach is to linearize the model part by part, and analyze or identify each linear part separately. For the worst case when no internal information about the system is available, there are still several techniques to model the object. For example, the input-output relationship can be approximated by a set of rules provided by people familiar with the system, and a rule is represented by a mapping from a fuzzy input variable to a fuzzy output variable. An artificial neural network model can also be employed to approximate a nonlinear function. It has been proven that a well-tuned fuzzy or neural network model can approximate any smooth nonlinear function within any error bound (Wang *et al*., 1994).

FUTURE TRENDS

Modeling database systems is a non-trivial task and may bear different challenges in dealing with different systems. Although system identification had provided useful models, a deeper understanding of the underlying dynamics that are common in all database systems would greatly help the modeling process. We expect to see research towards a fundamental principle to describe the dynamical behavior of database systems, as Newton's Law to physical systems.

Another trend is to address the database-specific challenges in applying control theory to database tuning problems from a control theoretical viewpoint. In our work (Tu *et al*., 2006), we have proposed solutions to

such challenges that are specific to the context in which we define the tuning problems. Systematic solutions that extend current control theory are being developed (Lightstone *et al*., 2007). More specifically, tuning strategies based on fuzzy control and neural network models are just over the horizon.

CONCLUSION

In this chapter, we introduce the new research direction of using feedback control theory for problems in the field of self-tuning databases under a dynamic workload. Via concrete examples and accomplished work, we show that various control techniques can be used to model and solve different problems in this field. However, there are some major challenges in applying control theory to self-tuning database problems and addressing such challenges is expected to become the main objectives in future research efforts in this direction. Thus, explorations in this direction can not only provide a better solution to the problem of database tuning, but also many opportunities to conduct synergistic research between the database and control engineering communities to extend our knowledge in both fields.

KEY TERMS

Control Theory: The mathematical theory and engineering practice of dealing with the behavior of dynamical systems by manipulating the inputs to a system such that the outputs of the system follow a desirable reference value over time.

Controllability and Observability: Controllability of a state means that the state can be controlled from any initial value to any final value within finite time by only the inputs. Observability of a state means that, for any possible sequence of state and control inputs, the current state can be determined in finite time using only the outputs.

Convergence Rate: Another evaluation metric for closed-loop performance. It is defined as the time needed for system to bring the system output back to the desirable value in response to disturbances.

Feedback Control: the control method that takes output signals into account in making control decisions. Feedback control is also called closed-loop control due to the existence of the feedback control loop. On the contrary, the control that does not use output in generating control signal is called open-loop control.

Nyquist-Shannon Sampling Theorem: A fundamental principle in the field of information theory, the theorem states that: when sampling a signal, the sampling frequency must be greater than twice the signal frequency in order to reconstruct the original signal perfectly from the sampled version. In practice, a sampling frequency that is one order of magnitude larger than the input signal frequency is often used. The Nyquist-Shannon sampling theorem is the basis for determining the control period in discrete control systems.

System Identification: The process of generating mathematical models that describe the dynamic behavior of a system from measured data. System identification has evolved into an active branch of control theory due to the difficulty of modeling complex systems using analytical methods (so-called white-box modeling).

System Stability: One of the main features to consider in designing control systems. Specifically, stability means that bounded input can only give rise to bounded output.

Workload: A collection of tasks with different features such as resource requirements and frequencies. In the database field, a workload generally consists of various groups of queries that hold different patterns of data accessing, arrival rates (popularity), and resource consumption. Representative workloads are encapsulated into well-known database benchmarks.

Cost-Sensitive Learning

INTRODUCTION

Classification is the most important task in inductive learning and machine learning. A classifier can be trained from a set of training examples with class labels, and can be used to predict the class labels of new examples. The class label is usually discrete and finite. Many effective classification algorithms have been developed, such as naïve Bayes, decision trees, neural networks, and so on. However, most original classification algorithms pursue to minimize the error rate: the percentage of the incorrect prediction of class labels. They ignore the difference between types of misclassification errors. In particular, they implicitly assume that all misclassification errors cost equally.

In many real-world applications, this assumption is not true. The differences between different misclassification errors can be quite large. For example, in medical diagnosis of a certain cancer, if the cancer is regarded as the positive class, and non-cancer (healthy) as negative, then missing a cancer (the patient is actually positive but is classified as negative; thus it is also called "false negative") is much more serious (thus expensive) than the false-positive error. The patient could lose his/her life because of the delay in the correct diagnosis and treatment. Similarly, if carrying a bomb is positive, then it is much more expensive to miss a terrorist who carries a bomb to a flight than searching an innocent person.

BACKGROUND

Cost-sensitive learning takes costs, such as the misclassification cost, into consideration. It is one of the most active and important research areas in machine learning, and it plays an important role in real-world data mining applications. A comprehensive survey (Turney, 2000) lists a large variety of different types of costs in data mining and machine learning, including misclassification costs, data acquisition cost (instance costs and attribute costs), active learning costs, computation cost, human-computer interaction cost, and so on. The misclassification cost is singled out as the most important cost, and it has also been mostly studied in recent years (e.g., (Domingos, 1999; Elkan, 2001; Zadrozny & Elkan, 2001; Zadrozny et al., 2003; Ting 1998; Drummond & Holte, 2000, 2003; Turney, 1995; Ling et al, 2004, 2006b; Chai et al., 2004; Sheng & Ling, 2006)).

Broadly speaking, cost-sensitive learning can be categorized into two categories. The first one is to design classifiers that are cost-sensitive in themselves. We call them the direct method. Examples of direct cost-sensitive learning are ICET (Turney, 1995) and cost-sensitive decision tree (Drummond & Holte, 2000, 2003; Ling et al, 2004, 2006b). The other category is to design a "wrapper" that converts any existing cost-insensitive (or cost-blind) classifiers into cost-sensitive ones. The wrapper method is also called cost-sensitive meta-learning method, and it can be further categorized into thresholding and sampling. Here is a hierarchy of the cost-sensitive learning and some typical methods. This paper will focus on cost-sensitive meta-learning that considers the misclassification cost only.

Cost-sensitive learning:

- Direct methods
  - ICET (Turney, 1995)
  - Cost-sensitive decision trees (Drummond & Holte, 2003; Ling et al, 2004, 2006b)
- Meta-learning
  - Thresholding
    - MetaCost (Domingos, 1999)
    - CostSensitiveClassifier *(CSC in short)* (Witten & Frank, 2005)

- Cost-sensitive naïve Bayes (Chai et al., 2004)
- Empirical Threshold Adjusting (*ETA* in short) (Sheng & Ling, 2006)

o Sampling
- Costing (Zadronzny et al., 2003)
- Weighting (Ting, 1998)

MAIN FOCUS

In this section, we will first discuss the general theory of cost-sensitive learning. Then, we will provide an overview of the works on cost-sensitive learning, focusing on cost-sensitive meta-learning.

Theory of Cost-Sensitive Learning

In this section, we summarize the theory of cost-sensitive learning, published mostly in (Elkan, 2001; Zadrozny & Elkan, 2001). The theory describes how the misclassification cost plays its essential role in various cost-sensitive learning algorithms.

Without loss of generality, we assume binary classification (i.e., positive and negative class) in this paper. In cost-sensitive learning, the costs of false positive (actual negative but predicted as positive; denoted as (*FP*), false negative (*FN*), true positive (*TP*) and true negative (*TN*) can be given in a cost matrix, as shown in Table 1. In the table, we also use the notation *C(i, j)* to represent the misclassification cost of classifying an instance from its actual class *j* into the predicted class *i*. (We use 1 for positive, and 0 for negative). These misclassification cost values can be given by domain experts. In cost-sensitive learning, it is usually assumed that such a cost matrix is given and known. For multiple classes, the cost matrix can be easily extended by adding more rows and more columns.

Note that *C(i, i)* (*TP* and *TN*) is usually regarded as the "benefit" (i.e., negated cost) when an instance is predicted correctly. In addition, cost-sensitive learning is often used to deal with datasets with very imbalanced class distribution (Japkowicz, 2000; Chawla et al., 2004). Usually (and without loss of generality), the minority or rare class is regarded as the positive class, and it is often more expensive to misclassify an actual positive example into negative, than an actual negative example into positive. That is, the value of *FN* or *C(0,1)* is usually larger than that of *FP* or *C(1,0)*. This is true for the cancer example mentioned earlier (cancer patients are usually rare in the population, but predicting an actual cancer patient as negative is usually very costly) and the bomb example (terrorists are rare).

Given the cost matrix, an example should be classified into the class that has the minimum expected cost. This is the minimum expected cost principle (Michie, Spiegelhalter, & Taylor, 1994). The expected cost *R(i|x)* of classifying an instance *x* into class *i* (by a classifier) can be expressed as:

$$R(i \mid x) = \sum_j P(j \mid x) C(i, j), \quad (1)$$

where *P(j|x)* is the probability estimation of classifying an instance into class *j*. That is, the classifier will classify an instance *x* into positive class if and only if:

$$P(0|x)C(1,0) + P(1|x)C(1,1) \leq P(0|x)C(0,0) + P(1|x)C(0,1)$$

This is equivalent to:

$$P(0|x)(C(1,0)-C(0,0)) \leq P(1|x)(C(0,1)-C(1,1))$$

Table 1. An example of cost matrix for binary classification

	Actual negative	Actual positive
Predict negative	C(0,0), or TN	C(0,1), or FN
Predict positive	C(1,0), or FP	C(1,1), or TP

Table 2. A simpler cost matrix with an equivalent optimal classification

	True negative	True positive
Predict negative	0	*C(0,1) - C(1,1)*
Predict positive	*C(1,0) - C(0,0)*	0

Thus, the decision (of classifying an example into positive) will not be changed if a constant is added into a column of the original cost matrix. Thus, the original cost matrix can always be converted to a simpler one by subtracting *C(0,0)* from the first column, and *C(1,1)* from the second column. After such conversion, the simpler cost matrix is shown in Table 2. Thus, any given cost-matrix can be converted to one with *C(0,0) = C(1,1) = 0*. This property is stronger than the one: the decision is not changed if a constant is added to each entry in the matrix (Elkan, 2001). In the rest of the paper, we will assume that *C(0,0) = C(1,1) = 0*. Under this assumption, the classifier will classify an instance *x* into positive class if and only if:

$$P(0|x)C(1,0) \leq P(1|x)C(0,1)$$

As $P(0|x)=1- P(1|x)$, we can obtain a threshold p^* for the classifier to classify an instance *x* into positive if $P(1|x) \geq p^*$, where

$$p^* = \frac{C(1,0)}{C(1,0)+C(0,1)}. \quad (2)$$

Thus, if a cost-insensitive classifier can produce a posterior probability estimation $p(1|x)$ for test examples *x*, we can make it cost-sensitive by simply choosing the classification threshold according to (2), and classify any example to be positive whenever $P(1|x) \geq p^*$. This is what several cost-sensitive meta-learning algorithms, such as Relabeling, are based on (see later for details). However, some cost-insensitive classifiers, such as C4.5 (Quinlan, 1993), may not be able to produce accurate probability estimation; they are designed to predict the class correctly. *ETA* (Sheng & Ling, 2006) does not require accurate estimation of probabilities – an accurate ranking is sufficient. *ETA* simply uses cross-validation to search the best probability from the training instances as the threshold.

Traditional cost-insensitive classifiers are designed to predict the class in terms of a default, fixed threshold of 0.5. (Elkan, 2001) shows that we can "rebalance" the original training examples by sampling such that the classifiers with the 0.5 threshold is equivalent to the classifiers with the p* threshold as in (2), in order to achieve cost-sensitivity. The rebalance is done as follows. If we keep all positive examples (as they are assumed as the rare class), then the number of negative examples should be multiplied by $C(1,0)/C(0,1) = FP/FN$. Note that as usually $FP < FN$, the multiple is less than 1. This is thus often called "under-sampling the majority class". This is also equivalent to "proportional sampling", where positive and negative examples are sampled by the ratio of:

$$p(1)\ FN : p(0)\ FP \quad (3)$$

where $p(1)$ and $p(0)$ are the prior probability of the positive and negative examples in the original training set. That is, the prior probabilities and the costs are interchangeable: doubling $p(1)$ has the same effect as doubling *FN*, or halving *FP* (Drummond & Holte, 2000). Most sampling meta-learning methods, such as Costing (Zadronzny et al., 2003), are based on (3) above (see later for details).

Almost all meta-learning approaches are either based on (2) or (3) for the thresholding- and sampling-based meta-learning methods respectively.

Cost-Sensitive Learning Algorithms

As mentioned in the Introduction, many cost-sensitive learning can be categorized into two categories. One is direct cost-sensitive learning, and the other is cost-

sensitive meta-learning. In this section, we will review typical cost-sensitive learning algorithms, focusing on cost-sensitive meta-learning.

Direct Cost-sensitive Learning. The main idea of building a direct cost-sensitive learning algorithm is to directly introduce and utilize misclassification costs into the learning algorithms. There are several works on direct cost-sensitive learning algorithms, such as ICET (Turney, 1995) and cost-sensitive decision trees (Ling et al., 2006b).

ICET (Turney, 1995) incorporates misclassification costs in the fitness function of genetic algorithms. On the other hand, cost-sensitive decision tree (Ling et al., 2006b), called *CSTree* here, uses the misclassification costs directly in its tree building process. That is, instead of minimizing entropy in attribute selection as in C4.5 (Quinlan, 1993), *CSTree* selects the best attribute by the expected total cost reduction. That is, an attribute is selected as a root of the (sub)tree if it minimizes the total misclassification cost.

Note that both ICET and *CSTree* directly take costs into model building. Besides misclassification costs, they can also take easily attribute costs (and perhaps other costs) directly into consideration, while cost-sensitive meta-learning algorithms generally cannot.

(Drummond & Holte, 2000) investigates the cost-sensitivity of the four commonly used attribute selection criteria of decision tree learning: accuracy, Gini, entropy, and DKM (Kearns & Mansour, 1996; Dietterich et al., 1996). They claim that the sensitivity of cost is highest with the accuracy, followed by Gini, entropy, and DKM.

Cost-Sensitive Meta-Learning. Cost-sensitive meta-learning converts existing cost-insensitive classifiers into cost-sensitive ones without modifying them. Thus, it can be regarded as a middleware component that pre-processes the training data, or post-processes the output, from the cost-insensitive learning algorithms.

Cost-sensitive meta-learning can be further classified into two main categories: thresholding and sampling, based on (2) and (3) respectively, as discussed in the theory of cost-sensitive learning (Section 2).

Thresholding uses (2) as a threshold to classify examples into positive or negative if the cost-insensitive classifiers can produce probability estimations. MetaCost (Domingos, 1999) is a thresholding method. It first uses bagging on decision trees to obtain accurate probability estimations of training examples, relabels the classes of training examples according to (2), and then uses the relabeled training instances to build a cost-insensitive classifier. *CSC* (Witten & Frank, 2005) also uses (2) to predict the class of test instances. More specifically, *CSC* uses a cost-insensitive algorithm to obtain the probability estimations $P(j|x)$ of each test instance. Then it uses (2) to predict the class label of the test examples. Cost-sensitive naïve Bayes (Chai et al., 2004) uses (2) to classify test examples based on the posterior probability produced by the naïve Bayes.

As we have seen, all thresholding-based meta-learning methods rely on accurate probability estimations of $p(1|x)$ for the test example x. To achieve this, (Zadrozny & Elkan, 2001) propose several methods to improve the calibration of probability estimates. Still, as the true probabilities of the training examples are usually not given, accurate estimation of such probabilities remains elusive.

ETA (Sheng & Ling, 2006) is an empirical thresholding-based meta-learning method. It does not require accurate estimation of probabilities. It works well on the base cost-insensitive classification algorithms that do not generate accurate estimation of probabilities. The only constrain is that the base cost-insensitive algorithm can generate an accurate ranking, like C4.5. The main idea of *ETA* is simple. It uses cross-validation to search the best probability from the training instances as the threshold, and uses the searched threshold to predict the class label of test instances. To reduce overfitting, *ETA* searches for the best probability as threshold from the validation sets. More specifically, an *m-fold* cross-validation is applied on the training set, and the classifier predicts the probability estimates on the validation sets.

On the other hand, sampling first modifies the class distribution of training data according to (3), and then applies cost-insensitive classifiers on the sampled data directly. There is no need for the classifiers to produce probability estimations, as long as it can classify positive or negative examples accurately. (Zadronzny et al., 2003) show that proportional sampling with replacement produces duplicated cases in the training, which in turn produces overfitting in model building. However, it is unclear if proper overfitting avoidance (without overlapping between the training and pruning sets) would work well (future work). Instead, (Zadronzny et al., 2003) proposes to use "rejection sampling" to avoid duplication. More specifically, each instance in

the original training set is drawn once, and accepted into the sample with the accepting probability $C(j,i)/Z$, where $C(j,i)$ is the misclassification cost of class i, and Z is an arbitrary constant such that $Z \geq maxC(j,i)$. When $Z = maxC(j,i)$, this is equivalent to keeping all examples of the rare class, and sampling the majority class without replacement according to $C(1,0)/C(0,1)$ – in accordance with (3). With a larger Z, the sample S' produced by rejection sampling can become much smaller than the original training set S (i.e. $|S'| << |S|$). Thus, the learning models built on the reduced sample S' can be unstable. To reduce instability, (Zadrozny et al., 2003) apply bagging (Brieman, 1996; Buhlmann & Yu, 2003; Bauer & Kohavi, 1999) after rejection sampling. The resulting method is called Costing.

Weighting (Ting, 1998) can also be viewed as a sampling method. It assigns a normalized weight to each instance according to the misclassification costs specified in (3). That is, examples of the rare class (which carries a higher misclassification cost) are assigned proportionally high weights. Examples with high weights can be viewed as example duplication – thus sampling. Weighting then induces cost-sensitivity by integrating the instances' weights directly into C4.5, as C4.5 can take example weights directly in the entropy calculation. It works whenever the original cost-insensitive classifiers can accept example weights directly. Thus, we can say that Weighting is a semi meta-learning method. In addition, Weighting does not rely on bagging as Costing does, as it "utilizes" all examples in the training set.

FUTURE TRENDS

These meta-learning methods can reuse not only all the existing cost-insensitive learning algorithms which can produce the probabilities for future predictions, but also all the improvement approaches, such as Bagging (Brieman, 1996; Bauer & Kohavi, 1999), Boosting (Schapire, 1999; Bauer & Kohavi, 1999), and Stacking (Witten & Frank, 2005). Thus, cost-sensitive meta-learning is the possible main trend of future research in cost sensitive learning. However, current cost-sensitive meta-learning algorithms only focus on minimizing the misclassification costs. In real-world applications, there are different types of costs (Turney, 2000), such as attribute costs, example costs, and misclassification costs. It is very interesting to integrate all costs together. Thus, we have to design novel cost-sensitive meta-learning algorithms with a single objection – minimizing the total cost,

CONCLUSION

Cost-sensitive learning is one of the most important topics in data mining and machine learning. Many real-world applications can be converted to cost-sensitive learning, for example, the software defect escalation prediction system (Ling et al. 2006a). All cost-sensitive learning algorithms can be categorized into directed cost-sensitive learning and cost-sensitive meta-learning. The former approach produces the specific cost-sensitive learning algorithms (such as ICET and *CSTree*). The later approach produces wrapper methods to convert cost-insensitive algorithms into cost-sensitive ones, such as Costing, MetaCost, Weighting, *CSC*, and *ETA*.

KEY TERMS

Binary Classification: A typical classification task of data mining that classifies examples or objects into

two known classes, in terms of the attribute values of each example or object.

Classification: One of the task of data mining that categories examples or objects into a set of known classes, in terms of the attribute values of each example or object.

Cost-Insensitive Learning: A type of learning in data mining that does not take the misclassification costs into consideration. The goal of this type of learning is to pursue a high accuracy of classifying examples into a set of known classes.

Cost Matrix: A type of matrix that each cell in the matrix represents the cost of misclassifying an example from its true class (shown in column) into a predicted class (shown in row).

Cost-Sensitive Learning: A type of learning in data mining that takes the misclassification costs (and possibly other types of cost) into consideration. The goal of this type of learning is to minimize the total cost. The key difference between cost-sensitive learning and cost-insensitive learning is that cost-sensitive learning treats the different misclassifications differently.

Cost-Sensitive Meta-Learning: A type of cost-sensitive learning that does not change the base cost-insensitive learning algorithms, but works as a wrapper on these cost-insensitive learning algorithms, to make them cost-sensitive.

Misclassification Cost: The cost of classifying an example into an incorrect class.

Threshold: The probability value in classification that serves as the criterion for assigning an example to one of a set of known classes.

Count Models for Software Quality Estimation

Kehan Gao

Florida Atlantic University, USA

INTRODUCTION

Timely and accurate prediction of the quality of software modules in the early stages of the software development life cycle is very important in the field of software reliability engineering. With such predictions, a software quality assurance team can assign the limited quality improvement resources to the needed areas and prevent problems from occurring during system operation. Software metrics-based quality estimation models are tools that can achieve such predictions. They are generally of two types: a classification model that predicts the class membership of modules into two or more quality-based classes (Khoshgoftaar et al., 2005b), and a quantitative prediction model that estimates the number of faults (or some other quality factor) that are likely to occur in software modules (Ohlsson et al., 1998).

In recent years, a variety of techniques have been developed for software quality estimation (Briand et al., 2002; Khoshgoftaar et al., 2002; Ohlsson et al., 1998; Ping et al., 2002), most of which are suited for either prediction or classification, but not for both. For example, logistic regression (Khoshgoftaar & Allen, 1999) can only be used for classification, whereas multiple linear regression (Ohlsson et al., 1998) can only be used for prediction. Some software quality estimation techniques, such as case-based reasoning (Khoshgoftaar & Seliya, 2003), can be used to calibrate both prediction and classification models, however, they require distinct modeling approaches for both types of models. In contrast to such software quality estimation methods, count models such as the Poisson regression model (PRM) and the zero-inflated Poisson (ZIP) regression model (Khoshgoftaar et al., 2001) can be applied to yield both with just one modeling approach. Moreover, count models are capable of providing the probability that a module has a given number of faults. Despite the attractiveness of calibrating software quality estimation models with count modeling techniques, we feel that their application in software reliability engineering has been very limited (Khoshgoftaar et al., 2001). This study can be used as a basis for assessing the usefulness of count models for predicting the number of faults and quality-based class of software modules.

BACKGROUND

Software Metrics and Software Quality Modeling

Software product and process metrics are essential in the software development process. With metrics, the software development team is able to evaluate, understand, monitor and control a software product or its development process from original specifications all the way up to implementation and customer usage.

In the software reliability engineering literature, the relationship between software complexity metrics and the occurrence of faults in program modules has been used by various metrics-based software quality estimation models, such as case-based reasoning (Khoshgoftaar & Seliya, 2003), regression trees (Khoshgoftaar et al., 2002), fuzzy logic (Xu et al., 2000), genetic programming (Liu & Khoshgoftaar, 2001) and multiple linear regression (Ohlsson et al., 1998). Typically, a software quality model for a given software system is calibrated using the software metrics and fault data collected from a previous system release or similar project. The trained model can then be applied to predict the software quality of a currently under-development release or comparable project. Subsequently, the resources allocated for software quality improvement initiatives can then be targeted toward program modules that are of low quality or are likely to have many faults.

Count Modeling Techniques

Count models have many applications in economics, medical and health care, and social science (Cameron & Windmeijer, 1996; Deb & Trivedi, 1997; Mullahy, 1997). Count models refer to those models where the values of the dependent variable are count numbers, i.e., zeros or positive integers. The typical count models include Poisson regression models (Khoshgoftaar et al., 2005a), negative binomial regression models (Cameron & Trivedi, 1998), hurdle models (Gurmu, 1997) and zero-inflated models (Lambert, 1992).

The Poisson regression method is the basis in count modeling approach. It requires *equidispersion*, i.e., equality of mean and variance of the dependent variable. However in real life systems, the variance of the dependent variable often exceeds its mean value. This phenomenon is known as *overdispersion*. In software quality estimation models, overdispersion is often displayed by an excess of zeros for the dependent variable, such as number of faults. In such cases, a pure PRM fails to make an accurate quality prediction. In order to overcome this limitation of the pure PRM, a few but limited numbers of modifications or alternatives to the pure PRM have been investigated.

Mullahy (1986) used a with-zeros (WZ) model instead of a standard PRM. In his study, it was assumed that the excess of zeros resulted from a mixture of two processes, both of which produced zeros. One process generated a binary outcome, for example: perfect or non-perfect, while the other process generated count quantities which might follow some standard distribution such as, Poisson or negative binomial. Consequently, the mean structure of the pure Poisson process was changed to the weighted combination of the means from each process.

Lambert (1992) used a similar idea to Mullahy's when introducing the zero-inflated Poisson (ZIP) model. An improvement of ZIP over WZ is that ZIP establishes a logit relationship between the "probability that a module is perfect" and the "independent variables of the data set". This relationship ensures that the probability distribution is between 0 and 1.

Similar to the zero-inflated model, another variation of count models is the hurdle model (Gurmu, 1997) which also consists of two parts. However, instead of having perfect and non-perfect groups of modules, the hurdle model divides them into a lower count group and a higher count group, based on a binary distribution. The dependent variable of each of these groups is assumed to follow a separate distribution process. Therefore, two factors may affect predictive quality of the hurdle models: the crossing or threshold value of the dependent variable that is used to form the two groups, and the specific distribution each group is assumed to follow.

Preliminary studies (Khoshgoftaar et al., 2001; Khoshgoftaar et al., 2005a) performed by our research team examined the ZIP regression model for software quality estimation. In the studies, we investigated software metrics and fault data collected for all the program modules from a commercial software system. It was found that over two thirds of the program modules had no faults. Therefore, we considered the ZIP regression method to develop the software quality estimation model.

MAIN FOCUS

Poisson Regression Model

The Poisson regression model is derived from the Poisson distribution by allowing the expected value of the dependent variable to be a function associated with the independent variables. Let $(y_i, \mathbf{x}_i)$ be an observation in a data set, such that y_i and $\mathbf{x}_i$ are the dependent variable and vector of independent variables for the i^{th} observation. Given $\mathbf{x}_i$, assume y_i is Poisson distributed with the probability mass function (*pmf*) of,

$$\Pr(y_i \mid \mu_i, \mathbf{x}_i) = \frac{e^{-\mu_i}\mu_i^{y_i}}{y_i!} \quad \text{for } y_i = 0, 1, 2, \cdots, \tag{1}$$

where μ_i is the mean value of the dependent variable y_i. The expected value (E) and the variance (Var) of y_i are identical, i.e., $E(y_i|\mathbf{x}_i) = Var(y_i|\mathbf{x}_i) = \mu_i$.

To ensure that the expected value of y_i is nonnegative, the link function, which displays a relationship between the expected value and the independent variables, should have the following form (Cameron & Trivedi, 1998):

$$\mu_i = E(y_i|\mathbf{x}_i) = e^{\mathbf{x}_i'\boldsymbol{\beta}} \tag{2}$$

where $\boldsymbol{\beta}$ is an unknown parameter vector and $\mathbf{x}_i'$ represents the transpose of the vector $\mathbf{x}_i$.

Zero-Inflated Poisson Regression Model

The zero-inflated Poisson regression model assumes that all zeros come from two sources: the source representing the perfect modules in which no faults occur, and the source representing the non-perfect modules in which the number of faults in the modules follows the Poisson distribution. In the ZIP model, a parameter, φ_i, is introduced to denote the probability of a module being perfect. Hence, the probability of the module being non-perfect is $1 - \varphi_i$. The *pmf* of the ZIP model is given by,

$$\Pr(y_i \mid \mathbf{x}_i, \mu_i \phi_i) = \begin{cases} \phi_i + (1-\phi_i)e^{-\mu_i}, & y_i = 0, \\ (1-\phi_i)\dfrac{e^{-\mu_i}\mu_i^{y_i}}{y_i!}, & y_i = 1, 2, 3, \cdots. \end{cases} \quad (3)$$

The ZIP model is obtained by adding the next two link functions:

$$\log(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta} \quad (4)$$

$$\text{logit}(\phi_i) = \log\frac{\phi_i}{1-\phi_i} = \mathbf{x}_i' \boldsymbol{\gamma}, \quad (5)$$

where log denotes the natural logarithm and $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ are unknown parameter vectors.

The maximum likelihood estimation (MLE) technique is used in the parameter estimation for the PRM and ZIP models (Khoshgoftaar et al., 2005a).

Software Quality Classification with Count Models

Software quality classification models are initially trained with known software metrics (independent variables) and class membership (dependent variable) data for the system being modeled. The dependent variable is indicated by class, i.e., fault-prone (*fp*) and not fault-prone (*nfp*). The quality-based class membership of the modules in the training data set is usually assigned based on a pre-determined threshold value of a quality factor, such as number of faults or number of lines of code churn. For example, a module is defined as *fp* if its number of faults exceeds the selected threshold value, and *nfp* otherwise. The chosen threshold value is usually dependent on the project management's quality improvement objectives. In a two-group classification model, two types of misclassifications can occur: Type I (*nfp* module classified as *fp*) and Type II (*fp* module classified as *nfp*).

We present a generic approach to building count models for classification. Given a data set with observations, $(y_i, \mathbf{x}_i)$, the following steps illustrate the approach for classifying software modules as *fp* and *nfp*:

1. Estimate probabilities of the dependent variable (number of faults) being distinct counts by the given *pmf*, $\hat{\Pr}(y_i)$, $y_i = 0, 1, 2, \ldots$.
2. Calculate the probabilities of a module being *fp* and *nfp*. The probability of a module being *nfp*, i.e., the probability of a module's dependent variable being less than the selected threshold (t_0), is given by $f_{nfp}(\mathbf{x}_i) = \sum_{y_i < t_0} \hat{\Pr}(y_i)$. Then, the probability of a module being *fp* is $f_{fp}(\mathbf{x}_i) = 1 - \sum_{y_i < t_0} \hat{\Pr}(y_i)$.
3. Apply the generalized classification rule (Khoshgoftaar & Allen, 2000) to obtain the class membership of all modules.

$$Class(\mathbf{x}_i) = \begin{cases} fault-prone, & \text{if } \frac{f_{fp}(\mathbf{x}_i)}{f_{nfp}(\mathbf{x}_i)} \geq c \\ not\ fault-prone, & \text{otherwise.} \end{cases} \quad (6)$$

where c is a model parameter, which can be varied to obtain a model with the preferred balance between the Type I and Type II error rates. The preferred balance is dependent on the quality improvement needs of the given project.

Quantitative Software Quality Prediction with Count Models

For count models, the expected value of the dependent variable is used to predict the number of faults for each module. The *pmf* is used to compute the probability of each module having various counts of faults (known as *prediction probability*). Prediction probability can be useful in assessing the uncertainty and risks associated with software quality prediction models.

The accuracy of fault prediction models are measured by the average absolute error (AAE) and the av-

erage relative error (ARE), i.e., $\text{AAE} = \frac{1}{n}\sum_{i=1}^{n} | \hat{y}_i - y_i |$; $\text{ARE} = \frac{1}{n}\sum_{i=1}^{n} \frac{|\hat{y}_i - y_i|}{y_i + 1}$, where n is the number of modules, y_i and $\hat{y}_i$ are the actual and predicted values of the dependent variable. In the case of ARE, since the actual value of the dependent variable may be zero, we add a '1' to the denominator to avoid division by zero.

A CASE STUDY

System Description

The software metrics and fault data for this case study were collected from a Command and Control Communication System (*CCCS*), which is a large military telecommunications system written in Ada using the procedural paradigm. Software product metrics were collected from the source code. A software module was identified as an Ada package, consisting of one or more procedures. The software product metrics used to model the software quality of this system are presented in Table 1. The dependent variable, *Fault*, was attributed to each module during the system integration and test phase. The top 20% of the modules contained 82.2% of the faults and 52% of the modules had no faults. The data set consisted of 282 program modules. A software module was considered as *fp* if it had at least four faults and *nfp* otherwise.

Calibrating Models

Using an impartial data splitting technique, we designated the 282 modules into the Fit (188) and Test (94) data sets for model-fitting and model-evaluation. The performance evaluation of software quality models on the test data set simulates the predictive capability of the models when applied to an under-development system release or similar project.

Principle components analysis (PCA) (Berenson et al., 1983) was used to remove existing correlation among the software product metrics and also to reduce the dimensionality of the multivariate data set. Two significant principle components were extracted from the original eight software metrics of the *CCCS* system. These two principle components accounted for about 94% of the explained variance in the data set and accordingly they are used to calibrate classification and prediction models for this case study. The estimated parameters based on the two principle components for PRM and ZIP are summarized in Table 2.

Results

Our modeling objective for the classification models was to obtain a model that depicted the preferred balance of equality between the error rates, with Type II being as low as possible. This model selection strategy was based on our discussions with the software development team of the telecommunications system. We have summarized the predictive performances (based on the Test data set) of the preferred classification models of PRM and ZIP in Table 3. We observe that though the predictive accuracies (numbers of Type I and Type II errors) of the two models are similar, the ZIP model is the closest match to our model selection strategy. Moreover, the overall misclassification error rate of the ZIP model is also slightly lower than that of PRM.

For software fault prediction, Table 4 presents both the quality-of-fit and the predictive abilities of the two count models. The table also shows standard deviations of the absolute error (std AE) and the relative error (std RE). A relative comparison suggests that the ZIP model has a better quality-of-fit and predictive power than the PRM. A further in-depth discussion on the relative

Table 1. Software product metrics for CCCS

Symbol	Description
η1	Number of unique operators
η2	Number of unique operands

Table 2. Regression count models for CCCS

Models	$\hat{\beta}_0$	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\gamma}_0$	$\hat{\gamma}_1$	$\hat{\gamma}_2$
PRM	0.2739	0.8971	-0.1398	-	-	-
ZIP	0.8714	0.6624	-0.0834	-0.6473	-2.0594	-1.2135

Table 3. Misclassification rates for CCCSTest

Model	Type I errors		Type II errors		Overall	
Type	Number	%	Number	%	Number	%
PRM	13	17.33%	3	15.79%	16	17.02%
ZIP	12	16.00%	3	15.79%	15	15.96%

performance of these two count models is presented in our recent work (Khoshgoftaar et al., 2005a). The prediction probabilities of each module having various counts of faults were computed by substituting the respective parameters of Table 2 in the *pmf* of the respective count models.

FUTURE TRENDS

Future work related to software quality modeling with count models will involve additional empirical case studies, and investigation of other count modeling techniques and comparing their classification and fault prediction performances with those of the PRM and ZIP models. The complexity of the count models' calibration (estimation of parameters) will greatly increase as the number of metrics involved in the modeling process increases. PCA is a statistical technique that can transform the original set of correlated variables into a smaller set of uncorrelated variables that are linear combinations of the original ones. However, PCA can not detect software metrics that significantly contribute to software quality. Therefore, the study that investigates the attribute selection problem for reducing the number of the software metrics in the context of count models is another interesting future research topic.

CONCLUSION

Software metrics-based quality estimation models include those that provide quality-based classification of program modules and those that provide quantitative prediction of a quality factor for the program modules. Generally speaking, software quality modeling techniques are suited for only one of these types of models, i.e., classification or prediction, but not for both. In contrast, count models can be adapted to calibrate both classification models and prediction models. Moreover, their unique ability to provide the probability that a given program module will have a specific number of faults can not be obtained by other prediction techniques. A promising use of such information is to assess the uncertainty and risks of software quality predictions obtained by the count models.

Since the number of faulty modules observed in high assurance systems, such as telecommunications systems, is usually a small fraction of the total number of modules, the ZIP model is suited for the software quality modeling of such systems: it uses a different process to model the program modules with no faults.

KEY TERMS

Overdispersion: *Overdispersion* occurs when the observed variance of the data is larger than the predicted variance. This is particularly apparent in the case of a Poisson regression model.

Poisson Regression Models: Poisson regression assumes that the data follows a Poisson distribution, which is frequently encountered when counting a number of events. Poisson regression also models the variance as a function of the mean.

Software Fault Prediction: To estimate the number of faults (or some other quality factor) that are likely to occur in software modules.

Software Metrics: A software metric is a measure of some property of a piece of software or its specifications.

Software Quality Classification: To predict the class membership of modules into two or more quality-based classes. For example, fault-prone and not fault-prone.

Prediction Probability: The probability that a given number of faults will occur in any given program module.

Zero-Inflated Poisson Regression Models: ZIP models incorporate Poisson probabilities but allow the probability of a zero to be larger than what a Poisson distribution might suggest. It is a mixture distribution where zero is set with a certain probability and larger

Data Analysis for Oil Production Prediction

Christine W. Chan

Hanh H. Nguygen
University of Regina, Canada

Xiongmin Li
University of Regina, Canada

INTRODUCTION

An economic evaluation of a new oil well is often required, and this evaluation depends heavily on how accurately production of the well can be estimated. Unfortunately, this kind of prediction is extremely difficult because of complex subsurface conditions of reservoirs. The industrial standard approach is to use either curve-fitting methods or complex and time-consuming reservoir simulations. In this study, we attempted to improve upon the standard techniques by using a variety of neural network and data mining approaches. The approaches differ in terms of prediction model, data division strategy, method, tool used for implementation, and the interpretability of the models. The objective is to make use of the large amount of data readily available from private companies and public sources to enhance understanding of the petroleum production prediction task. Additional objectives include optimizing timing for initiation of advanced recovery processes and identifying candidate wells for production or injection.

BACKGROUND

The production of an oil well is influenced by a variety of factors, many of which are unknown and unpredictable. Core logs, drill steam test (DST), and seismic data can provide geological information about the surrounding area; however, this information alone cannot explain all the characteristics about the entire reservoir. While core analysts and reservoir engineers can analyze and interpret geoscience data from several wells with the help of numerical reservoir simulations, the process is technically difficult, time consuming and expensive in terms of both labor and computational resources.

For a quick estimation of petroleum production only, the decline curve analysis remains the most popular methods among engineers (Baker et al., 1998; Li, Horne, 2003). However, a weakness with the decline curve analysis technique is that it is difficult to foresee which equation can adequately describe production of a reservoir. Moreover, a single curve is often inadequate for describing production data generated during the entire life of the reservoir. Therefore, fitting production data to a decline curve is a difficult process and can result in unreliable predictions (El-Banbi, Wattenbarger, 1996).

To overcome the weakness of conventional decline curve analysis techniques, we adopted data mining techniques for the task of modeling non-linear production data. We compared the use of neural networks versus curve estimation technique in the prediction of oil production (Nguyen et al, 2003) and found that with sufficient training data, the neural network approach can perform better on unknown data. In our exploration on modeling production data using artificial intelligence techniques, we introduced variations along six dimensions, which will be discussed in the next section.

MAIN FOCUS: VARIATIONS IN NEURAL NETWORK MODELING APPROACHES

Prediction Model

The first step of our research was to identify the variables involved in the petroleum production prediction task. The first modeling effort included both production time series and geoscience parameters as input variables for the model. Eight factors that influence production were identified; however, since only data for

the three parameters of permeability, porosity, and first shut-in pressure were available, the three parameters were included in the model. The production rates of the three months prior to the target prediction month were also included as input variables. The number of hidden units was determined by trial and error. After training the neural network, a sensitivity test was conducted to measure the impact of each input variable on the output. The results showed that all the geoscience variables had limited (less than 5%) influence on the production prediction.

Therefore, the second modeling effort relied on a model that consists of time series data only. The training and testing error was only slightly different from those of the first model. Hence, we concluded that it is reasonable to omit the geoscience variables from our model. More details on the modeling efforts can be found in (Nguyen et al., 2004).

Data Manipulation Strategy

Since different ways of data preprocessing can influence model accuracy and usage, we investigated the following three approaches for processing the monthly oil production data (Nguyen and Chan, 2004 b): (1) **sequential**, when data from individual wells were arranged sequentially, (2) **averaging**, when data from individual wells were averaged over their lifetimes, and (3) **individual**, when data from each individual well were treated independently. Two types of models were used: one with past productions as input and another with time indices as input.

The results showed that with production volumes as input, the average and the individual approaches suffered from forecast inaccuracy when training data was insufficient: the resulting neural networks only performed well when the training data covered around 20 years of production. This posed a problem since many wells in reality cannot last that long, and it is likely that intervention measures such as water flooding would have been introduced to the well before that length of time has elapsed. Hence, these two approaches were not suitable for prediction at the initial stage of the well. On the other hand, the sequential approach used a large number of training samples from both early and late stages, therefore the resulting models worked better when provided with unseen data.

The neural networks with production months as input usually required less data for training. However, it was also observed that long-life wells generated smoother decline curves. We believe it is recommendable to use all three data preprocessing approaches, i.e. sequential, averaging and individual, when the time index is used. The individual approach can provide reference points for new infill wells while the other two approaches give some estimation of what would happen to a typical well in the study area.

Multiple Neural Networks

Several researchers have attempted to use multiple neural networks to improve model accuracy. Hashem et al. (1994) proposed using optimal linear combinations of a number of trained neural networks in order to integrate the knowledge required by the component networks. Cho and Kim (1995) presented a method using fuzzy integral to combine multiple neural networks for classification problems. Lee (1996) introduced a multiple neural network approach in which each network handles a different subset of the input data. In addition to a main processing neural network, Kadaba et al. (1989) used data-compressing neural networks to decrease the input and output cardinalities.

The multiple-neural-network (MNN) approach proposed in (Nguyen and Chan, 2004 a) aims to improve upon the classical recursive one-step-ahead neural network approach. The objective of the new approach is to reduce the number of recursions needed to reach the lead time. A MNN model is a group of neural networks working together to perform a task. Each neural network was developed to predict a different time period ahead, and the prediction terms increased at a binary exponential rate. A neural network that predict 2^n step ahead is called an n-ordered neural network.

The choice of binary exponential was made due to two reasons. First, big gaps between two consecutive neural networks are not desirable. Forecasting is a process of reducing the lead time to zero and smaller. The smaller the gaps are, the fewer steps the model needs to take in order to make a forecast. Secondly, binary exponential does not introduce bias on the roles of networks while a higher exponential puts a burden onto the lower-ordered neural networks.

To make a prediction, the neural network with the highest possible order is used first. For example, to predict 7 units ahead (x_{t+7}), a 2-ordered neural network is used first. It then calculates temporary variables backward using lower-ordered neural networks.

Implementation Tools

In order to implement our neural networks, we used two development tools from Gensym Corporation, USA, called NeurOn-Line (NOL) and NeurOnline Studio (NOL Studio). However, these tools cannot be extended to support the development of multiple neural network systems described in the previous section. Therefore, we implemented an in-house tool in Java™ for this purpose (Nguyen and Chan, 2004 a). The MNN system includes several classes that implement methods for training and testing neural networks, making forecasts, and connecting sub-neural networks together. The structure of the system is illustrated in Figure 1.

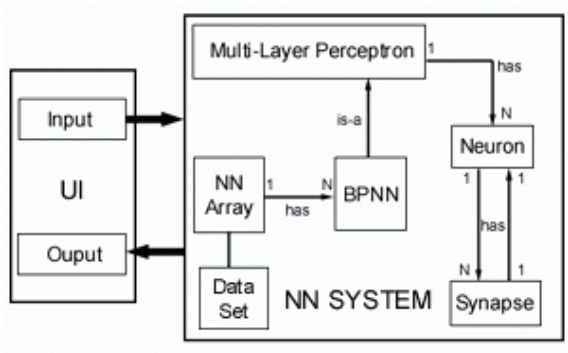
Decision Support System for Best and Worst Case Scenarios

In addition to predicting a crisp number as the production volume, we also developed a decision support system (DSS) that predicts a range of production for an in-fill well based on existing wells in the reservoir (Nguyen and Chan, 2005). The DSS consists of three main components: history-matching models, an analogue predictor, and a user interface.

The history-matching models include both neural network and curve estimation models, and they were developed offline based on historical data for each existing wells in the study area. Using the multiplicative analogue predictor, the best and worst case scenarios were calculated from these models with respect to initial condition of the new well. The system generates a table of predicted production rate and production life in months with respect to each reference well, and also graphs of the best and worse case scenarios for each method among all the wells in the group.

We carried out a test on how accurate the system can predict based on available data. Since some wells in our data set had not come to the end of their production lives, complete sets of observed data were not available. We compensated for this limitation by restricting the comparison of the predicted results of each well against those of other wells in the same group only for the available data sets. The results showed that the ranges of values that the decision support system predicts were relatively wide. A possible reason is that even though the wells come from the same area, they have different characteristics.

Figure 1. Main components of multiple neural network system



Learning Rules with Neural Based Decision Learning Model

While the artificial neural network technology is a powerful tool for predicting oil production, it cannot give explicit explanation of the result. To obtain explicit information on the processing involved in generating a prediction, we adopted the neural based decision-learning approach.

The decision-tree learning algorithms (such as C4.5) derive decision trees and rules based on the training dataset. These derived trees and rules can be used to predict the classes of new instances. Since the decision-tree learning algorithms usually work with only one attribute at a time, without considering the dependencies among attributes, the results generated by those algorithms are not optimal. However, considering multiple attributes simultaneously can introduce a combinatorial explosion problem.

In reality, the process of oil production is influenced by many interdependent factors, and an approach which can handle the complexity is needed. The Neural-Based Decision Tree Learning (NDT) proposed by (Lee and Yen 2002) combines neural network and decision tree algorithms to handle the problem. The NDT model is discussed as follows. The architecture of the NDT model for a mix-type data set, with squared boxes showing the main processing components of the neural network and decision tree is shown below. The NDT algorithm models a single pass process initialized by the acceptance of the training data as input to the neural network model. The generated output is then passed on for decision tree construction, and the resulting rules will be the net output of the NDT model. The arrows

show the direction of data flow from the input to the output, with the left-hand-side downward arrows indicating the processing stages of nominal attributes, and the right-hand-side arrows showing the corresponding process for numeric-type data.

As illustrated in Figure 2 below, the rule extraction steps in this NDT model include the following:

1. Divide the numerical-categorical-mixed dataset into two parts, e.g. numerical subset and nominal subset. For a pure-type data set, no division of the data set is necessary.
2. For the numerical subset, train a feed-forward back-propagation neural network and collect weights between the input layer and the first hidden layer. Then, change each attribute value according to the weights generated by the neural network model.
3. For the categorical subset, train a back-propagation neural network and classify categorical attributes according to the weights generated by the neural network model.
4. Combine the new numerical subset and new categorical subset into a new numerical-categorical-mixed dataset.
5. The new dataset is fed as input to the C4.5 system to generate the decision tree and rules.

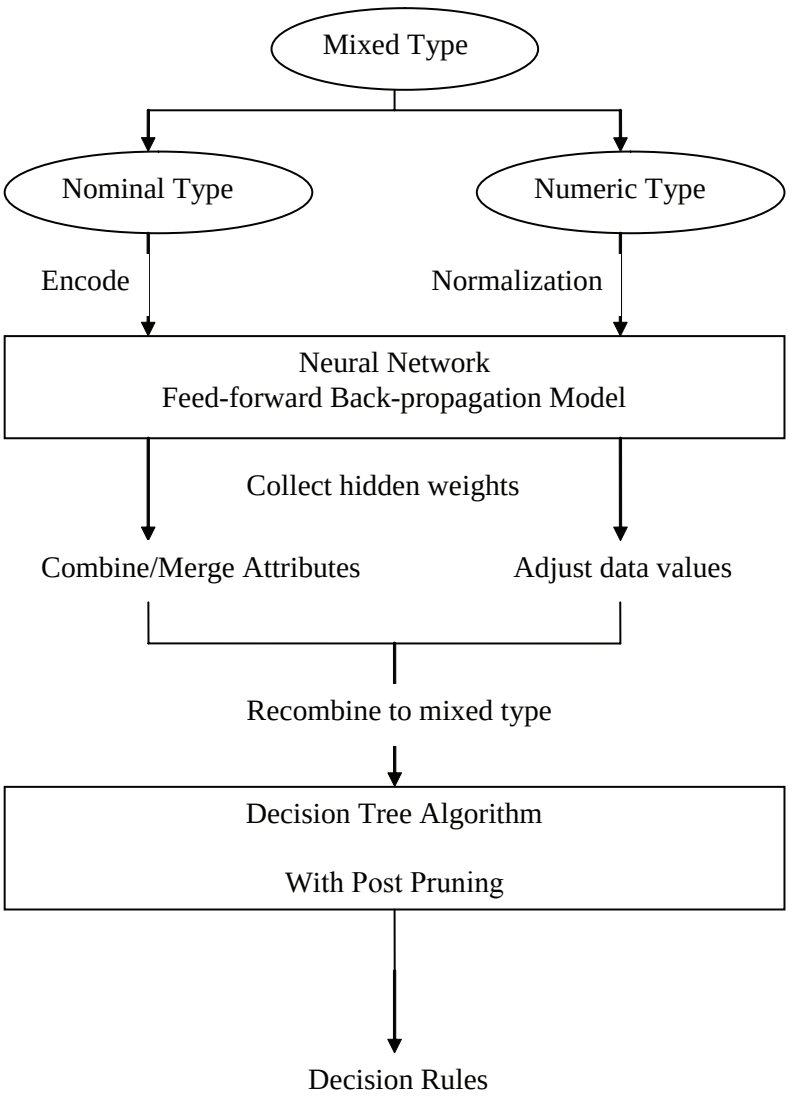

Figure 3. Training result of the original dataset

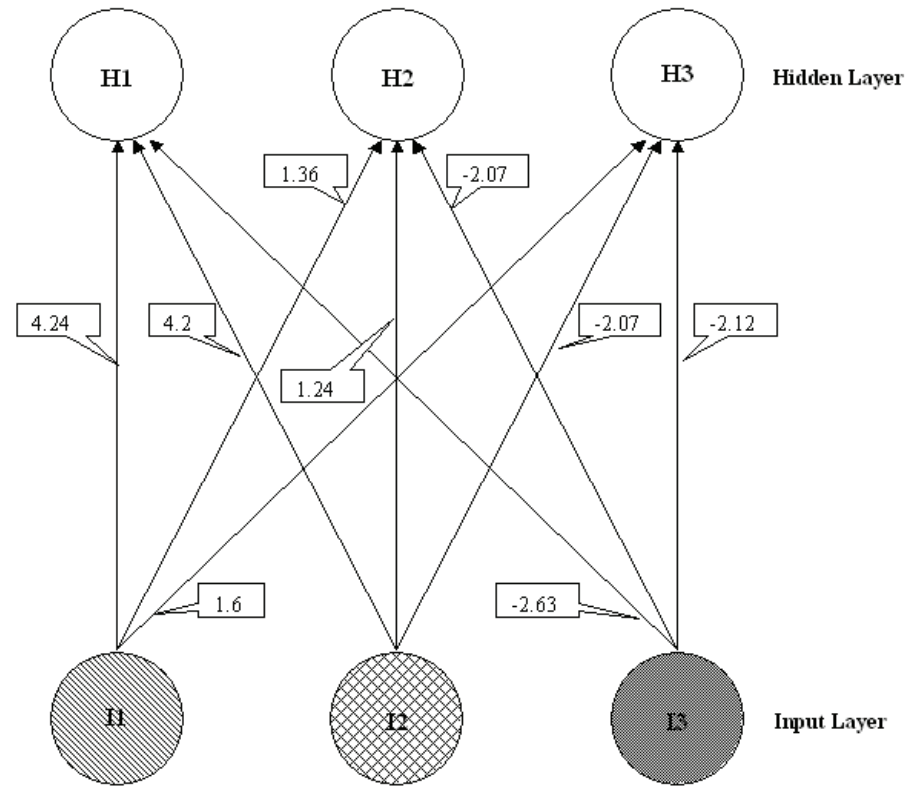

Application of NDT Model for Petroleum Production Data Classification

The proposed NDT model was developed and applied for classifying data on 320 wells from the Midale field in SaskatFchewan, Canada, Some preliminary results are presented in (Li. and Chan, 2007). A 10-fold cross-validation was used in all the decision-tree experiments, where the 10 samples were randomly selected without replacement from the training set. The dataset contains three numeric attributes that describe geoscientific properties which are significant factors in oil production: Permeability, Porosity and First-Shut-In-Pressure. With only numerical-type data in this dataset, the neural network model was trained with the following parameters:

- Number of Hidden Layers: 1
- Input Nodes: 3
- Hidden Nodes: 3
- Learning Rate: 0.3
- Momentum: 0.2
- Activation function: Sigmoid Function

The training result of the model is shown in Figure 3. Based on the result, we examine the link weights between the input layer and hidden layer. Then, the original numeric data set was trained using Eq.(1),(2), (3) shown below into a new dataset which has equivalent values as the inputs to the hidden layer of the trained neural network.

$$H_1 = -0.37 + 4.24 \times Permeability + 4.2 \times Porosity + (-2.63) \times Pressure \quad (1)$$

$$H_2 = -0.76 + 1.36 \times Permeability + 1.24 \times Porosity + (-2.07) \times Pressure \quad (2)$$

$$H_3 = -0.82 + 1.6 \times Permeability + 1.31 \times Porosity + (-2.12) \times Pressure \quad (3)$$

Figure 4. Sample rule generated by C4.5 decision-tree model

```
IF Porosity <= 11.7348 (Unit: Percent) THEN
    IF Permeability <= 4.6188 (Unit: Millidarcy) THEN
       IF Pressure <= 14893.0 (Unit: MPa) THEN
          Oil Production = Low [2000, 97767] (Unit: m³)
```

Figure 5. Sample rule generated by NDT model

```
IF H1 <= -38035.40 THEN
    IF H2 <= -30334.39 THEN
        IF H3 <= -31559.88 THEN
           Oil Production = Low [2000, 97767] (Unit: m³)
```

The decision tree model was then applied to the new dataset to generate decision rules. Some sample rules generated by the original dataset using the decision tree model are shown in Figure 4 and the rules generated with the new dataset using the NDT model are shown in Figure 5.

The results of the two applications are summarized in Table 1, where the results are the averages generated from 10-fold cross-validations for all data sets. Since the sampling used in cross-validation was randomly taken for each run, the results listed include only the ones with the best observed classification rates.

FUTURE TRENDS

Currently, we have two directions for our future work. First, we plan to work with petroleum engineers who would preprocess the geoscience data into different rock formation groups and develop one model for each group. The values for the parameters of permeability and porosity will not be averaged from all depths, instead, the average of values from one formation only will be taken. The production value will be calculated as the summation of productions from different formations of one well. The focus of the work will extend the original focus on petroleum production prediction to include the objectives of characterizing the reservoir and data workflow organization. Secondly, we plan to focus on predicting behaviors or trends of an infill well instead of directly estimating its production.

CONCLUSION

It can be seen from our works that the problem of predicting oil production presents significant challenges for artificial intelligence technologies. Although we have varied our approaches on different aspects of the solution method, such as employing different data division strategies, including different parameters in the model, and adopting different AI techniques, the results are not as accurate as desired. It seems that production depends on many factors, some of which are unknown. To further complicate the problem, some factors such as permeability, cannot be accurately measured because its value varies depending on the production location and rock formation. Our future work will involve acquiring more domain knowledge and incorporating them into our models.

KEY TERMS

Artificial Neural Network: An interconnected group of artificial neurons (or processing units) that uses a mathematical model or computational model for information processing based on a connectionist approach to computation.

Curve Estimation: A procedure for finding a curve which matches a series of data points and possibly other constraints. It involves computing the coefficients of a function to approximate the values of the data points.

Decision Tree: A decision tree is an idea generation tool that generally refers to a graph or model of decisions and their possible consequences, including chance event outcomes, resource costs, and utility. In data mining, a decision tree is a predictive model.

Decision Support System (DSS): A DSS is an interactive computer-based system intended to help managers make decisions. A DSS helps a manager retrieve, summarize and analyze decision relevant data.

Multiple Neural Networks: A multiple neural network system is a set of single neural networks integrated into a cohesive architecture. Multiple neural networks have been demonstrated to improve performance on tasks such as classification and regression when compared to single neural networks.

Neural-Based Decision Tree (NDT): The NDT model proposed by Lee and Yen attempts to use neural network to extract the underlying attribute dependencies that are not directly observable by humans. This model combines neural network and decision tree algorithms to handle the classification problem.

Prediction of Oil Production: A forecast on future volume of oil extracted from a production oil well based on historical production records.

Data Confidentiality and Chase-Based Knowledge Discovery

Seunghyun Im

INTRODUCTION

This article discusses data security in Knowledge Discovery Systems (KDS). In particular, we presents the problem of confidential data reconstruction by Chase (Dardzinska and Ras, 2003c) in KDS, and discuss protection methods. In conventional database systems, data confidentiality is achieved by hiding sensitive data from unauthorized users (e.g. Data encryption or Access Control). However, hiding is not sufficient in KDS due to Chase. Chase is a generalized null value imputation algorithm that is designed to predict null or missing values, and has many application areas. For example, we can use Chase in a medical decision support system to handle difficult medical situations (e.g. dangerous invasive medical test for the patients who cannot take it). The results derived from the decision support system can help doctors diagnose and treat patients. The data approximated by Chase is particularly reliable because they reflect the actual characteristics of the data set in the information system.

Chase, however, can create data security problems if an information system contains confidential data (Im and Ras, 2005) (Im, 2006). Suppose that an attribute in an information system S contains medical information about patients; some portions of the data are not confidential while others have to be confidential. In this case, part or all of the confidential data in the attribute can be revealed by Chase using knowledge extracted at S. In other words, self-generated rules extracted from non-confidential portions of data can be used to find secret data.

Knowledge is often extracted from remote sites in a Distributed Knowledge Discovery System (DKDS) (Ras, 1994). The key concept of DKDS is to generate global knowledge through knowledge sharing. Each site in DKDS develops knowledge independently, and they are used jointly to produce global knowledge without complex data integrations. Assume that two sites S_1 and S_2 in a DKDS accept the same ontology of their attributes, and they share their knowledge in order to obtain global knowledge, and an attribute of a site S_1 in a DKDS is confidential. The confidential data in S_1 can be hidden by replacing them with null values. However, users at S_1 may treat them as missing data and reconstruct them with Chase using the knowledge extracted from S_2. A distributed medical information system is an example that an attribute is confidential for one information system while the same attribute may not be considered as secret information in another site. These examples show that hiding confidential data from an information system does not guarantee data confidentiality due to Chase, and methods that would protect against these problems are essential to build a security-aware KDS.

BACKGROUND

Data Security and Knowledge Discovery System

Security in KDS has been studied in various disciplines such as cryptography, statistics, and data mining. A well known security problem in cryptography area is how to acquire global knowledge in a distributed system while exchanging data securely. In other words, the objective is to extract global knowledge without disclosing any data stored in each local site. Proposed solutions are based primarily on the idea of secure multiparty protocol (Yao, 1996) that ensures each participant cannot learn more than its own input and outcome of

a public function. Various authors expanded the idea to build a secure data mining systems. Clifton and Kantarcioglou employed the concept to association rule mining for vertically and horizontally partitioned data (Kantarcioglou and Clifton, 2002). Du et al, (Du and Zhan, 2002) and Lindell et al, (Lindell and Pinkas, 2000) used the protocol to build a decision tree. They focused on improving the generic secure multiparty protocol for ID3 algorithm [Quinlan, 1993]. All these works have a common drawback that they require expensive encryption and decryption mechanisms. Considering that real world system often contain extremely large amount of data, performance has to be improved before we apply these algorithms. Another research area of data security in data mining is called perturbation. Dataset is perturbed (e.g. noise addition or data swapping) before its release to the public to minimize disclosure risk of confidential data, while maintaining statistical characteristics (e.g. mean and variable). Muralidhar and Sarathy (Muralidhar and Sarathy, 2003) provided a theoretical basis for data perturbation in terms of data utilization and disclosure risks. In KDD area, protection of sensitive rules with minimum side effect has been discussed by several researchers. In (Oliveira & Zaiane, 2002), authors suggested a solution to protecting sensitive association rules in the form of "sanitization process" where protection is achieved by hiding selective patterns from the frequent itemsets. There has been another interesting proposal (Saygin & Verykios & Elmagarmid, 2002) for hiding sensitive association rules. They introduced an interval of minimum support and confidence value to measure the degree of sensitive rules. The interval is specified by the user and only the rules within the interval are to be removed. In this article, we focus on data security problems in distributed knowledge sharing systems. Related works concentrated only on a standalone information system, or did not consider knowledge sharing techniques to acquire global knowledge.

Chase Algorithm

The overall steps for Chase algorithm is the following.

1. Identify all incomplete attribute values in S.
2. Extract rules from S describing these incomplete attribute values.
3. Null values in S are replaced by values (with their weights) suggested by the rules.
4. Steps 1-3 are repeated until a fixed point is reached.

More specifically, suppose that we have an incomplete information system $S = (X,A,V)$ where X is a finite set of object, A is a finite set of attributes, and V is a finite set of their values. Incomplete information system is a generalization of an information system introduced by (Pawlak, 1991). It is understood by having a set of weighted attribute values as a value of an attribute. In other words, multiple values can be assigned as an attribute value for an object with their weights (w). Assuming that a knowledge base $KB = \{(t \rightarrow v_c) \in D : c \in In(A)\}$ is a set of all classification rules extracted from S by $ERID(S, \lambda_1 \lambda_2)$, where $In(A)$ is the set of incomplete attributes in S, v_c is a value of attribute c, and λ_1, λ_2 are thresholds for minimum support and minimum confidence, correspondingly. *ERID* (Dardzinska and Ras, 2003b) is the algorithm for discovering rules from incomplete information systems, which can handle weighted attribute values. Assuming further that $Rs(x_i) \subseteq KB$ is the set of rules that all of the conditional part of the rules match with the attribute values in $x_i \in S$, and $d(x_i)$ is a null value, then, there are three cases for null value imputations (Dardzinska and Ras, 2003a, 2003c):

1. $Rs(x_i) = \Phi$. $d(x_i)$ cannot be replaced.
2. $Rs(x_i) = \{ r_1 = [t_1 \rightarrow d_1], r2 = [t_1 \rightarrow d_1], \ldots r_k = [t_k \rightarrow d_i]\}$. $d(x_i) = d_1$ because every rule predicts a single decision attribute value.
3. $Rs(x_i) = \{ r_1 = [t1 \rightarrow d_1], r2 = [t_1 \rightarrow d_2], \ldots r_k = [t_k \rightarrow d_k]\}$. Multiple values can replace $d(x_i)$.

Clearly, the weights of predicted values, which represent the strength of prediction, are 1 for case 2. For case 3, weight is calculated based on the confidence and support of rules used by Chase (Ras and Dardzinska, 2005b). Chase is an iterative process. An execution of the algorithm for all attributes in S typically generates a new information system, and the execution is repeated until it reaches a state where no improvement is achieved.

MAIN FOCUS OF THE ARTICLE

Reconstruction of Confidential Data by Chase

Suppose that an information system *S* is part of a knowledge discovery system (either single or distributed). Then, there are two cases in terms of the source of knowledge.

1. Knowledge is extracted from local site, *S*
2. Knowledge is extracted from remote site, S_i, *for* $S_i \neq S$

Let's first consider a simple example that illustrates how locally extracted rules can be used to reveal confidential data. Suppose that part of an attribute *d* is confidential and it is denoted as $v_{conf} = \{d(x_3), d(x_4)\}$. To protect v_{conf}, we hide them by constructing a new information system S_d, where

1. $a_{S(x)} = a_{S_d(x)}$, for any $a \in A - \{d\}, x \in X$
2. $d_{S_d(x)} = d_{S_d(x)} - v_{conf}$,

Now, we extract rules from S_d in terms of *d*. Assuming that a rule, $r_1 = a_1 \rightarrow d_3$ is extracted. It is applicable to objects that d_3 was hidden, meaning the conditional part of r_1 overlaps with the attribute value in the object. We can use Chase to predict the confidential data d_3. Clearly, it is possible that predicted values are not equal to the actual values or its weight is low. In general, there are three different cases.

1. $d_{S_d(x)} = d_{S(x)}$ and $w \geq \lambda$
2. $d_{S_d(x)} = d_{S(x)}$ and $w < \lambda$
3. $d_{S_d(x)} \neq d_{S(x)}$

where λ is the minimum threshold value for an information system (Ras and Dardzinska, 2005). Clearly, $d_{S_d(x)}$ in case 1 is our major concern because the confidence of approximated data is higher than λ. We do not need to take any action for case 2 and case 3.

The notion of confidential data disclosure by Chase can be extended to Distributed Knowledge Discovery System. The principal of DKDS is that each site develops knowledge independently, and the knowledge is used jointly to produce global knowledge (Ras, 1994), so that each site acquires global knowledge without implementing complex data integrations. The security problem in this environment is created by the knowledge extracted from remote sites. For example, assume that an attribute *d* in an information system *S* (See Table 1) is confidential and we hide *d* from *S* and construct $S_d = (X,A,V)$, where:

1. $a_{S(x)} = a_{S_d(x)}$, for any $a \in A - \{d\}, x \in X$
2. $d_{S_d(x)}$ is undefined, for any $x \in X$,

In this scenario, there exists no local rule describing *d* because *d* is completely hidden. Instead, rules are extracted from remote sites (e.g. r_1,r_2 in Table 2). Now, the process of missing value reconstruction is similar to that of local Chase. For example, $r_1 = b_1 \rightarrow d_1$ supports objects $\{x_1,x_3\}$, and $r_2 = a_2 \cdot b_2 \rightarrow d_2$ supports objects $\{x_4\}$. The confidential data, d_1, and d_2, can be reconstructed using these two rules.

Rules are extracted from different information systems in DKDS. Inconsistencies in semantics (if exists) have to be resolved before any null value imputation can be applied (Ras and Dardzinska, 2004a). In general, we assume that information stored in an ontology of a system (Guarino, and Giaretta, 1995),(Sowa, 1999, 2000) and in inter-ontologies among systems (if they are required and provided) are sufficient to resolve

Table 1. Information system S_d

X	a	B	c	d
x_1	a_1	b_1	c_1	hidden
x_2	a_1	b_2	c_1	hidden
x_3	a_2	b_1	c_3	hidden
x_4	a_2	b_2	c_2	hidden
x_5	a_3	b_2	c_2	hidden
x_6	a_3	b_2	c_4	hidden

Table 2. Rules in Knowledge Base

Rid	Rule	Support	confidence	Source
r_1	$b_1 \rightarrow d_1$	20%	100%	Remote

r_3	$c_1 \rightarrow a_1$	33%	100%	Local

inconsistencies in semantics of all sites involved in Chase.

Achieving Data Confidentiality

Clearly, additional data have to be hidden or modified to avoid reconstruction of confidential data by Chase. In particular, we need to change data from non-confidential part of the information system. An important issue in this approach is how to minimize data loss in order to preserve original data set as much as possible. The search space for finding the minimum data set is, in general, very large because of the large number of predictions made by Chase. In addition, there are multiple ways to hide data for each prediction. Several algorithms have been proposed to improve performance based on the discovery of Attribute Value Overlap (Im and Ras, 2005) and Chase Closure (Im , Ras and Dardzinska 2005a).

We can minimize data loss further by taking advantage of hierarchical attribute structure (Im , Ras and Dardzinska, 2005b). Unlike single-level attribute system, data collected with different granularity levels are assigned to an information system with their semantic relations. For example, when the age of Alice is recorded, its value can be either 20 or *young*. Assuming that exact age is sensitive and confidential, we may show her age as 'young' if revealing the value, *'young',* does not compromise her privacy. Clearly, such system provides more data to users compared to the system that has to hide data completely.

Unlike the previous example where knowledge is extracted and stored in KB before we apply a protection algorithm, some systems need to generate rules after we hide a set of data from an information system. In this case, we need to consider knowledge loss (in the form of rules). Now, the objective is that secrecy of data is being maintained while the loss of knowledge in each information systems is minimized (Ras and Dardzinska and Im, 2006). Clearly, as we start hiding additional attribute values from an information system S, we also start losing some knowledge because the data set may be different. One of the important measurements of knowledge loss can be its interestingness. The interestingness of knowledge (Silberschatz and Tuzhilin, 1996) is classified largely into two categories (Silberschatz and Tuzhilin, 1996): subjective and objective. Subjective measures are user-driven, domain-dependent. This type of measurement includes unexpectedness, novelty, actionable (Ras and Tsay, 2005) (Ras and Tsay, 2003) rules. Objective measures are data-driven and domain-independent. They evaluate rules based on statistics and structures of patterns, (e.g., support, confidence, etc).

If the KDS allows for users to use Chase with the rules generated with any support and confidence value, some of the confidential data protected by the described methods may be disclosed. This is obvious because Chase does not restrict minimum support and confidence of rules when it reconstructs null values. A naive solution to this problem is to run the algorithm with a large number of rules generated with wide range of confidence and support values. However, as we increase the size of KB, more attribute values will most likely have to be hidden. In addition, malicious users may use even lower values for rule extraction attributes, and we may end up with hiding all data. In fact, ensuring data confidentiality against all possible rules is difficult because Chase does not enforce minimum support and confidence of rules when it reconstructs missing data. Therefore, in these knowledge discovery systems, the security against Chase should aim to reduce the confidence of the reconstructed values, particularly, by meaningful rules, such as rules with high support or high confidence, instead of trying to prevent data reconstruction by all possible rules. One of the ways to protect confidential data in this environment is to find object reducts (Skowron and Rauszer 1992) and use

the reducts to remove attribute values that will more likely be used to predict confidential attribute values with high confidence.

FUTURE TRENDS

More knowledge discovery systems will use Chase as a key tool because Chase provides robust prediction of missing or unknown attribute values in knowledge discovery systems. Therefore, further research and development for data security and Chase (or privacy in data mining in general) will be conducted. This includes providing data protection algorithms for dynamic information system or improving usability of the methods for knowledge experts.

CONCLUSION

Hiding confidential data from an information system is not sufficient to provide data confidentiality against Chase in KDS. In this article, we presented the process of confidential data reconstruction by Chase, and solutions to reduce the risk. Additional data have to be hidden or modified to ensure the safekeeping of the confidential data from Chase. Data and knowledge loss have to be considered to minimize the changes to existing data and knowledge. If the set of knowledge used to Chase is not completely known, we need to hide data that will more likely be used to predict confidential data with high confidence

KEY TERMS

Chase: A recursive strategy applied to a database V, based on functional dependencies or rules extracted from V, by which a null value or an incomplete value in V is replaced by more complete values.

Distributed Chase: A recursive strategy applied to a database V, based on functional dependencies or rules extracted both from V and other autonomous databases, by which a null value or an incomplete value in V is replaced by more complete values. Any differences in semantics among attributes in the involved databases have to be resolved first.

Data Confidentiality: Secrecy of confidential data by hiding a set of attribute values from unauthorized users in the knowledge discovery system.

Knowledge Base: A collection of rules defined as expressions written in predicate calculus. These rules have a form of associations between conjuncts of values of attributes.

Knowledge Discovery System: A set of information systems that is designed to extract and provide patterns and rules hidden from a large quantity of data. The system can be standalone or distributed.

Ontology: An explicit formal specification of how to represent objects, concepts and other entities that are assumed to exist in some area of interest and relationships holding among them. Systems that share the same ontology are able to communicate about domain of discourse without necessarily operating on a globally shared theory. System commits to ontology if its observable actions are consistent with the definitions in the ontology.

Data Cube Compression Techniques: A Theoretical Review

Alfredo Cuzzocrea
University of Calabria, Italy

INTRODUCTION

OnLine Analytical Processing (OLAP) research issues (Gray, Chaudhuri, Bosworth, Layman, Reichart & Venkatrao, 1997) such as data cube modeling, representation, indexing and management have traditionally attracted a lot of attention from the Data Warehousing research community. In this respect, as a fundamental issue, the problem of *efficiently compressing the data cube* plays a leading role, and it has involved a vibrant research activity in the academic as well as industrial world during the last fifteen years.

Basically, this problem consists in dealing with massive-in-size data cubes that make access and query evaluation costs prohibitive. The widely accepted solution consists in generating a *compressed representation* of the target data cube, with the goal of reducing its size (given an input space bound) while admitting loss of information and approximation that are considered irrelevant for OLAP analysis goals (e.g., see (Cuzzocrea, 2005a)). Compressed representations are also referred-in-literature under the term "*synopsis data structures*", i.e. succinct representations of original data cubes introducing a limited loss of information. Benefits deriving from the data cube compression approach can be summarized in a relevant reduction of computational overheads needed to both represent the data cube and evaluate resource-intensive OLAP queries, which constitute a wide query class allowing us to extract useful knowledge from huge amounts of multidimensional data repositories in the vest of summarized information (e.g., *aggregate information* based on popular SQL aggregate operators such as SUM, COUNT, AVG etc), otherwise infeasible by means of traditional OLTP approaches. Among such queries, we recall: (*i*) *range-queries*, which extract a sub-cube bounded by a given range; (*ii*) *top-k queries*, which extract the k data cells (such that k is an input parameter) having the highest aggregate values; (*iii*) *iceberg queries*, which extract the data cells having aggregate values above a given threshold.

This evidence has given raise to the proliferation of a number of *Approximate Query Answering* (AQA) techniques, which, based on data cube compression, aim at providing *approximate answers* to resource-intensive OLAP queries instead of computing exact answers, as decimal precision is usually negligible in OLAP query and report activities (e.g., see (Cuzzocrea, 2005a)).

Starting from these considerations, in this article we first provide a comprehensive, rigorous survey of main data cube compression techniques, i.e. histograms, wavelets, and sampling. Then, we complete our analytical contribution with a detailed theoretical review focused on spatio-temporal complexities of these techniques.

BACKGROUND

A *data cube* $\mathcal{L}$ is a tuple $\mathcal{L} = \langle C,\mathcal{J},\mathcal{H},\mathcal{M}\rangle$, such that: (*i*) C is the data domain of $\mathcal{L}$ containing (OLAP) *data cells*, which are the basic SQL aggregations of $\mathcal{L}$ computed against the relational data source S alimenting $\mathcal{L}$; (*ii*) $\mathcal{J}$ is the set of *dimensions* of $\mathcal{L}$, i.e. the *functional attributes* (of S) with respect to which the underlying OLAP analysis is defined (in other words, $\mathcal{J}$ is the set of attributes with respect to which relational tuples in S are aggregated); (*iii*) $\mathcal{H}$ is the set of *hierarchies* related to the dimensions of $\mathcal{L}$, i.e. hierarchical representations of the functional attributes shaped-in-the-form-of generic trees; (*iv*) $\mathcal{M}$ is the set of *measures* of $\mathcal{L}$, i.e. the *attributes of interest* (of S) for the underlying OLAP analysis (in other words, $\mathcal{M}$ is the set of attributes with respect to which SQL aggregations stored in data cells of $\mathcal{L}$ are computed).

HISTOGRAMS

Histograms have been extensively studied and applied in the context of *Selectivity Estimation* (Kooi, 1980), and are effectively implemented in commercial systems (e.g., Oracle Database, IBM DB2 Universal Database, Microsoft SQL Server) to query optimization purposes. In statistical databases (Shoshani, 1997), histograms represent a method for approximating probability distributions. They have also been used in data mining activities, intrusion detection systems, scientific databases, i.e. in all those applications which (*i*) operate on huge numbers of detailed records, (*ii*) extract useful knowledge only from condensed information consisting of summary data, (*iii*) but are not usually concerned with detailed information. Indeed, histograms can reach a surprising efficiency and effectiveness in approximating the actual distributions of data starting from summarized information. This has led the research community to investigate the use of histograms in the fields of *DataBase Management Systems* (DBMS) (Kooi, 1980; Poosala & Ioannidis, 1997; Ioannidis & Poosala, 1999; Acharya, Poosala & Ramaswamy, 1999; Gunopulos, Kollios, Tsotras & Domeniconi, 2000; Bruno, Chaudhuri & Gravano, 2001), and *OnLine Analytical Processing* (OLAP) systems (Poosala & Ganti, 1999; Buccafurri, Furfaro, Saccà & Sirangelo, 2003; Cuzzocrea, 2005a; Cuzzocrea & Wang, 2007; Leng, Bao, Wang & Yu, 2007).

Histogram literature has a long history, what confirms the prominence of histogram research within the broader context of database/data-cube compression techniques. They are data structures obtained by partitioning a data distribution (or, equally, a data domain) into a number of mutually disjoint blocks, called *buckets*, and then storing, for each bucket, some aggregate information of the corresponding range of values, like the sum of values in that range (i.e., applying the SQL aggregate operator SUM), or the number of occurrences (i.e., applying the SQL aggregate operator COUNT), such that this information retains a certain "summarizing content".

Histograms are widely used to support two kinds of applications: (*i*) selectivity estimation inside *Query Optimizers* of DBMS, as highlighted before, and (*ii*) *approximate query answering* against databases and data cubes. In the former case, the data distribution to be compressed consists of the frequencies of values of attributes in a relation (it should be noted that, in this vest, histograms are mainly used within the core layer of DBMS, thus dealing with databases properly). In the latter case, the data distribution to be compressed consists of the data items of the target domain (i.e., a database or a data cube) directly, and the goal is to provide fast and approximate answers to resource-intensive queries instead of waiting-for time-consuming exact evaluations of queries. They are a very-popular class of synopsis data structures, so that they have been extensively used in the context of approximate query answering techniques. Early experiences concerning this utilization of histograms are represented by the work of Ioannidis and Poosala (1999), that propose using histograms to provide approximate answers to set-valued queries, and the work of Poosala and Ganti (1999), that propose using histograms to provide approximate answers to range-queries in OLAP.

There are several classes of histograms in literature. We distinguish between *one-dimensional histograms*, i.e. histograms devoted to compress one-dimensional data domains, and *multidimensional histograms*, i.e. histograms working on multidimensional data domains, which are more interesting than the former, and can be found in a wide range of modern, large-scale, *data-intensive* applications. Moreover, we can also further distinguish between *static histograms* and *dynamic histograms*. The first ones are statically computed against the target domain, and are not particularly suitable to efficiently accomplish data updates occurring on original data sources; the second ones are dynamically computed by taking into consideration, beyond the target domain, or, in some cases, a synopsis of it, other entities related to the dynamics of the target DBMS/OLAP server such as *query-workloads*, *query feedbacks*, *load balancing issues* etc. Contrarily to the previous histogram class, dynamic histograms efficiently support update management, being their partition dependent on a "parametric" configuration that can be easily (re-)computed at will.

With respect to our work, we are mainly interested in multidimensional histograms, since multidimensional data domains well-represent OLAP data cubes. A popular and conventional approach is based on the well-known *Attribute-Value Independence* (AVI) assumption, according to which any query involving a set of attributes can be answered by applying it on each attribute singularly. This approach is theoretically

reasonable, but it has been recognized as source of gross errors in practice (e.g., (Poosala & Ioannidis, 1997)). To cope with this problem, multidimensional histograms use a small number of multidimensional buckets to *directly* approximate the joint data distribution.

Static Histograms

Among all the alternatives, we focus our attention on the following static multidimensional histograms, mainly because they can be considered as representative and significant experiences in this context: *Min-Skew* (Acharya, Poosala & Ramaswamy, 1999) and *GenHist* (Gunopulos, Kollios, Tsotras & Domeniconi, 2000) histograms.

Min-Skew histogram was originally designed in (Acharya, Poosala & Ramaswamy, 1999) to tackle the problem of selectivity estimation of *spatial data* in *Geographical Information Systems* (GIS). Spatial data are referred to *spatial* (or *geographical*) *entities* such as points, lines, poly-lines, polygons and surfaces, and are very often treated by means of minimal rectangles containing them, namely *Minimum Bounding Rectangles* (MBR). *Min-Skew* is more sophisticated than *MHist*. The main idea behind a *Min-Skew* histogram $H_{M\text{-}S}(D)$ is to follow the criterion of minimizing the *spatial skew* of the histogram by performing a *Binary Space Partitioning* (BSP) via recursively dividing the space along one of the dimensions each time. More formally, each point in the space of a given GIS instance is associated to a *spatial density*, defined as the number of MBR that contain such a point.

(Gunopulos, Kollios, Tsotras, & Domeniconi, 2000) proposes *GenHist histogram*, a new kind of multidimensional histogram that is different from the previous ones with respect to the build procedure. The key idea is the following: given an histogram H whit h_b buckets on an input data domain D, a *GenHist* histogram $H_{GH}(D)$ is built by finding n_b overlapping buckets on H, such that n_b is an input parameter. To this end, the technique individuates the number of distinct regions that is much larger than the original number of buckets h_b, thanks to a greedy algorithm that considers *increasingly-coarser grids*. At each step, such algorithm selects the set of cells J of highest density, and moves enough randomly-selected points from J into a bucket to make J and its neighbors "close-to-uniform".

Dynamic Histograms

Dynamic multidimensional histograms extend capabilities of static multidimensional histograms by incorporating inside their generating algorithms the amenity of building/refining the underlying partition in dependence on non-conventional entities related to the dynamic behavior of the target DBMS/OLAP server, such as query-workloads. Among this class of histograms, relevant proposal are: *STHoles* (Bruno, Chaudhuri & Gravano, 2001) histograms and the innovative data structure **TP**-*Tree* (Cuzzocrea & Wang, 2007).

(Bruno, Chaudhuri & Gravano, 2001) proposes a different kind of multidimensional histogram, based on the analysis of the query-workload on it: the *workload-aware histogram*, which they call *STHoles*. Rather than an arbitrary overlap, a *STHoles* histogram $H_{ST}(D)$ allows bucket nesting, thus achieving the definition of the so-called *bucket tree*. Query-workloads are handled as follows: the query result stream Q^R to be analyzed is intercepted and, for each query Q_j belonging to Q^R and for each bucket b_i belonging to the current bucket tree, the number $|Q_j \cap b_i|$ is counted. Then, "holes" in b_i for regions of different *tuple density* are "drilled" and "pulled out" as children of b_i. Finally, buckets of similar densities are merged in such a way as to keep the number of buckets constant.

T*unable*-**P***artition*-*Tree* (**TP**-*Tree*) (Cuzzocrea & Wang, 2007) is a tree-like, highly-dynamic data structure that codifies a multidimensional histogram for massive (multidimensional) data cubes, denoted by $H_{TP}(D)$, whose partition *varies over time* according to the query-workload against the target OLAP server. For this reason, partitions of $H_{TP}(D)$ are named as *tunable partitions*, and $H_{TP}(D)$ is said to be a "workload-aware" synopsis data structure. The main contribution of the **TP**-*Tree* proposal with respect to previous techniques consists in introducing models and algorithms having low computational costs, whereas previous techniques are, usually, time-consuming and resource-intensive. Data stored inside buckets of **TP**-*Tree* partitions are obtained by (*i*) *sampling* the input data cube (from this solution, low computational costs required by the **TP**-*Tree* approach follow), and (*ii*) separately representing, storing, and indexing *outliers* via high performance *quad-tree* based (data) structures. Also, **TP**-*Tree* is able to provide *probabilistic guarantees* over the degree of approximation of the answers, which is a leading

research topic very often neglected by the research community (e.g., see (Cuzzocrea, 2005b)).

WAVELETS

Wavelets (Stollnitz, Derose & Salesin, 1996) are a mathematical transformation which defines a hierarchical decomposition of functions (representing signals or data distributions) into a set of coefficients, called *wavelet coefficients*. In more detail, wavelets represent a function in terms of a coarse overall shape, plus details that range from coarse to fine. They were originally applied in the field of image and signal processing. Recent studies have shown the applicability of wavelets to selectivity estimation, as well as to the approximation of both specific forms of query (like range-queries) (Vitter, Wang & Iyer, 1998), and "general" queries (Chakrabarti, Garofalakis, Rastogi & Shim, 2000) (using join operators) over data cubes.

Specifically, the compressed representation of data cubes via wavelets (Vitter, Wang & Iyer, 1998) is obtained in two steps. First, a wavelet transform is applied to the data cube, thus generating a sequence of coefficients. At this step no compression is obtained (the number of wavelet coefficients is the same as the number of data points in the examined distribution), and no approximation is introduced, as the original data distribution can be reconstructed exactly applying the inverse of the wavelet transform to the sequence of coefficients. Next, among the N wavelet coefficients, only the $m << N$ most "significant" ones are retained, whereas the others are "thrown away", and their value is implicitly set to zero. The set of retained coefficients defines the compressed representation, called *wavelet synopses*, which refer to synopses computed by means of wavelet transformations. This selection is driven by a some criterion, which determines the lost of information that introduces approximation.

SAMPLING

Random sampling-based methods propose mapping the original multidimensional data domain in a smaller subset by sampling: this allows a more compact representation of the original data to be achieved. Query performances can be significantly improved by pushing sampling to Query Engines, with computational overheads that are very low when compared to more resource-intensive techniques such as multidimensional histograms and wavelet decomposition. (Hellerstein, Haas & Wang, 1997) proposes a system for effectively supporting online aggregate query answering, and also providing probabilistic guarantees about the accuracy of the answers in terms of *confidence intervals*. Such system allows a user to execute an aggregate query and to observe its execution in a graphical interface that shows both the partial answer and the corresponding (partial) confidence interval. The user can also stop the query execution when the answer has achieved the desired degree of approximation. No synopses are maintained since the system is based on a random sampling of the tuples involved in the query. Random sampling allows an *unbiased estimator* for the answer to be built, and the associated confidence interval is computed by means of the Hoeffding's inequality. The drawback of this proposal is that response time needed to compute answers can increase since sampling is done at query time. The absence of synopses ensures that there are not additional computational overheads because no maintenance tasks must be performed.

(Gibbons & Matias, 1998) propose the idea of using sampling-based techniques to tame spatio-temporal computational requirements needed for evaluating resource-intensive queries against massive data warehouses (e.g., OLAP queries). Specifically, they argue to build synopses via sampling, such that these synopses provide a *statistical description* of data they model. Synopses are built in dependence on the specific class of queries they process (e.g., based on popular random sampling, or more complex sampling schemes), and are stored in the target data warehouse directly. (Acharya, Gibbons, Poosala & Ramaswamy, 1999) extends this approach as to deal with more interesting data warehouse queries such as join queries, which extract correlated data/knowledge from multiple fact tables. To this end, authors propose using a *pre-computed* sample synopses that considers samples of a small set of distinguished joins rather than accessing all the data items involved by the actual join. Unfortunately, this method works well only for queries with foreign-key joins which are known beforehand, and does not support arbitrary join queries over arbitrary schema.

THEORETICAL ANALYSIS AND RESULTS

In order to complement the actual contribution of the Data Warehousing research community to the data cube compression problem, in this Section we provide a theoretical analysis of main approaches present in literature, and derive results in terms of complexities of all the phases of data cube management activities correlated to such problem, e.g. computing/updating the compressed representation of the data cube and evaluating approximate queries against the compressed representation. First, we formally model the complexities which are at the basis of the theoretical analysis we provide. These complexities are:

- *Temporal complexity* of computing/updating the compressed representation of the data cube, denoted by $C_{\{C,U\}}[t]$;
- *Spatial complexity* of the compressed representation of the data cube, denoted by $C_{\{C,U\}}[s]$;
- *Temporal complexity* of evaluating approximate queries against the compressed representation of the data cube, denoted by $C_Q[t]$.

Being infeasible to derive closed formulas of spatio-temporal complexities such that these formulas are valid for all the data cube compression techniques presented in this paper (as each technique makes use of particular, specialized synopsis data structures and build, update and query algorithms), we introduce ad-hoc *complexity classes* modeling an *asymptotic analysis* of spatio-temporal complexities of the investigated techniques.

These complexity classes depend on (*i*) the size of input, denoted by *N*, which, without loss of generality, can be intended as the number of data cells of the original data cube, and (*ii*) the size of the compressed data structure computed on top of the data cube, denoted by *n*. Contrarily to *N*, the parameter *n* must be specialized for each technique class. For what regards histograms, *n* models the number of buckets; for wavelets, *n* models the number of number of wavelet coefficients; finally, for sampling, *n* models the number of sampled data cells.

To meaningfully support our theoretical analysis according to the guidelines given above, the complexity classes we introduce are:

- LOG(•), which models a logarithmic complexity with respect to the size of input;
- LINEAR(•), which models a linear complexity with respect to the size of input;
- POLY(•), which models a polynomial complexity with respect to the size of input.

It is a matter to note that the complexity modeled by these classes grows from LOG to POLY class. However, these classes are enough to cover all the cases of complexities of general data cube compression techniques, and to put in evidence similar and differences among such techniques.

Table 1 summarizes the results of our theoretical analysis. For what regards the temporal complexity of building/updating the compressed data cube, we observe that sampling-based techniques constitute the best case, whereas histograms and wavelets require a higher temporal complexity to accomplish the build/update task. For what regards the spatial complexity of the compressed data cube, we notice that all the techniques give us, at the asymptotic analysis, the same complexity, i.e. we approximately obtain the same benefits in terms of space occupancy from using any of such techniques. Finally, for what regards

Table 1. Theoretical analysis of data cube compression techniques

Technique	$C_{\{C,U\}}[t]$	$C_{\{C,U\}}[s]$	$C_Q[t]$
Histograms	POLY(N)	POLY(n)	LOG(n)
Wavelets	POLY(N)	POLY(n)	LOG(n)
Sampling	LINEAR(N)	POLY(n)	LINEAR(n)

temporal complexity of evaluating approximate queries against the compressed data cube, histograms and wavelets are better that sampling-based techniques. This because histograms and wavelets make use of specialized hierarchical data structures (e.g., bucket tree, decomposition tree etc) that are particularly efficient in supporting specialized kinds of OLAP queries, such as range-queries. This allows the query response time to be improved significantly.

FUTURE TRENDS

Future research efforts in the field of data cube compression techniques include the following themes: (*i*) ensuring *probabilistic guarantees* over the degree of approximate answers (e.g., (Garofalakis & Kumar, 2004; Cuzzocrea, 2005b; Cuzzocrea & Wang, 2007)), which deals with the problem of how to retrieve approximate answers that are probabilistically-close to exact answers (which are unknown at query time); (*ii*) devising *complex indexing schemes* for compressed OLAP data able to be *adaptive* in dependence on the query-workload of the target OLAP server, which plays a primary role in next-generation highly-scalable OLAP environments (e.g., those inspired to the novel publish/subscribe deployment paradigm).

CONCLUSION

Data-intensive research and technology have evolved from traditional relational databases to more recent data warehouses, and, with a prominent emphasis, to OLAP. In this context, the problem of efficiently compressing a data cube and providing approximate answers to resource-intensive OLAP queries plays a leading role, and, due to a great deal of attention from the research communities, a wide number of solutions dealing with such a problem have appeared in literature. These solutions are mainly focused to obtain an effective and efficient data cube compression, trying to mitigate computational overheads due to accessing and processing massive-in-size data cubes. Just like practical issues, theoretical issues are interesting as well, and, particularly, studying and rigorously formalizing spatio-temporal complexities of state-of-the-art data cube compression models and algorithms assumes a relevant role in order to meaningfully complete the contribution of these proposals.

KEY TERMS

OLAP Query: A query defined against a data cube that introduces a multidimensional range and a SQL aggregate operator, and returns as output the aggregate value computed over cells of the data cube contained in that range.

On-Line Analytical Processing (OLAP): A methodology for representing, managing and querying massive DW data according to multidimensional and multi-resolution abstractions of them.

On-Line Transaction Processing (OLTP): A methodology for representing, managing and querying DB data generated by user/application transactions according to flat (e.g., relational) schemes.

Relational Query: A query defined against a database that introduces some predicates over tuples stored in the database, and returns as output the collection of tuples satisfying those predicates.

Selectivity of a Relational Query: A property of a relational query that estimates the cost required to evaluate that query in terms of the number of tuples involved.

Selectivity of an OLAP Query: A property of an OLAP query that estimates the cost required to evaluate that query in terms of the number of data cells involved.

A Data Distribution View of Clustering Algorithms

INTRODUCTION

Cluster analysis (Jain & Dubes, 1988) provides insight into the data by dividing the objects into groups (clusters), such that objects in a cluster are more similar to each other than objects in other clusters. Cluster analysis has long played an important role in a wide variety of fields, such as psychology, bioinformatics, pattern recognition, information retrieval, machine learning, and data mining. Many clustering algorithms, such as K-means and Unweighted Pair Group Method with Arithmetic Mean (UPGMA), have been well-established.

A recent research focus on clustering analysis is to understand the strength and weakness of various clustering algorithms with respect to data factors. Indeed, people have identified some data characteristics that may strongly affect clustering analysis including high dimensionality and sparseness, the large size, noise, types of attributes and data sets, and scales of attributes (Tan, Steinbach, & Kumar, 2005). However, further investigation is expected to reveal whether and how the data distributions can have the impact on the performance of clustering algorithms. Along this line, we study clustering algorithms by answering three questions:

1. What are the systematic differences between the distributions of the resultant clusters by different clustering algorithms?
2. How can the distribution of the "true" cluster sizes make impact on the performances of clustering algorithms?
3. How to choose an appropriate clustering algorithm in practice?

The answers to these questions can guide us for the better understanding and the use of clustering methods. This is noteworthy, since 1) in theory, people seldom realized that there are strong relationships between the clustering algorithms and the cluster size distributions, and 2) in practice, how to choose an appropriate clustering algorithm is still a challenging task, especially after an algorithm boom in data mining area. This chapter thus tries to fill this void initially. To this end, we carefully select two widely used categories of clustering algorithms, i.e., K-means and Agglomerative Hierarchical Clustering (AHC), as the representative algorithms for illustration. In the chapter, we first show that K-means tends to generate the clusters with a relatively uniform distribution on the cluster sizes. Then we demonstrate that UPGMA, one of the robust AHC methods, acts in an opposite way to K-means; that is, UPGMA tends to generate the clusters with high variation on the cluster sizes. Indeed, the experimental results indicate that the variations of the resultant cluster sizes by K-means and UPGMA, measured by the Coefficient of Variation (CV), are in the specific intervals, say [0.3, 1.0] and [1.0, 2.5] respectively. Finally, we put together K-means and UPGMA for a further comparison, and propose some rules for the better choice of the clustering schemes from the data distribution point of view.

BACKGROUND

People have investigated clustering algorithms from various perspectives. Many data factors, which may strongly affect the performances of clustering schemes, have been identified and addressed. Among them the

high dimensionality, the large size, and the existence of noise and outliers are typically the major concerns.

First, it has been well recognized that high dimensionality can make negative impact on various clustering algorithms which use Euclidean distance (Tan, Steinbach, & Kumar, 2005). To meet this challenge, one research direction is to make use of dimensionality reduction techniques, such as Multidimensional Scaling, Principal Component Analysis, and Singular Value Decomposition (Kent, Bibby, & Mardia, 2006). A detailed discussion on various dimensionality reduction techniques for document data sets has been provided by Tang et al. (2005). Another direction is to redefine the notions of proximity, e.g., by the Shared Nearest Neighbors similarity (Jarvis & Patrick, 1973). Some similarity measures, e.g., cosine, have also shown appealing effects on clustering document data sets (Zhao & Karypis, 2004).

Second, many clustering algorithms that work well for small or medium-size data sets are unable to handle large data sets. For instance, AHC is very expensive in terms of its computational and storage requirements. Along this line, a discussion of scaling K-means to large data sets was provided by Bradley et al. (1998). Also, Ghosh (2003) discussed the scalability of clustering methods in depth. A more broad discussion of specific clustering techniques can be found in the paper by Murtagh (2000). The representative techniques include CURE (Guha, Rastogi, & Shim, 1998), BIRCH (Zhang, Ramakrishnan, & Livny, 1996), CLARANS (Ng & Han, 2002), etc.

Third, outliers and noise in the data can also degrade the performance of clustering algorithms, such as K-means and AHC. To deal with this problem, one research direction is to incorporate some outlier removal techniques before conducting clustering. The representative techniques include LOF (Breunig, Kriegel, Ng, & Sander, 2000), HCleaner (Xiong, Pandey, Steinbach, & Kumar, 2006), etc. Another research direction is to handle outliers during the clustering process. There have been several techniques designed for such purpose, e.g., DBSCAN (Ester, Kriegel, Sander, & Xu, 1996), Chameleon (Karypis, Han, & Kumar, 1999), SNN density-based clustering (Ertoz, Steinbach, & Kumar, 2001), and CURE (Guha, Rastogi, & Shim, 1998).

In this chapter, however, we focus on understanding the impact of the data distribution, i.e., the distribution of the "true" cluster sizes, on the performances of K-means and AHC, which is a natural extension of our previous work (Xiong, Wu, & Chen, 2006; Wu, Xiong, Wu, & Chen, 2007). Also, we propose some useful rules for the better choice of clustering algorithms in practice.

MAIN FOCUS

Here, we explore the relationship between the data distribution and the clustering algorithms. Specifically, we first introduce the statistic, i.e., Coefficient of Variation (CV), to characterize the distribution of the cluster sizes. Then, we illustrate the effects of K-means clustering and AHC on the distribution of the cluster sizes, respectively. Finally, we compare the two effects and point out how to properly utilize the clustering algorithms on data sets with different "true" cluster distributions. Due to the complexity of this problem, we also conduct extensive experiments on data sets from different application domains. The results further verify our points.

A Measure of Data Dispersion Degree

Here we introduce the Coefficient of Variation (CV) (DeGroot & Schervish, 2001), which measures the dispersion degree of a data set. The CV is defined as the ratio of the standard deviation to the mean. Given a set of data objects $X = \{x_1, x_2,...,x_n\}$, we have $CV = s/\bar{x}$ where

$$\bar{x} = \sum_{i=1}^{n} x_i / n \text{ and}$$

$$s = \sqrt{\sum_{i=1}^{n} (x_i - \bar{x})^2 / (n-1)}.$$

Note that there are some other statistics, such as standard deviation and skewness (DeGroot & Schervish, 2001), which can also be used to characterize the dispersion of a data distribution. However, the standard deviation has no scalability; that is, the dispersion of the original data and stratified sample data is not equal if the standard deviation is used. Indeed, this does not agree with our intuition. Meanwhile, skewness cannot catch the dispersion in the situation that the data is symmetric but has high variance. In contrast, the CV is a dimensionless number that allows comparison of

the variation of populations that have significantly different mean values. In general, the larger the CV value is, the greater the variability is in the data.

In our study, we use CV to measure the dispersion degree of the cluster sizes before and after clustering. In particular, we use CV_0 to denote the "true" cluster distribution, i.e., the dispersion degree of the cluster sizes before clustering, and CV_1 to denote the resultant cluster distribution, i.e., the dispersion degree of the cluster sizes after clustering. And the difference of CV_1 and CV_0 is denoted by DCV, i.e., $DCV=CV_1-CV_0$.

The Uniform Effect of K-means

K-means is a prototype-based, simple partitional clustering technique which attempts to find a user-specified *K* number of clusters. These clusters are represented by their centroids (a cluster centroid is typically the mean of the points in the cluster). The clustering process of K-means is as follows. First, *K* initial centroids are selected, where *K* is specified by the user and indicates the desired number of clusters. Every point in the data is then assigned to the closest centroid, and each collection of points assigned to a centroid forms a cluster. The centroid of each cluster is then updated based on the points assigned to it. This process is repeated until no point changes clusters.

Figure 1 shows a sample data set with three "true" clusters. The numbers of points in Cluster 1, 2 and 3 are 96, 25 and 25, respectively. Thus the CV_0 value is 0.84. In this data, Cluster 2 is much closer to Cluster 1 than Cluster 3. Figure 2 shows the clustering results by K-means on this data set. One observation is that Cluster 1 is broken: part of Cluster 1 is merged with Cluster 2 as new Cluster 2 and the rest of cluster 1 forms new Cluster 1. However, the size distribution of the resulting two clusters is much more uniform now, i.e., the CV_1 value is 0.46. This is called the "uniform effect" of K-means on "true" clusters with different sizes. Another observation is that Cluster 3 is precisely identified by K-means. It is due to the fact that the objects in Cluster 3 are far away from Cluster 1. In other words, the uniform effect has been dominated by the large distance between two clusters. Nevertheless, our experimental results below show that the uniform effect of K-means clustering is dominant in most of applications, regardless the present of other data factors that may "mitigate" it.

The Dispersion Effect of UPGMA

The key component in agglomerative hierarchical clustering (AHC) algorithms is the similarity metric used to determine which pair of sub-clusters to be merged. In this chapter, we focus on the UPGMA (Unweighted Pair Group Method with Arithmetic mean) scheme which can be viewed as the tradeoff between the simplest single-link and complete-link schemes (Jain & Dubes, 1988). Indeed, UPGMA defines cluster similarity in terms of the average pair-wise similarity between the objects in the two clusters. UPGMA is widely used because it is more robust than many other agglomerative clustering approaches.

Figure 1. Clusters before k-means clustering

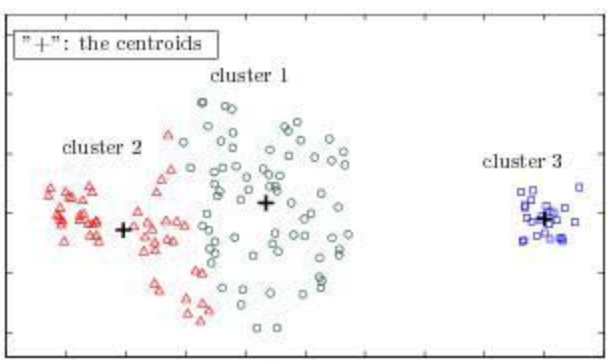

Figure 2. Clusters after k-means clustering

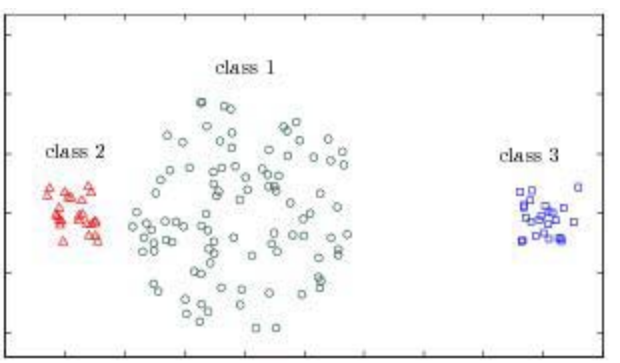

Figure 3. Clusters before employing UPGMA

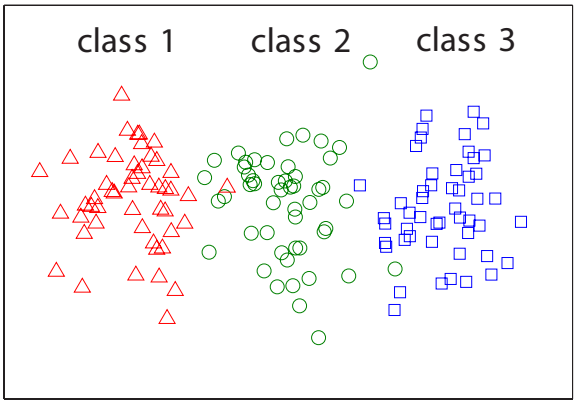

Figure 4. Clusters after employing UPGMA

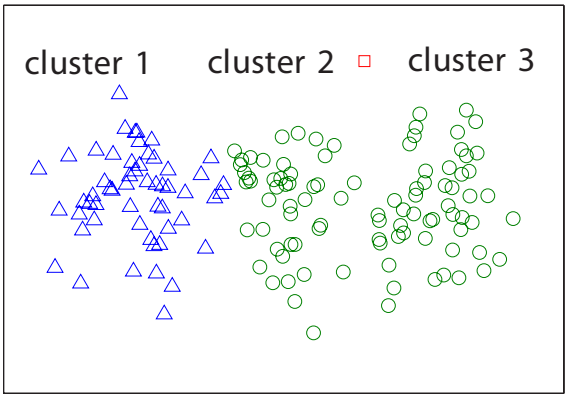

Figure 3 shows a sample data set with three "true" clusters, each of which contains 50 objects generated by one of three normal distributions. After exploiting UPGMA on this data set, we have three resultant clusters shown in Figure 4. Apparently, Class 3 is totally "disappeared", for all of its objects have been "absorbed" by the objects of Class 2. And the only one object farthest from the population forms Cluster 3. We can also capture this by the data distribution information. Actually, the CV_1 value of the resultant cluster sizes is 0.93, much higher than the CV_0 value of the "true" cluster sizes, i.e., 0. This is called the "dispersion effect" of UPGMA. From the above case, we can conclude that UPGMA tends to show the dispersion effect on data sets with noise or some small groups of objects that are far away from the populations. Considering the wide existences of noise or remote groups of objects in real-world data sets, we can expect that the dispersion effect of UPGMA holds in most of the cases. We leave this to the experiment results.

Experimental Results

Here we present experimental results to verify the different effects of K-means clustering and AHC on the resultant cluster sizes.

Experimental Setup

In the experiments, we used CLUTO implementations of K-means and UPGMA (Karypis, 2003). For all the experiments, the cosine similarity is used in the objective function. Other parameters are set with the default values.

For the experiments, we used a number of real-world data sets that were obtained from different application domains. Some characteristics of these data sets are shown in Table 1. Among the data sets, 12 out of 16 are the benchmark document data sets which were distributed with the CLUTO software (Karypis, 2003). Two biomedical data sets from the Kent Ridge Biomedical Data Set Repository (Li & Liu, 2003) were also used in our experiments. Besides the above high-dimensional data sets, we also used two UCI data sets (Newman, Hettich, Blake, & Merz, 1998) with normal dimensionality.

The Uniform Effect of K-means

Table 1 shows the experimental results by K-means. As can be seen, for 15 out of 16 data sets, K-means reduced the variation of the cluster sizes, as indicated by the negative DCV values. We can also capture this information from Figure 5. That is, the square-line figure representing the CV_1 values by K-means is almost enveloped by the dot-line figure, i.e., the CV_0 values of all data sets. This result indicates that, for data sets with high variation on the "true" cluster sizes, the uniform effect of K-means is dominant. Furthermore, an interesting observation is that, while the range of CV_0 is between 0.27 and 1.95, the range of CV_1 by K-means is restricted into a much smaller range from 0.33 to 0.94. Thus the empirical interval of CV_1 values is [0.3, 1.0].

Figure 5. A comparison of CV_1 values by k-means and UPGMA on all data sets

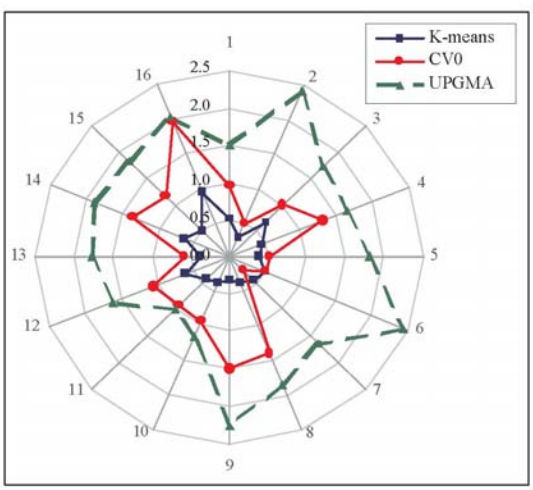

Figure 6. The problems of the two effects

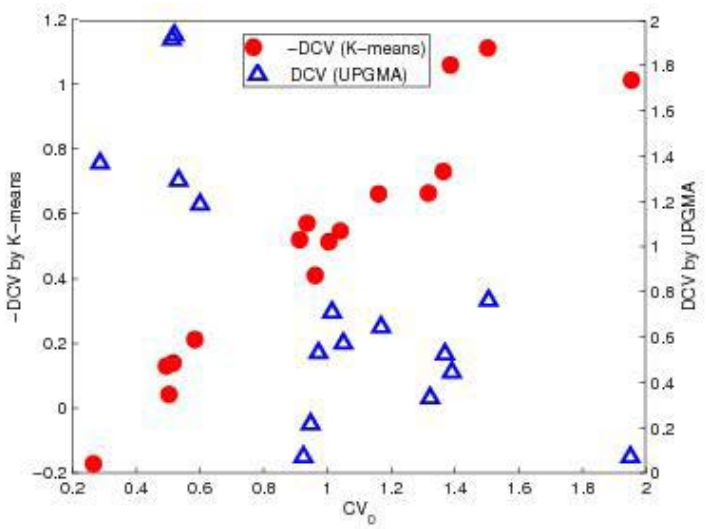

The Dispersion Effect of UPGMA

Table 1 also shows the experimental results by UPGMA. As can be seen, for all data sets, UPGMA tends to increase the variation of the cluster sizes. Indeed, no matter what the CV_0 values are, the corresponding CV_1 values are no less than 1.0, with only one exception: the "tr41" data set. Therefore, we can empirically estimate the interval of CV_1 values as [1.0, 2.5]. Also, the radar figure in Figure 5 directly illustrates the dispersion effect of UPGMA, in which the triangle-dashed line figure of UPGMA envelops the other two figures.

Discussions on the Two Diverse Effects

From the above illustrations and experimental validations, we can draw the conclusion that the uniform effect of K-means and the dispersion effect of UPGMA hold for many real-world data sets. This implies that the distribution of the "true" cluster sizes can make impact on the performance of the clustering algorithms.

Consider the data set "re0" in table 1 which consists of highly imbalanced "true" clusters, i.e., CV_0= 1.502. If K-means is employed on this data set, the resultant cluster sizes can be much more uniform, say CV_1=0.390, due to the uniform effect of K-means. The great difference on the CV values indicates that the clustering result is very poor indeed. In fact, as Figure 6 shows, the absolute DCV values increase linearly as the CV_0 values increase when employing K-means clustering. Therefore, for data sets with high variation on the "true" cluster sizes, i.e., CV_0>>1.0, K-means is not a good choice for the clustering task.

Consider another data set "ohscal" in table 1 which contains rather uniform "true" clusters, i.e., CV_0=0.266. After employing UPGMA, however, the CV_1 value of the resultant cluster sizes goes up to 1.634, which also indicates a very poor clustering quality. Actually, as Figure 6 shows, due to the dispersion effect of UPGMA, the DCV values increase rapidly as the CV_0 values decrease. Therefore, for data sets with low variation on the "true" cluster sizes, i.e., CV_0<<1.0, UPGMA is not an appropriate clustering algorithm.

FUTURE TRENDS

As we know, data mining emerges as a prosperous discipline when the real-world practices produce more and more new data sets. To analyze these data sets is rather challenging, since the traditional data analysis techniques may encounter difficulties (such as addressing the problems of high dimensionality and scalability), or many intrinsic data factors can not be well characterized or even be totally unknown to us. The hardness of solving the former problem is obvious, but the latter problem is more "dangerous" – we may get a poor data analysis result without knowing this due to the data characteristics inherently. For example, applying K-means on highly imbalanced data set is often ineffective, and the ineffectiveness may not be identified by some cluster validity measures (Xiong, Wu, & Chen, 2006), thus the clustering result can be misleading. Also, the density of data in the feature space can be uneven, which can bring troubles to the clustering algorithms based on the graph partitioning scheme. Moreover, it is well-known that outliers and noise in the data can disturb the clustering process; however, how to identify them is still an open topic in the field of anomaly detection. So in the future, we can expect that, more research efforts will be put on capturing and characterizing the intrinsic data factors (known or unknown) and their impacts on the data analysis results. This is crucial for the successful utilization of data mining algorithms in practice.

CONCLUSION

In this chapter, we illustrate the relationship between the clustering algorithms and the distribution of the "true" cluster sizes. Our experimental results show that K-means tends to reduce the variation on the cluster sizes if the "true" cluster sizes are highly imbalanced, and UPGMA tends to increase the variation on the cluster sizes if the "true" cluster sizes are relatively uniform. Indeed, the variations of the resultant cluster sizes by K-means and UPGMA, measured by the Coefficient of Variation (CV), are in the specific intervals, say [0.3, 1.0] and [1.0, 2.5] respectively. Therefore, for data sets with highly imbalanced "true" cluster sizes, i.e., CV_0>>1.0, K-means may not be the good choice of clustering algorithms. However, for data sets with low variation on the "true" cluster sizes, i.e., CV_0<<1.0, UPGMA may not be an appropriate clustering algorithm.

KEY TERMS

Cluster Analysis: Cluster analysis provides insight into the data by dividing the objects into clusters of objects, such that objects in a cluster are more similar to each other than objects in other clusters. In pattern recognition community, it is often called "unsupervised learning".

Coefficient of Variation (CV): A statistic that measures the dispersion of a data vector. CV is defined as the ratio of the standard deviation to the mean.

Dispersion Effect: If the distribution of the cluster sizes by a clustering method has more variation than the distribution of the "true" cluster sizes, we say that this clustering method shows the dispersion effect.

Hierarchical Clustering: Hierarchical clustering analysis provides insight into the data by assembling all the objects into a dendrogram, such that each sub-cluster is a node of the dendrogram, and the combinations of sub-clusters create a hierarchy. The process of the hierarchical clustering can be either divisive or agglomerative. Single-link, complete-link and UPGMA are the well-known agglomerative hierarchical clustering methods.

High Dimensional Data: The data with hundreds or thousands of dimensions from the areas of text/web mining, bioinformatics, etc. Also, these data sets are often sparse. Analyzing such high-dimensional data sets is a contemporary challenge.

K-Means: A prototype-based, simple partitional clustering technique which attempts to find a user-specified *K* number of clusters.

Uniform Effect: If the distribution of the cluster sizes by a clustering method has less variation than the distribution of the "true" cluster sizes, we say that this clustering method shows the uniform effect.

Data Driven vs. Metric Driven Data Warehouse Design

John M. Artz
The George Washington University, USA

INTRODUCTION

Although data warehousing theory and technology have been around for well over a decade, they may well be the next hot technologies. How can it be that a technology sleeps for so long and then begins to move rapidly to the foreground? This question can have several answers. Perhaps the technology had not yet caught up to the theory or that computer technology 10 years ago did not have the capacity to delivery what the theory promised. Perhaps the ideas and the products were just ahead of their time. All these answers are true to some extent. But the real answer, I believe, is that data warehousing is in the process of undergoing a radical theoretical and paradigmatic shift, and that shift will reposition data warehousing to meet future demands.

BACKGROUND

Just recently I started teaching a new course in data warehousing. I have only taught it a few times so far, but I have already noticed that there are two distinct and largely incompatible views of the nature of a data warehouse. A prospective student, who had several years of industry experience in data warehousing but little theoretical insight, came by my office one day to find out more about the course. "Are you an Inmonite or a Kimballite?" she inquired, reducing the possibilities to the core issues. "Well, I suppose if you put it that way," I replied, "I would have to classify myself as a Kimballite." William Inmon (2000, 2002) and Ralph Kimball (1996, 1998, 2000) are the two most widely recognized authors in data warehousing and represent two competing positions on the nature of a data warehouse.

The issue that this student was trying to get at was whether or not I viewed the dimensional data model as the core concept in data warehousing. I do, of course, but there is, I believe, a lot more to the emerging competition between these alternative views of data warehouse design. One of these views, which I call the data-driven view of data warehouse design, begins with existing organizational data. These data have more than likely been produced by existing transaction processing systems. They are cleansed and summarized and are used to gain greater insight into the functioning of the organization. The analysis that can be done is a function of the data that were collected in the transaction processing systems. This was, perhaps, the original view of data warehousing and, as will be shown, much of the current research in data warehousing assumes this view.

The competing view, which I call the metric-driven view of data warehouse design, begins by identifying key business processes that need to be measured and tracked over time in order for the organization to function more efficiently. A dimensional model is designed to facilitate that measurement over time, and data are collected to populate that dimensional model. If existing organizational data can be used to populate that dimensional model, so much the better. But if not, the data need to be acquired somehow. The metric-driven view of data warehouse design, as will be shown, is superior both theoretically and philosophically. In addition, it dramatically changes the research program in data warehousing. The metric-driven and data-driven approaches to data warehouse design have also been referred to, respectively, as metric pull versus data push (Artz, 2003).

MAIN THRUST

Data-Driven Design

The classic view of data warehousing sees the data warehouse as an extension of decision support systems. Again, in a classic view, decision support systems sit atop management information systems and use data extracted from management information and transaction processing systems to support decisions within

the organization. This view can be thought of as a data-driven view of data warehousing, because the exploitations that can be done in the data warehouse are driven by the data made available in the underlying operational information systems.

This data-driven model has several advantages. First, it is much more concrete. The data in the data warehouse are defined as an extension of existing data. Second, it is evolutionary. The data warehouse can be populated and exploited as new uses are found for existing data. Finally, there is no question that summary data can be derived, because the summaries are based upon existing data. However, it is not without flaws. First, the integration of multiple data sources may be difficult. These operational data sources may have been developed independently, and the semantics may not agree. It is difficult to resolve these conflicting semantics without a known end state to aim for. But the more damaging problem is epistemological. The summary data derived from the operational systems represent something, but the exact nature of that something may not be clear. Consequently, the meaning of the information that describes that something may also be unclear. This is related to the semantic disintegrity problem in relational databases. A user asks a question of the database and gets an answer, but it is not the answer to the question that the user asked. When the somethings that are represented in the database are not fully understood, then answers derived from the data warehouse are likely to be applied incorrectly to known somethings. Unfortunately, this also undermines data mining. Data mining helps people find hidden relationships in the data. But if the data do not represent something of interest in the world, then those relationships do not represent anything interesting, either.

Research problems in data warehousing currently reflect this data-driven view. Current research in data warehousing focuses on a) data extraction and integration, b) data aggregation and production of summary sets, c) query optimization, and d) update propagation (Jarke, Lenzerini, Vassiliou, & Vassiliadis, 2000). All these issues address the production of summary data based on operational data stores.

A Poverty of Epistemology

The primary flaw in data-driven data warehouse design is that it is based on an impoverish epistemology. *Epistemology* is that branch of philosophy concerned with theories of knowledge and the criteria for valid knowledge (Fetzer & Almeder, 1993; Palmer, 2001). That is to say, when you derive information from a data warehouse based on the data-driven approach, what does that information mean? How does it relate to the work of the organization? To see this issue, consider the following example. If I asked each student in a class of 30 for their ages, then summed those ages and divided by 30, I should have the average age of the class, assuming that everyone reported their age accurately. If I were to generate a list of 30 random numbers between 20 and 40 and took the average, that average would be the average of the numbers in that data set and would have nothing to do with the average age of the class. In between those two extremes are any number of options. I could guess the ages of students based on their looks. I could ask members of the class to guess the ages of other members. I could rank the students by age and then use the ranking number instead of age. The point is that each of these attempts is somewhere between the two extremes, and the validity of my data improves as I move closer to the first extreme. That is, I have measurements of a specific phenomenon, and those measurements are likely to represent that phenomenon faithfully. The epistemological problem in data-driven data warehouse design is that data is collected for one purpose and then used for another purpose. The strongest validity claim that can be made is that any information derived from this data is true about the data set, but its connection to the organization is tenuous. This not only creates problems with the data warehouse, but all subsequent data-mining discoveries are suspect also.

METRIC-DRIVEN DESIGN

The metric-driven approach to data warehouse design begins by defining key business processes that need to be measured and tracked in order to maintain or improve the efficiency and productivity of the organization. After these key business processes are defined, they are modeled in a dimensional data model and then further analysis is done to determine how the dimensional model will be populated. Hopefully, much of the data can be derived from operational data stores, but the metrics are the driver, not the availability of data from operational data stores.

A relational database models the entities or objects of interest to an organization (Teorey, 1999). These objects of interest may include customers, products, employees, and the like. The entity model represents these things and the relationships between them. As occurrences of these entities enter or leave the organization, that addition or deletion is reflected in the database. As these entities change in state, somehow, those state changes are also reflected in the database. So, theoretically, at any point in time, the database faithfully represents the state of the organization. Queries can be submitted to the database, and the answers to those queries should, indeed, be the answers to those questions if they were asked and answered with respect to the organization.

A data warehouse, on the other hand, models the business processes in an organization to measure and track those processes over time. Processes may include sales, productivity, the effectiveness of promotions, and the like. The dimensional model contains facts that represent measurements over time of a key business process. It also contains dimensions that are attributes of these facts. The fact table can be thought of as the dependent variable in a statistical model, and the dimensions can be thought of as the independent variables. So the data warehouse becomes a longitudinal dataset tracking key business processes.

A Parallel with Pre-Relational Days

You can see certain parallels between the state of data warehousing and the state of database prior to the relational model. The relational model was introduced in 1970 by Codd but was not realized in a commercial product until the early 1980s (Date, 2004). At that time, a large number of nonrelational database management systems existed. All these products handled data in different ways, because they were software products developed to handle the problem of storing and retrieving data. They were not developed as implementations of a theoretical model of data. When the first relational product came out, the world of databases changed almost overnight. Every nonrelational product attempted, unsuccessfully, to claim that it was really a relational product (Codd, 1985). But no one believed the claims, and the nonrelational products lost their market share almost immediately.

Similarly, a wide variety of data warehousing products are on the market today. Some are based on the dimensional model, and some are not. The dimensional model provides a basis for an underlying theory of data that tracks processes over time rather than the current state of entities. Admittedly, this model of data needs quite a bit of work, but the relational model did not come into dominance until it was coupled with entity theory, so the parallel still holds. We may never have an announcement in data warehousing as dramatic as Codd's paper in relational theory. It is more likely that a theory of temporal dimensional data will accumulate over time. However, in order for data warehousing to become a major force in the world of databases, an underlying theory of data is needed and will eventually be developed.

The Implications for Research

The implications for research in data warehousing are rather profound. Current research focuses on issues such as data extraction and integration, data aggregation and summary sets, and query optimization and update propagation. All these problems are applied problems in software development and do not advance our understanding of the theory of data.

But a metric-driven approach to data warehouse design introduces some problems whose resolution can make a lasting contribution to data theory. Research problems in a metric-driven data warehouse include a) How do we identify key business processes? b) How do we construct appropriate measures for these processes? c) How do we know those measures are valid? d) How do we know that a dimensional model has accurately captured the independent variables? e) Can we develop an abstract theory of aggregation so that the data aggregation problem can be understood and advanced theoretically? and, finally, f) can we develop an abstract data language so that aggregations can be expressed mathematically by the user and realized by the machine?

Initially, both data-driven and metric-driven designs appear to be legitimate competing paradigms for data warehousing. The epistemological flaw in the data-driven approach is a little difficult to grasp, and the distinction — that information derived from a data-driven model is information about the data set, but information derived from a metric-driven model is information about the organization — may also be a bit elusive. However, the implications are enormous. The data-driven model has little future in that it is founded on a model of data exploitation rather than a model of

data. The metric-driven model, on the other hand, is likely to have some major impacts and implications.

FUTURE TRENDS

The Impact on White-Collar Work

The data-driven view of data warehousing limits the future of data warehousing to the possibilities inherent in summarizing large collections of old data without a specific purpose in mind. The metric-driven view of data warehousing opens up vast new possibilities for improving the efficiency and productivity of an organization by tracking the performance of key business processes. The introduction of quality management procedures in manufacturing a few decades ago dramatically improved the efficiency and productivity of manufacturing processes, but such improvements have not occurred in white-collar work.

The reason that we have not seen such an improvement in white-collar work is that we have not had metrics to track the productivity of white-collar workers. And even if we did have the metrics, we did not have a reasonable way to collect them and track them over time. The identification of measurable key business processes and the modeling of those processes in a data warehouse provides the opportunity to perform quality management and process improvement on white-collar work.

Subjecting white-collar work to the same rigorous definition as blue-collar work may seem daunting, and indeed that level of definition and specification will not come easily. So what would motivate a business to do this? The answer is simple: Businesses will have to do this when the competitors in their industry do it. Whoever does this first will achieve such productivity gains that competitors will have to follow suit in order to compete. In the early 1970s, corporations were not revamping their internal procedures because computerized accounting systems were fun. They were revamping their internal procedures because they could not protect themselves from their competitors without the information for decision making and organizational control provided by their accounting information systems. A similar phenomenon is likely to drive data warehousing.

Dimensional Algebras

The relational model introduced *Structured Query Language (SQL),* an entirely new data language that allowed nontechnical people to access data in a database. SQL also provided a means of thinking about record selection and limited aggregation. Dimensional models can be exploited by a dimensional query language such as MDX (Spofford, 2001), but much greater advances are possible.

Research in data warehousing will likely yield some sort of a dimensional algebra that will provide, at the same time, a mathematical means of describing data aggregation and correlation and a set of concepts for thinking about aggregation and correlation. To see how this could happen, think about how the relational model led us to think about the organization as a collection of entity types or how statistical software made the concepts of correlation and regression much more concrete.

A Unified Theory Of Data

In the organization today, the database administrator and the statistician seem worlds apart. Of course, the statistician may have to extract some data from a relational database in order to do his or her analysis. And the statistician may engage in limited data modeling in designing a data set for analysis by using a statistical tool. The database administrator, on the other hand, will spend most of his or her time in designing, populating, and maintaining a database. A limited amount of time may be devoted to statistical thinking when counts, sums, or averages are derived from the database. But these two individuals will largely view themselves as participating in greatly differing disciplines.

With dimensional modeling, the gap between database theory and statistics begins to close. In dimensional modeling we have to begin thinking in terms of construct validity and temporal data. We need to think about correlations between dependent and independent variables. We begin to realize that the choice of data types (e.g., interval or ratio) will affect the types of analysis we can do on the data and will hence potentially limit the queries. So the database designer has to address concerns that have traditionally been the domain of the statistician. Similarly, the statistician cannot afford the luxury of constructing a data set for a single purpose or a single type of analysis. The data

set must be rich enough to allow the statistician to find relationships that may not have been considered when the data set was being constructed. Variables must be included that may potentially have impact, may have impact at some times but not others, or may have impact in conjunction with other variables. So the statistician has to address concerns that have traditionally been the domain of the database designer.

What this points to is the fact that database design and statistical exploitation are just different ends of the same problem. After these two ends have been connected by data warehouse technology, a single theory of data must be developed to address the entire problem. This unified theory of data would include entity theory and measurement theory at one end and statistical exploitation at the other. The middle ground of this theory will show how decisions made in database design will affect the potential exploitations, so intelligent design decisions can be made that will allow full exploitation of the data to serve the organization's needs to model itself in data.

CONCLUSION

Data warehousing is undergoing a theoretical shift from a data-driven model to a metric-driven model. The metric-driven model rests on a much firmer epistemological foundation and promises a much richer and more productive future for data warehousing. It is easy to haze over the differences or significance between these two approaches today. The purpose of this article was to show the potentially dramatic, if somewhat speculative, implications of the metric-driven approach.

KEY TERMS

Data-Driven Design: A data warehouse design that begins with existing historical data and attempts to derive useful information regarding trends in the organization.

Data Warehouse: A repository of time-oriented organizational data used to track the performance of key business processes.

Dimensional Data Model: A data model that represents measurements of a process and the independent variables that may affect that process.

Epistemology: A branch of philosophy that attempts to determine the criteria for valid knowledge.

Key Business Process: A business process that can be clearly defined, is measurable, and is worthy of improvement.

Metric-Driven Design: A data warehouse design that beings with the definition of metrics that can be used to track key business processes.

Relational Data Model: A data model that represents entities in the form of data tables.

Data Mining and Privacy

Esma Aïmeur
Université de Montréal, Canada

Sébastien Gambs
Université de Montréal, Canada

INTRODUCTION

With the emergence of Internet, it is now possible to connect and access sources of information and databases throughout the world. At the same time, this raises many questions regarding the privacy and the security of the data, in particular how to mine useful information while preserving the privacy of sensible and confidential data. *Privacy-preserving data mining* is a relatively new but rapidly growing field that studies how data mining algorithms affect the privacy of data and tries to find and analyze new algorithms that preserve this privacy.

At first glance, it may seem that data mining and privacy have orthogonal goals, the first one being concerned with the discovery of useful knowledge from data whereas the second is concerned with the protection of data's privacy. Historically, the interactions between privacy and data mining have been questioned and studied since more than a decade ago, but the name of the domain itself was coined more recently by two seminal papers attacking the subject from two very different perspectives (Agrawal & Srikant, 2000; Lindell & Pinkas, 2000). The first paper (Agrawal & Srikant, 2000) takes the approach of randomizing the data through the injection of noise, and then recovers from it by applying a reconstruction algorithm before a learning task (the induction of a decision tree) is carried out on the reconstructed dataset. The second paper (Lindell & Pinkas, 2000) adopts a cryptographic view of the problem and rephrases it within the general framework of secure multiparty computation.

The outline of this chapter is the following. First, the area of privacy-preserving data mining is illustrated through three scenarios, before a classification of privacy-preserving algorithms is described and the three main approaches currently used are detailed. Finally, the future trends and challenges that await the domain are discussed before concluding.

BACKGROUND

The area of privacy-preserving data mining can still be considered in its infancy but there are already several workshops (usually held in collaboration with different data mining and machine learning conferences), two different surveys (Verykios *et al.*, 2004; Výborný, 2006) and a short book (Vaidya, Clifton & Zhu, 2006) on the subject. The notion of privacy itself is difficult to formalize and quantify, and it can take different flavours depending on the context. The three following scenarios illustrate how privacy issues can appear in different data mining contexts.

- **Scenario 1:** A famous Internet-access provider wants to release the log data of some of its customers (which include their personal queries over the last few months) to provide a public benchmark available to the web mining community. How can the company anonymize the database in such a way that it can guarantee to its clients that no important and sensible information can be mined about them?
- **Scenario 2:** Different governmental agencies (for instance the Revenue Agency, the Immigration Office and the Ministry of Justice) want to compute and release some joint statistics on the entire population but they are constrained by the law not to communicate any individual information on citizens, even to other governmental agencies. How can the agencies compute statistics that are sufficiently accurate while at the same time, safeguarding the privacy of individual citizens?

- **Scenario 3:** Consider two bioinformatics companies: Alice Corporation and Bob Trust. Each company possesses a huge database of bioinformatics data gathered from experiments performed in their respective labs. Both companies are willing to cooperate in order to achieve a learning task of mutual interest such as a clustering algorithm or the derivation of association rules, nonetheless they do not wish to exchange their whole databases because of obvious privacy concerns. How can they achieve this goal without disclosing any unnecessary information?

When evaluating the potential privacy leak caused by a data mining process, it is important to keep in mind that the adversary may have some side information that could be used to infringe this privacy. Indeed, while the data mining process by itself may not be directly harmful, it is conceivable that associated with the help of linking attacks (derived from some *a priori* knowledge), it may lead to a total breakdown of the privacy.

MAIN FOCUS

The privacy-preserving techniques can generally be classified according to the following dimensions:

- *The distribution of the data*. During the data mining process, the data can be either in the hands of a single entity or distributed among several participants. In the case of distributed scenarios, a further distinction can be made between the situation where the attributes of a single record are split among different sites (*vertical partitioning*) and the case where several databases are situated in different locations (*horizontal partitioning*). For example, in scenario 1 all the data belongs to the Internet provider, whereas in scenario 2 corresponds to a vertical partitioning of the data where the information on a single citizen is split among the different governmental agencies and scenario 3 corresponds to an horizontal partitioning.
- *The data mining algorithm*. There is not yet a single generic technique that could be applied to any data mining algorithm, thus it is important to decide beforehand which algorithm we are interested in. For instance, privacy-preserving variants of association rules, decision trees, neural networks, support vector machines, boosting and clustering have been developed.
- *The privacy-preservation technique*. Three main families of privacy-preserving techniques exist: the *perturbation-based approaches*, the *randomization methods* and the *secure multiparty solutions*. The first two families protect the privacy of data by introducing noise whereas the last family uses cryptographic tools to achieve privacy-preservation. Each technique has his pros and cons and may be relevant in different contexts. The following sections describe and explicit these three privacy-preservation techniques.

PERTURBATION-BASED APPROACHES

The perturbation-based approaches rely on the idea of *modifying the values of selected attributes using heuristics in order to protect the privacy of the data*. These methods are particularly relevant when the dataset has to be altered so that it preserves privacy before it can be released publicly (such as in scenario 1 for instance). Modifications of the data can include:

- *Altering the value of a specific attribute* by either perturbing it (Atallah *et al.*, 1999) or replacing it by the "unknown" value (Chang & Moskowitz, 2000).
- *Swapping the value of an attribute* between two individual records (Fienberg & McIntyre, 2004).
- *Using a coarser granularity* by merging several possible values of an attribute into a single one (Chang & Moskowitz, 2000).

This process of increasing uncertainty in the data in order to preserve privacy is called *sanitization*. Of course, introducing noise in the data also decreases the utility of the dataset and renders the learning task more difficult. Therefore, there is often a compromise to be made between the privacy of the data and how useful is the sanitized dataset. Moreover, finding the optimal way to sanitize the data has been proved to be a NP-hard problem in some situations (Meyerson & Williams, 2004). However, some sanitization procedures offer privacy guarantees about how hard it is to pinpoint a particular individual. For instance, the

k-anonymization procedure (Sweeney, 2002), which proceeds through suppression and generalizations of attribute values, generates a *k*-anonymized dataset in which each individual record is indistinguishable from at least *k*-1 other records within the dataset. This guarantees that no individual can be pinpointed with probability higher than 1/*k*-1, even with the help of linking attacks.

RANDOMIZATION METHODS

While the perturbation-based approaches will alter the value of individual records, the randomization methods *act on the data in a global manner by adding independent Gaussian or uniform noise to the attribute values*. The goal remains, as for the perturbation approach, to hide particular attribute values while preserving the joint distribution of the data. The "polluted" data set can either be used to reconstruct the data distribution, for instance by using an Expectation-Maximization type of algorithm (Agrawal & Aggarwal, 2001), or to build directly a classifier out of the noisy data (Agrawal & Srikant, 2000). The randomization methods are well adapted to the situation where the data is distributed (horizontally and/or vertically) and the participants are willing to send a randomized version of their data to a central site which will be responsible to perform the data mining process (see for example the related work on privacy-preserving online analytical processing (Agrawal, Srikant & Dilys, 2005)). For instance, in scenario 2 the different governmental agencies could agree to send a randomized version of their dataset to a *semi-trusted* third party that will carry out the computation of the data mining algorithm and then release publicly the results.

The intensity and the type of the noise are the parameters that can be tuned to balance between the data privacy and the accuracy of the model. Two notions are commonly used to measure privacy: the *conditional entropy* (Agrawal & Aggarwal, 2001) and *privacy breaches* (Evfimievski, Gerhke & Srikant, 2003). Conditional entropy is an information-theoretic measure that computes the mutual information between the original and the randomized dataset. Low mutual information is generally an indication of high privacy preservation but also a sign that the learning will be less accurate. A privacy breach might occur when there is a change of confidence regarding the estimated value of a particular attribute in a specific record. Evfimievski, Gerhke and Srikant (2003) were the first to formally analyze the trade-off between noise addition and data utility and to propose a method which limits privacy breaches without any knowledge of the data distribution.

SECURE MULTIPARTY SOLUTIONS

Secure multiparty computation is the branch of cryptography which deals with the realization of distributed tasks in a secure manner (Goldreich, 2004). The definition of security usually includes preserving the privacy of the data and protecting the computation against malicious participants. A typical task is to compute some function $f(x,y)$ in which the input x is in the hands of one participant while input y is the hands of the other. An example of possible inputs could be the personal datasets of two companies (for instance Alice Corporation and Bob Trust in scenario 3) and the output of the function could be for instance a classifier or a set of rules jointly extracted from their datasets. Within the usual cryptographic paradigm, a protocol is considered perfectly secure if its execution does not reveal more information than the protocol itself. In particular, the participants should not be able to learn anything from the completion of the task, except what they can infer from their own inputs and the output of the function (such as the resulting classifier).

Two security models are generally considered in cryptography (Goldreich, 2004). In the *honest-but-curious* (also known as passive or semi-honest) model, the participants are assumed to follow the directives of the protocol, without any attempt to cheat, but they may try to learn as much information as possible by analyzing the communication exchanged during the protocol. This model is weaker than if we had considered the model where the participants can be *malicious* and cheat *actively* during the execution of the protocol, but it is nonetheless useful and almost always considered by privacy-preserving algorithms. In particular, the semi-honest model is relevant in the situation where the participants are willing to cooperate to achieve a task of mutual interest but cannot communicate directly their dataset because of confidentiality issues.

General results in the domain guarantee that any function can be implemented with unconditional security (in the sense of information theory) provided that at least some proportion of the participants is honest

(see for instance Chaum, Crépeau & Damgård, 1988). Although these methods are very generic and universal, they can be quite inefficient in terms of communication and computational complexity, when the function to compute is complex and the input data is large (which is typically the case in data-mining). Therefore, it is usually worthwhile to develop an efficient secure implementation of a specific learning task that offers a lower communicational and computational cost than the general technique. Historically, Lindell and Pinkas (2000) were the first to propose an algorithm that followed this approach. They described a privacy-preserving, distributed bipartite version of ID3. Since this seminal paper, other efficient privacy-preserving variants of learning algorithms have been developed such as neural networks (Chang & Lu, 2001), naïve Bayes classifier (Kantarcioglŭ & Vaidya, 2004), *k*-means (Kruger, Jha & McDaniel, 2005), support vector machines (Laur, Lipmaa & Mielikäinen, 2006) and boosting (Gambs, Kégl & Aïmeur, 2007).

FUTURE TRENDS

Understanding privacy better and finding relevant measures to compare different privacy-preserving approaches are some of the major challenges in the domain. For instance, it seems that the traditional "model" of secure multiparty computation may not be perfectly adequate for data mining. In particular, the participants of a multiparty protocol might not be only interested in how much information is leaked during the computation of the function *f*, but rather in the total direct information on their datasets that is revealed, including the information contained in *f* itself. At least two directions of research could be explored to solve this problem. First, some studies have already considered the computation of an *approximation* of the function *f* instead of the function itself (Feigenbaum *et al.*, 2001). Approximation algorithms are usually utilized when the exact version of the function is hard to compute. Nonetheless, approximation algorithms could also be used with a different purpose in mind, such as hiding information about the function (see for instance Ishai *et al.*, 2007). The second direction to explore is the introduction of some kind of randomization in the learning process (and not in the data itself). Some algorithms, such as neural networks with randomly initialized weights, seem naturally suited for this type of approach, while others could be changed explicitly to include randomization.

Another important research avenue is the development of *hybrid algorithms* that are able to take the best of both worlds. For instance, the randomization approach could be used as preprocessing to disturb the data before a secure multiparty protocol is run on it. This guarantees that even if the cryptographic protocol is broken, some privacy of the original dataset will still be preserved.

Finally, a last trend of research concerns the migration from the semi-honest setting, where participants are considered to be honest-but-curious, to the malicious setting where participants may actively cheat and try to tamper with the output of the protocol. Moreover, it is important to consider the situation where a participant may be involved in the data mining process but without putting his own data at stake and instead run the algorithm on a deliberately forged dataset. Is there a way to detect and avoid this situation? For instance by forcing the participant to commit his dataset (in a cryptographic sense) before the actual protocol is run.

CONCLUSION

Privacy-preserving data mining is an emerging field that studies the interactions between privacy and data mining following two main directions. The first direction seeks to evaluate the impact of the data mining process on privacy, and particularly the privacy of specific individuals. The second direction concerns how to accomplish the data mining process without disclosing unnecessary information regarding the data on which the mining process is performed. Several different algorithms have been developed in the last years that can be classified in three different broad families of privacy-preservation techniques. It is now time for the domain to reflect on what has been achieved, and more importantly on what should be achieved next. In particular, it seems important to find objective ways of comparing two different algorithms and the level of privacy they offer. This task is made harder by the complexity of defining the concept of privacy itself. Regarding this direction of research, a formal framework was proposed (Bertino, Fovino & Provenza, 2005) which allows to compare different privacy-preserving algorithms using criteria such as efficiency, accuracy,

scalability or level of privacy. Regarding the future trends, understanding how much the result of a data mining process reveals about the original dataset(s) and how to cope with malicious participants are two main challenges that lie ahead.

KEY TERMS

ID3 (Iterative Dichotomiser 3): Learning algorithm for the induction of decision tree (Quinlan, 1986) that uses an entropy-based metric to drive the construction of the tree.

***k*-Anonymization:** Process of building a *k*-anonymized dataset in which each individual record is indistinguishable from at least *k*-1 other records within the dataset.

Conditional Entropy: Notion of information theory which quantifies the remaining entropy of a random variable Y given that the value of a second random variable X is known. In the context of privacy-preserving data mining, it can be used to evaluate how much information is contained in a randomized dataset about the original data.

Expectation-Maximization (EM): Family of algorithms used in statistics for finding maximum likelihood estimates of parameters in probabilistic models, where the model depends on unobserved latent variables.

Privacy Breach: Regarding the particular attribute of a particular record, a privacy breach can occur if the release of the randomized dataset causes a change of confidence regarding the value of this attribute which is above the *privacy breach level*.

Sanitization: Process of removing sensitive information from a dataset so that it satisfies some privacy constraints before it can be release publicly.

Secure Multiparty Computation: Area of cryptography interested in the realization of distributed tasks in a secure manner. The security of protocols can either be computational (for instance based on some cryptographic assumptions such as the difficulty of factorization) or unconditional (in the sense of information theory).

Semi-Trusted Party: Third party that is assumed to follow the instructions that are given to him but can at the same time "spy" on all the information that he sees during the execution of the protocol. A virtual trusted third party can be emulated by combining a semi-trusted third party together with cryptographic tools.

Data Mining and the Text Categorization Framework

Paola Cerchiello
University of Pavia, Italy

INTRODUCTION

The aim of this contribution is to show one of the most important application of text mining. According to a wide part of the literature regarding the aforementioned field, great relevance is given to the classification task (Drucker et al., 1999, Nigam et al., 2000).

The application contexts are several and multitask, from text filtering (Belkin & Croft, 1992) to word sense disambiguation (Gale et al., 1993) and author identification (Elliot and Valenza, 1991), trough anti spam and recently also anti terrorism. As a consequence in the last decade the scientific community that is working on this task, has profuse a big effort in order to solve the different problems in the more efficient way.

The pioneering studies on text categorization (TC, a.k.a. topic spotting) date back to 1961 (Maron) and are deeply rooted in the Information Retrieval context, so declaring the engineering origin of the field under discussion. Text categorization task can be briefly defined as the problem of assigning every single textual document into the relative class or category on the basis of the content and employing a classifier properly trained.

In the following parts of this contribution we will formalize the classification problem detailing the main issues related.

BACKGROUND

In a formal way, text categorization is the task of assigning a Boolean value to:

$$(d_j, c_i) \in D \times C$$

where D is a domain of documents and $C = [c_1, \ldots\ldots, c_{|C|}]$ is a set of predefined categories. A value of T assigned to (d_j, c_i) indicates a decision to file d_j (also called *positive example*) under c_i , and a value of F assigned to (d_j, c_i) indicates a decision not to file d_j (also called *negative example*) under c_i. In other words a function, able to approximate the relation between the set D of documents and the set C of categories, is needed by means of a classifier able to learn the main characteristic of each categories on the basis of the information contained in the documents.

We emphasize that the *c* categories are simply symbolic labels (authors' name, spam or not spam, different topics) and often no further information is available.

Regarding the relation between documents and categories two different formulations should be mentioned (Sebastiani, 2003):

- Given a document $d_j \in D$, all the categories under which it could be filed, are checked, (*document-pivoted categorization*-DPC);
- Given a category $c_i \in C$, all the documents that could be filed under it, are checked (*category-pivoted categorization*-CPC).

Actually the above distinction is more practical than theoretical, in any case it can be useful whenever C and D are not fully available from the beginning.

Now we want to refer two main approaches employed in the construction of a text classifier.

The first one is the *Knowledge Engineering*, born in '80, dealing with the manual construction of several decision rules, of type *if (some characteristic) then (category i-th)*. As the reader can simply infer this approach was too expensive either from a human or a time point of view. In fact those rules needed, not only to be thought about by an human expert of the relative topic, but also to be updated every time some constitutive elements change.

The ideal field for TC was found in *Machine learning* community that introduced the idea of a supervised classifier able to learn the key elements of each category on the basis of some preclassified documents. We underline that according to this formulation, the

wish is not simply constructing a classifier, but mainly creating a builder of classifier automatizing the whole process.

Another important aspect of every application of text mining, not only text categorization, is the transformation of a textual document in a analyzable database. The idea is to represent a document d_j with a vector of weights $d_j = (w_{1j},....,w_{|T|j})$ according to which T is the dictionary, that is the set of terms present at least once in at least *k* documents, and *w* measures the importance of the term. With the concept of term the field literature is usual to refer to a single word from the moment that this kind of representation produces the best performance (Dumais et al. 1998).

On the other side w_i is commonly identified with the count of the i-th word in the document d_j, or with some variation of it like *tf-idf* (Salton & Buckley, 1988).

The data cleaning step is a key element of a text mining activity in order to avoid the presence of highly language dependant words. That latter objective is obtained by means of several activities such as conversion to lower case, managing of acronym, removing of white space special characters, punctuation, stop words, handling of synonymous and also word stemming.

A specific word frequency gives us information about the importance of it in the document analyzed, but it does not mean that the number they appear with, is proportional to the importance in the description of the above document. What is typically more important, it is the proportion between the frequencies of words to each other in the text.

Even after all the activities of data cleaning presented, the number of relevant words

is still very high (in the order of 10^3), thereby features selection methods must be applied (Forman, 2003).

MAIN THRUST

Once defined the preprocessing aspects of a text categorization analysis, it is necessary to focus on one or more classifiers that will assign every single document to the specific category according to the general rule specified above:

- The first and oldest algorithm employed in the field under analysis is the Rocchio method (Joachims, 1997) belonging to the linear classifier class and based on the idea of a category profile (document prototype). A classifier built with such methodology rewards the proximity of a document to the centroid of the training positive examples and its distance from the centroid of the negative examples. This kind of approach is quite simple and efficient however, because of the introduction of the linear division of the documents space, as all the linear classifiers do, it shows a low effectiveness giving rise to the classification of many documents under the wrong category.
- Another interesting approach is represented by the memory based reasoning methods (Masand et al., 1992) that, rather than constructing and explicit representation of the category (like Rocchio method does), rely on the categories assigned to training documents that result more similar to the test documents. Unlike the linear classifiers, this approach doesn't linearly divide the space and therefore we are not expected to have the same problems seen before. However the weak point of such formulation resides in the huge time of classification due to the fact that it doesn't exist a real phase of training and the whole computational part is left to classification time.
- Among the class of non numeric (or symbolic) classifier, we mention decision trees (Mitchell, 1996) which internal nodes represent terms, branches are tests on weights for each words and finally leaves are the categories. That kind of formulation classifies a document d_j by means of a recursive control of weights from the main root, trough internal nodes, to final leaves. A possible training method for a decision tree consists in a 'divide and conquer' strategy according to which first, all the training examples should present the same label, and if it is not so, the selection of a term t_k is needed on the basis of which the document set is divided. Documents presenting the same value for t_k are selected and each class is put in a separated sub-tree. That process is repeated recursively on each sub-tree until every single leaf contains documents belonging to the same category. The key phase of this formulation relies on the choice of the term based on indexes like information gain or entropy.
- According to another formulation, the probabilistic one, the main objective is to fit $P(c_i/d_j)$ that

represents the probability for each document to belong to category c_i. This value is calculated on the basis of the Bayes theorem:

$$P(c_i \mid d_j) = \frac{P(c_i)P(d_j \mid c_i)}{P(d_j)}$$

where $P(d_j)$ represents the probability for a document, randomly chose, to present the vector d_j as its representation, and $P(c_i)$ to belong to the category c_i.

One of the most famous formulation of a probabilistic classifier is constituted by the Naïve Bayes one (Kim et al., 2000) that uses the independence assumption regarding the terms present in the vector d_j. As the reader can simply infer that assumption is quite debatable but surely comfortable and useful in calculations and it constitutes the main reason why the classifier is called Naïve:

- Great relevance is given also to the support vector machines (SVMs) model, introduced by Joachims in 1998 in the TC field and which origin is typically not statistic but relies on machine learning area. They were born as linear classifier and represent a set of related supervised learning methods used both for classification and regression scope. When used for classification, the SVM algorithm (Diederich et al., 2003) creates a hyperplane that separates the data into two (or more) classes with the maximum margin. In the simplest binary case, given training examples labelled either c_i or $\neg c_i$, a maximum-margin hyperplane is identified which splits the c_i from the $\neg c_i$ training examples, such that the distance between the hyperplane and the closest examples (the margin) is maximized. We underline the best hyperplane is located by a small set of training example, called support vectors.

The undisputed advantages of the aforementioned classifier are:

1. the capacity of manage dataset with huge number of variables (as typically is the case of TC) without requiring activity of variable selection.
2. the robustness to problems of overfitting.

The more important disadvantage of the technique, especially at the beginning of its application, was the big computational cost that anyway has been overcome with the development of more efficient algorithms.

We add that, because of the inadequacy of the linear approach, as already said before, the non linear version of SVMs is more appropriate in high-dimensional TC problems:

- We also report some notes about ensembles classifiers (Larkey & Croft, 1996), representing one of the more recent development in the research of efficient methods for TC.

The basic idea of that approach is simple: if the best performance of each classifier are put together, the final results should be considerably better. In order to get that objective, those classifiers must be combined properly, that is in the right order and applying the correct combination function.

From an operational point of view each classifier is built by the learner given different parameters or data and is run on the test instances getting finally a ``vote". The votes are then collected and the category with the greatest number of votes becomes the final classification.

We refer the main approaches:

1. Bagging (Breiman, 1996): The training set is randomly sampled with replacement so that each learner gets a different input. The results are then voted.
2. Boosting (Schapire et al., 1999): The learner is applied to the training set as usual, except that each instance has an associated weight and all instances start with an equal weight. Every time a training example is misclassified, a greater weight is assigned by the algorithm. The process is recursive and it is repeated until there are no incorrectly classified training instances or, alternatively, a threshold defining the maximum number of misclassified examples is established.

Research papers (Bauer & Kohavi, 1999) indicate that bagging gives a reliable (i.e. it can be applied in many domains) but modest improvement in accuracy; whereas boosting produces a less reliable but greater improvement in accuracy (when you can use it):

- We finally offer some notes about another interesting and recent approach, rooted in the fuzzy logic context. In order to classify a text is, of course, necessary to determine the main faced topic. However the complete and exhaustive definition of a topic, or in general of a concept, is not an easy task. In this framework, the fuzzy approach can be usefully employed, by means of fuzzy sets. They are sets containing measure of the degree of membership for each contained element. The values are contained in the range [0;1] and the larger the value, the more the element is supposed to be a member of the set. The principal advantage of this formulation lays in the possible specification of topics in terms of hierarchy. The main disadvantage is the inevitable degree of subjectivity in the values assignation.

FUTURE TRENDS

In classical contest the aforementioned classifiers shows performance related to the specific advantages and disadvantages of the methods. However, when the context of analysis changes and the number of categories is not fixed but it can vary randomly without knowing the exact proportion of the increase, those methods fulfil.

A typical example can be represented by the situation in which a new document, belonging to an unknown class, has to be classified and the classical classifiers are not able to detect the text as an example of a new category.

In order to overcome this problem, a recently proposed approach, employed in the author identification context (Cerchiello, 2006), is based on the combined employment of feature selection, by means of decision trees and Kruskal-Wallis test.

That methodology selects terms located both by the decision tree and the non parametric Kruskal-Wallis test (Conover, 1971) and characterized by distribution profiles more heterogeneous and different from each other so that they can reveal a typical and personal style of writing for every single author. This part of the analysis is useful to eliminate words used in a constant or semi-constant way in the different documents composed by every single author.

What proposed above can be evaluated in terms of correspondence analysis, a typical descriptive method able to plot in a bidimensional space rows and columns profiles, underlying the below relationship between observations and variables (in our case documents and words).

The resulting plot is useful to locate documents that can possibly belong to a new category not previously considered.

CONCLUSION

To conclude this contribution we summarize the key elements of the aforementioned research field. As we have already said among the several application of text mining, great relevance is given to text classification task The area literature has proposed in the last decade the employment of the most important classifiers, some rooted in purely statistical field, some other instead in the machine learning one. Their performance depends mainly on the constitutive elements of the learner and among them SVMs and ensembles classifiers deserve more attention.

The formulation of the problem changes when the number of categories can vary, theoretically, in random way: that is documents not always belong to a preclassified class.

In order to achieve the solution of the problem a feature selection activity is needed enriched by a visual representation of documents and words, obtained in terms of correspondence analysis.

KEYTERMS

Correspondence Analysis: It is a method of factoring categorical variables and displaying them in a property space which maps their association in two or more dimensions. It is often used where a tabular approach is less effective due to large tables with many rows and/or columns. It uses a definition of chi-square distance rather than Euclidean distance between points, also known as "profile points". A point is one of the values (categories) of one of the discrete variables in the analysis.

Decision Trees: They are also known as classification tree and constitute a good choice when the task of

the analysis is classification or prediction of outcomes and the goal is to generate rules that can be easily understood and explained. They belong to the family of non parametric models and in text mining field they represent trees in which, internal nodes are labelled by terms, branches departing from them are labelled by tests on the weight that the term has in the test document, and finally leafs represent category.

Information Retrieval: The term "information retrieval" was coined by Calvin Mooers in 1948-50 and it represents the science of searching for information in documents, searching for documents themselves or searching for metadata which describe documents. IR derives from the fusion of interdisciplinary fields such as information architecture, human information behavior, linguistics, semiotics, information science and computer science.

Knowledge Engineering: It is the process of building intelligent Knowledge-based systems and is deeply rooted in other areas such as databases, datamining, expert systems and decision support systems.

Kruskal-Wallis Test: It is the non parametric version of ANOVA analysis and it represents a simple generalization of the Wilcoxon test for two independent sample. On the basis of K independent samples n_1, …, n_k , a unique big sample is created by means of fusion of the originals k samples. The above result is ordered from the smaller sample to the bigger one, and the rank is assigned to each one. Finally R_i is calculated, that is the mean of the ranks of the observations in the ì-th sample. The statistic is:

$$KW=\left[\frac{12}{N(N+1)}\sum_{j=1}^{k}\frac{R_j^2}{n_j}\right]-3(N+1)$$

and the null hypothesis, that all the k distributions are the same, is rejected if:

$KW > X^2_{ü(k-1)}$.

Machine Learning: It is an area of artificial intelligence concerned with the development of techniques which allow computers to "learn". In particular it is a method for creating computer programs by the analysis of data sets.

Text Mining: It is a process of exploratory data analysis applied to data in textual format that leads to the discovery of unknown information, or to answers to questions for which the answer is not currently known.

Data Mining Applications in Steel Industry

Ana González-Marcos
University of León, Spain

INTRODUCTION

The industrial plants, beyond subsisting, pursue to be leaders in increasingly competitive and dynamic markets. In this environment, quality management and technological innovation is less a choice than a must. Quality principles, such as those comprised in ISO 9000 standards, recommend companies to make their decisions with a based on facts approach; a policy much easily followed thanks to the all-pervasive introduction of computers and databases.

With a view to improving the quality of their products, factory owners are becoming more and more interested in exploiting the benefits gained from better understanding their productive processes. Modern industries routinely measure the key variables that describe their productive processes while these are in operation, storing this raw information in databases for later analysis. Unfortunately, the distillation of useful information might prove problematic as the amount of stored data increases. Eventually, the use of specific tools capable of handling massive data sets becomes mandatory.

These tools come from what it is known as 'data mining', a discipline that plays a remarkable role at processing and analyzing massive databases such as those found in the industry. One of the most interesting applications of data mining in the industrial field is system modeling. The fact that most frequently the relationships amongst process variables are nonlinear and the consequent difficulty to obtain explicit models to describe their behavior leads to data-based modeling as an improvement over simplified linear models.

BACKGROUND

The iron and steel making sector, in spite of being a traditional and mature activity, strives to approach new manufacturing technologies and to improve the quality of its products. The analysis of process records, by means of efficient tools and methods, provides deeper knowledge about the manufacturing processes, therefore allowing the development of strategies to cut costs down, to improve the quality of the product, and to increase the production capability.

On account of their anticorrosive properties, the galvanized steel is a product experiencing an increasing demand in multiple sectors, ranging from the domestic appliances manufacturing to the construction or automotive industry. Steel making companies have established a continuous improvement strategy at each of the stages of the galvanizing process in order to lead the market as well as to satisfy the, every time greater, customer requirements (Kim, Cheol-Moon, Sam-Kang, Han, C. & Soo-Chang, 1998; Tian, Hou & Gao, 2000; Ordieres-Meré, González-Marcos, González & Lobato-Rubio, 2004; Martínez-de-Pisón, Alba, Castejón & González, 2006; Pernía-Espinoza, Castejón-Limas, González-Marcos & Lobato-Rubio, 2005).

The quality of the galvanized product can be mainly related to two fundamental aspects (Lu & Markward, 1997; Schiefer, Jörgl, Rubenzucker & Aberl, 1999; Tenner, Linkens, Morris & Bailey, 2001):

- As to the anticorrosive characteristics, the quality is determined by the thickness and uniformity of the zinc coat. These factors basically depend on

the base metal surface treatment, the temperature of its coating and homogenization, the bath composition, the air blades control and the speed of the band.

- As to the steel properties, they mainly depend on the steel composition and on the melting, rolling and heat treatment processes prior to the immersion of the band into the liquid zinc bath.

MAIN FOCUS

Data mining is, essentially, a process lead by a problem: the answer to a question or the solution to a problem is found through the analysis of the available records. In order to facilitate the practice of data mining, several standardization methods have been proposed. These divide the data mining activities in a certain number of sequential phases (Fayyad, Piatetsky-Shapiro, & Smyth, 1996; Pyle, 1999; Chapman, Clinton, Kerber, Khabaza, Reinartz, Shearer, & Wirth, 2000). Nevertheless, the names and contents of these phases slightly differ. The same general concept is present in every proposal: first the practitioner becomes familiar with the problem and the data set; later on, the data is adapted to suit the needs of the algorithms; then, models are built and tested; finally, newly acquired knowledge provides support for an enhanced decision making process.

Nowadays, nonlinear modeling comprises important techniques that have reached broad applicability thanks to the increasing speed and computing capability of computers. Genetic algorithms (Goldberg & Sastry, 2007) , fuzzy logic (Wang, Ruan & Kerre, 2007) and cluster analysis (Abonyi & Feil, 2007), to name a few, could be mentioned amongst these techniques. Nevertheless, if there is a simple and efficient technique that has made inroads into the industry, that definitely is the artificial neural network.

Amongst the currently existing neural networks, one of the most adequate for defining systems and processes by means of their inputs and outputs is the multilayer perceptron (MLP), which can be considered a universal function approximator (Funahashi, 1989; Hornik, Stinchcombe. & White, 1989); a MLP network with one hidden layer only needs a large enough number of nonlinear units in its hidden layer to mimic any type of function or continuous relationship amongst a group of input and output variables.

The following lines show the successful application of the MLP network, along with other data mining tools, in the modeling of a hot dip galvanizing line whose existing control systems were improved.

Estimation of The Mechanical Properties of Galvanized Steel Coils

The core of the control engineering strategies relies on the capability of sensing the process variables at a rate high enough so as to be able to act in response to the observed behavior. 'Closed loop' control strategies, as they are commonly referred to, are based on acting over the commanding actions to correct the differences amongst the observed and expected behavior. In that scenario, control engineers can choose amongst many effective and well known approaches.

Unfortunately, nowadays the mechanical properties of the galvanized steel coils (yield strength, tensile strength and elongation) cannot be directly measured. Instead, they have to be obtained through slow laboratory tests, using destructive methods after the galvanizing process. The lack of online (fast enough) measures compels the control engineers to adopt an 'open loop' control strategy: the estimation of the best commanding actions in order to provide the desired outputs.

As it has already been mentioned, the mechanical properties of the galvanized steel coils change during the manufacturing processes: from the steel production processes that determine their chemical composition, to the very last moment in which it becomes a finished product, either in the shape of galvanized coils or flat plates.

Ordieres-Meré, González-Marcos, González & Lobato-Rubio (2004) proposed a neural network model based on the records of the factory processes in operation. The model was able to predict the mechanical properties of the galvanized steel not only with great accuracy, which is mandatory to improve the quality of the products, but also fast enough, what is critical to close the loop and further improve the quality thanks to a wider range of more complex strategies.

This particular data-based approach to system modeling was developed to satisfy the needs of ARCELOR SPAIN. Following data mining practice standards, the 1731 samples of the data set were analyzed and prepared by means of visualization techniques (histograms, scatter plots, etc.) and projection techniques (Sammon projection (Sammon, 1969) and principal components

Table 1. Test samples mean relative error for each mechanical property and cluster analysed.

Mechanical property	Cluster1	Cluster2
Yield strength (MPa)	3.19 %	2.60 %
Tensile strength (MPa)	0.88 %	1.82 %
Elongation (%)	3.07 %	4.30 %

analysis, PCA (Dunteman, 1989)); later on, the outliers were identified and the data set was split according to the cluster analysis results; then, a MLP network was selected amongst a set of different candidates.

In this case, only two out of the three detected clusters contained a large enough number of samples to make posible a later analysis. One of the clusters, 'cluster 1', comprised 1142 samples, while the other, 'cluster 2', contained 407 samples. For these two clusters, a set of MLP networks was trained. These networks featured an input layer with 17 inputs, a hidden layer with a variable number of neurons ranging from 3 to 20, and an output layer with a single output neuron. The selected learning algorithm was backpropagation with weight decay for preventing the network from overfitting.

The obtained results were pretty good and the test pattern mean relative error (see Table I) was within tolerance, showing the feasibility of online estimations. The advantages of these models in terms of economic savings, derived from the online forecast of these mechanical characteristics, are admirable.

In the past, the mechanical characteristics were only measured at discrete points. Currently, this neural model provides a continuous map of the estimates of the mechanical characteristics of the coils, thus identifying which portions comply with customer requirements. Instead of reprocessing the whole coil, the rejected portion can be removed from the coil with the consequent economic saving.

Modeling the Speed of the Steel Strip in the Annealing Furnace

Heat treatment is a key process to obtain the desired properties of the band and one that greatly determines the good adhesion of the zinc coating. Before a neural model was built, the temperature of the band during the heat treatment was controlled only by acting over the furnace temperature. Martínez-de-Pisón (2003) proposed a more effective temperature control by means of changing the speed of the band as well. Following this approach, Pernía-Espinoza, Castejón-Limas, González-Marcos & Lobato-Rubio (2005) made a step forward improving ARCELOR SPAIN annealing process quality by means of a robust model of the strip speed with which more adequate temperatures were obtained.

The data set supporting the model contained a small fraction of samples, (1040 out of 30920 samples) with values of speed outside the normal operation range. They were due to transient regimes, such as those caused by the welding of a coil or the addition of an atypical coil (with unusual dimensions) to the line. In this situation, an abrupt reduction of the speed stands to reason, making advisable the use of a neural model to express the relationships amongst the temperature and the speed.

In order to diminish the influence of the outliers, a robust approach was considered. The robust neural network proposed by Liano (1996) was selected because of its high breakdown point along with its high efficiency against normally distributed errors. The MLP networks training was perform by the conjugated gradient Fletcher-Reeves method.

The results on the test pattern (20% of the samples: 6184 patterns) showed a 4.43% relative mean error, against a 5.66% obtained with a non-robust neural network. That reflected the good behavior of the robust model and proved right the feasibility of a much more effective control of the coils temperature. Moreover, the robust model might be useful while planning the operation of the line, sorting the queue of coils to be processed, or forecasting the speed conditions during transients.

Skin-Pass Artificial Lock

The development of an artificial lock in the skin-pass (González-Marcos, Ordieres-Meré, Pernía-Espinoza & Torre-Suárez, to appear), a phase of the galvanizing process that, inter alia, endows the desired roughness to the surface of the band, illustrates the spawn of new ideas and perceptions that the data mining process bears.

The idea of creating this lock arouse as a consequence of the good results obtained in the prediction of the mechanical properties of the galvanized steel coils. The faulty labeling of the coils is a problem that, although uncommon, used to have severe consequences. Under

these circumstances, a coil with a wrong label used to be treated according to false parameters, thus ending up with hidden and unexpected mechanical properties. Failing to comply with the customer requirements can cause important damages to the customers' machinery, such as fractures while handling a material that is way stronger that expected. In order to avoid this kind of mistakes, an artificial lock was developed in the skin-pass. The lock is a model able to provide online forecast of the elongation of the coils in the skin-pass using the manufacturing and chemical composition data. Thus, a significant difference amongst the expected and observed elongation would warn about a probable mistake during the labeling. Such warning causes the coil to be removed and further analyzed in order to identify the cause of such difference.

The results obtained (Table II) show the goodness of the developed models. Besides, Their utility to solve the problem that originated the study was proved with coils whose incorrect chemical composition was previously known. In these cases, the observed and estimated elongation were significantly different, with errors ranging from -0.334 to -1.224, what would identify, as desired, that the coils under process were wrongly labeled.

The training of the MLP network was performed in a computer with two Xeon 64 processors running at 2.4 GHz, with 8 Gb of RAM memory and Linux operative system. As an example, the training of a network with 26 input neurons, 35 hidden neurons and a single output neuron took 438 minutes, using 3580 training patterns and 1760 validation patterns and running 50000 cycles.

FUTURE TRENDS

Data mining opens a world of new opportunities for many industries. The iron and steel making sector has already taken advantage of a few of the tools the data mining has to offer, successfully applying them in an effective manner at otherwise very hard problems. But the box has just been opened, and many more advanced tools and techniques are on their way to come. Fortunately, the industry has already recognized the benefits of data mining and is eager to exploit its advantages.

CONCLUSION

Data mining is useful wherever data can be collected. Of course, in some instances, cost/benefit calculations might show that the time and effort of the analysis is not worth the likely return. Obviously, the idea of 'Data Mining wherever and whenever' is not advisable. If an application requires a model that can be provided by classical tools, then that is preferable insofar as this procedure is "less energy consuming" than those linked to DM methodologies.

We have presented various types of problems where data management can yield process improvements and where usually they are not so frequent due to the non-direct way of implementation.

In spite of these difficulties, these tools can provide excellent results based on a strict methodology like CRISP-DM (Chapman, Clinton, Kerber, Khabaza, Reinartz, Shearer, & Wirth, 2000) in combination with an open mind.

Data mining can yield significant, positive changes in several ways. First, it may give the talented manager a small advantage each year, on each project, with each customer/facility. Compounded over a period of time, these small advantages turn into a large competitive edge.

Table 2. Mean absolute error for each steel class analysed.

Steel class	Total samples	Test samples	Test mean absolute error
0	1022	153	0.0874
1	6282	942	0.0712
2	2003	300	0.0652
4	1484	222	0.1285

KEY TERMS

Artificial Neural Network: A set of connected artificial neurons.

Artificial Neuron: A mathematical model that applies a function to a linear combination of the input variables in order to provide an output value.

Closed Loop Control System: A system that utilizes feedback as a mean to act over the driving signal according to the differences found amongst the observed and expected behavior.

Multilayer Perceptron: A specific kind of artificial neural network whose neurons are organized in sequential layers and where the connections amongst neurons are established only amongst the neurons of two subsequent layers.

Learning Algorithm: In the artificial neural network area, the procedure for adjusting the network parameters in order to mimic the expected behavior.

Open loop Control System: A system that does not rely on feedback to establish the control strategies.

Outlier: An observation that does not follow the model or pattern of the majority of the data.

Overfitting: Fitting a model to best match the available data while loosing the capability of describing the general behavior.

Robust: Not affected by the presence of outliers.

Steady-state Regime: Status of a system that stabilized.

Transient Regime: Status of a system that is changing from one steady-state regime to another.

Data Mining Applications in the Hospitality Industry

INTRODUCTION

Some people say that "success or failure often depends not only on how well you are able to collect data but also on how well you are able to convert them into knowledge that will help you better manage your business (Wilson, 2001, p. 26)." It is said the $391 billion restaurant industry generates a massive amount of data at each purchase (Wilson, 2001), and once collected, such collected data could be a gigantic tool for profits. In the hospitality industry, knowing your guests in terms of where they are from, how much they spend money, and when and what they spend it can help hospitality managers formulate marketing strategies, enhance guest experiences, increase retention and loyalty and ultimately, maximize profits. Data mining techniques are suitable for profiling hotel and restaurant customers due to their proven ability to create customer value (Magnini, Honeycutt, & Hodge, 2003; Min, Min & Emam, 2002). Furthermore, if the hospitality industry uses such data mining processes as collecting, storing, and processing data, the industry can get strategic competitive edge (Griffin, 1998). Unfortunately, however, the hospitality industry and managers are behind of using such data mining strategies, compared to the retail and grocery industries (Bogardus, 2001; Dev & Olsen, 2000). Therefore, there is a need for learning about such data mining systems for the hospitality industry. The purpose of this paper is to show the applications of data mining systems, to present some successes of the systems, and, in turn, to discuss some benefits from the systems in the hospitality industry.

BACKGROUND

Simply speaking, data mining is the use of the data from the warehouse to discover unpredictable patters, trends and threats through multidimensional analysis or on-line analytical processing, or OLAP (Peacock, 1998; Ross, 1997). The hospitality industry is known as a highly customer-centered business and accumulates large amounts of customer data from central reservation systems (CRS), property management system (PMS), point-of-sale (POS), and guest loyalty program databases. Therefore, data mining application can play a huge role in the hospitality industry (Monash, 2006). The volume of guest information collected via electronic transactions is greater than what humans can easily manage without the aid of technology (Magnini, Honeycutt, & Hodge, 2003). Data-warehousing and data-mining technologies can easily handle large and complex databases and assist hoteliers and restaurateurs in predicting future customers' behaviors, designing marketing campaigns, supporting market analysis, evaluating and refining loyalty programs, creating strategies, and conducting trends analysis (Buchthal, 2006; Singh & Kasavana, 2005; Magnini, Honeycutt, & Hodge, 2003; Min, Min & Emam, 2002; Rowe, 1999).

MAIN FOCUS

Success Story in the Restaurant Industry

As there has been a request for using the data information for hotels and restaurants to survive in a competitive world, Atlanta-based AFC Enterprises and Boston Market have achieved their goals through a data mining process. Using such data mining technique, they eventually try to cultivate more loyal customers, retain core customers, and maximize profits (Ross, 1997).

For instance, AFC first gathers customer-purchase data by item, day, and combination of them. Then, it stores the data in a data warehouse using AIX RISC 6000 hardware and a mix of software tools. While doing such process, the management clearly learns about what factors affect profits and promotions, and who loyal customers are. AFC also uses data mining techniques to manage cash management, inventory management, and customer relationship management (CRM). More successful exams are Red Robin International, a 135-unit casual-dining chain based in Englewood, Colorado and Pizzeria Uno. In additions, these two companies use data mining technique for changing menu or for giving instant and right information to the marketing department for promotions and for customer satisfaction.

Another case for successfully implementing data mining systems is a 13-unit Italian dinner-house, Louise's Trattoria. Luoise's Trattoria, which was bankruptcy in late 1997 and now successfully come back to the business, has been using analysis of credit-card transactions and customer-purchase data, part of data mining. President of this restaurant chain strongly believed that such credit-card transactions could give him more accurate information regarding his customers than traditional guest surveys did (Liddle, 2000; Magnini, Honeycutt, & Hodge, 2003).

Clever Ideas Inc. provides CLICK/Valued Member, the system that uses data collected from credit-card transactions and POS systems to better identify, track, reward, and communicate frequent diners. After having complete customers' information from credit-card transaction and POS systems, the company also sends direct-mail, a quarterly newsletter offering special events or menu changes, and a thank-you email to the frequent diners. Not only customers like such system, but employees like the system, because the employees can get tipped on the full amount (Waters, 2000).

Success Story in the Hotel Industry

Harrah's Entertainment (an official name of the company), a leading company in the hotel and gaming industry, has gained great success from a customer-service oriented strategy centered on data-mining techniques. In 1997, Harrah's hotels and casinos introduced a loyalty-card program "Total Rewards", which tracked customers' purchasing activities and provided incentives to visit Harrah's properties throughout the country (Loveman, 2003). Harrah's tracked customers' purchasing and gaming patterns and then provided its customers with most-effective incentives. Through data mining techniques, Harrah's developed quantitative models to predict lifetime value of its customer and used them to center marketing and service delivery programs in increasing customer loyalty (Bligh & Turk, 2004; Freedman, 2003).

Harrah's also discovered that 26 percent of its customers accounted for 82 percent of company revenue (Magnini, Honeycutt, & Hodge, 2003). Harrah's continues integrating data across properties, developing models, mining the data, and running marketing and service delivery programs and propels it to be the leading position within gaming industry (Bligh & Turk, 2004).

Web-Enabled Customer Relationship Management

Swift (2001, p. 12) defined customer relationship management (CRM) as "enterprise approach to understanding and influencing customer behavior through meaningful communications in order to improve customer acquisition, customer retention, customer loyalty, and customer profitability." CRM evolves from direct sales to mass marketing, target marketing and then to customer relationship marketing with an emphasis that marketing and CRM are inseparable (Ling & Yen, 2001). CRM is used to identify individual preferences, demographics, psychographic profiles and other measures to predict future behaviors and customize marketing efforts (Hendler & Hendler, 2004). In addition, CRM often identifies valued customers who repeatedly purchase a great deal of hotel and restaurant services (Min, Min & Emam, 2002).

It is clear that data mining plays a critical role in CRM systems and helps transform customer data into useful information and knowledge (Ngai, 2005). For

example, Townsend Hotel in Birmingham, MI and the Red Mountain Spa in St. George, UT have used CRM and e-marketing services, Digital Alchemy, to understand their frequent guests and to provide them with excellent guest services. If both hotels know guests' email address, for instance, they send a confirmation email and a follow-up email to the guests. They also use CRM as a marketing tool to track special guests who got married in the hotels to offer an anniversary stay (Ostrowski, 2005).

The information can be used to tailor marketing strategies more effectively to specific customers. Web-enabled CRM systems have gained popularity in the hospitality industry by cutting the cost, time, and energy normally associated with database marketing (Oliva, 2001). What makes Web-based CRM systems so ideal for such hospitality operations is the data stored in one common place – the Internet, instead of individual property management systems (PMSs). Most Web-based CRM systems work as a data warehouse, pulling data from central reservation systems (CRSs) and PMSs. In addition, Web-based CRM is so accessible that every hotelier and restaurateur only needs a password to log on the Internet and run reports according to behavior segmentation, customer profiles and geo-demographic statistics (Oliva, 2001). In the example of Townsend Hotel and the Red Mountain Spa, the hotels' property management system (PMS) and e-marketing service provider Digital Alchemy have a direct link so that CRM mines data from the PMS and sends reservation emails (Ostrowski, 2005).

Another example of the use of CRM in the hospitality industry is that Wyndham International, one of the five largest U. S. based hotel chains, has used its membership-based CRM initiative: Wyndham ByRequest, which includes the web-site, the preferences databases, and integrated operational systems (e.g., PMS). When a guest provides his/her information in ByRequest, it completes guest profile including guest's general and contact information, room preferences, credit-card and express check-in/check-out preferences, airline frequent-flyer preferences, personal interests, and beverage preference for a consistent level of personalized service (Piccoli, O'Connor, Capaccioli, & Alvarez, 2003).

FUTURE TRENDS

Although the hospitality industry plunged into the world of data mining later than the traditional retail industry, the hospitality industry's use of data mining will catch up the retail industry's soon (Ross, 1997). It is obvious that there have been such successful trends in the hotel and restaurant businesses and more successes can be found at Dunkin's Brands, Logans' Roadhouse, Buffalo Wild Wings, McAlister's Deli, Papa Murphy's Take 'n' Bake Pizza, IHOP (Prewitt, 2007). Based on the review from the previous sections regarding successful stories of using data mining, more hotels and restaurants should deploy data mining engines in their work sites. In addition, cooperation with food and beverage manufacturers, such as beer, wine and spirits, will be helpful for the industry, since such manufacturers also have been looking for reliable customer purchasing databases (Bogardus, 2001).

CONCLUSION

As can be presented in the previous sections, the ultimate goal of data mining is strong customer relationship in the hospitality industry. In addition, as defined, customer relationship management (CRM) stresses maximizing benefits for the business (Ling & Yen, 2001; Piccol et al., 2003). This technique can be especially valuable for the hospitality industry, given the fact that hospitality companies often miss customer demographics or psycho-graphics. Such data mining engines can be useful and helpful tools for any hotel and restaurant companies (Monash, 2006; Murphy, Hofacker, & Bennett, 2001). Although several successful examples have been mentioned in this paper, more companies should investigate benefits of data mining systems and received the benefits from the systems.

KEY TERMS

Central Reservation System (CRS): Centralized control of the booking of hotels rooms. The major features include: instant booking and confirmation, on line room inventory status, booking acceptance for events and venues, arrival list generation, multiple type of revenue reports, customer profile, comprehensive tariff management, and performance auditing.

CLICK/Valued Member: A marketing program targeted at frequent customers using a restaurants' credit card transactions. It identifies, tracks, rewards, and communicates with frequent diners and also sends the diners postcards to keep them abreast of special events, offers or menu changes.

Customer Relationship Management (CRM): A managerial philosophy that enables a firm to become intimately familiar with its customers. CRM focuses on maximizing revenue from each customer over the lifetime of the relationship by getting to know each one intimately.

Database Marketing: Extensive analysis of guest history, reservation databases, guest accounting/history, guest comment cards, brochure requests, Internet and other sources of guest data.

Data Mining in the Hospitality Industry: A largely automated process that uses statistical analyses to sift through massive data sets to detect useful, non-obvious, and previously unknown patterns or data trends for the hospitality industry. It emphasizes the computer-based exploration of previously uncharted relationship.

Data Warehouse: A corporate-wide database-management system that allows a company to manipulate large volumes of data in ways that are useful to the company: establishing sources, cleaning, organizing, summarizing, describing, and storing large amounts of data to be transformed, analyzed, and reported.

On-Line Analytical Processing (OLAP) Engines: Systems that generate query-based correlations in line with use-defined parameters and that make restaurants compare sales relative to plan by quarter and region.

Point-of-Sales (POS): Efficient data communications and affordable data storage using computers or specialized terminals that are combined with cash registers, bas code readers, optical scanners and magnetic stripe readers for accurately and instantly capturing the transaction.

Property Management System (PMS): Computerized system which deals with guest bookings, online reservations, point of sale, telephone and other amenities. Some property management systems also include payroll, back office and accounts.

Data Mining for Fraud Detection System

Roberto Marmo
University of Pavia, Italy

INTRODUCTION

As a conseguence of expansion of modern technology, the number and scenario of fraud are increasing dramatically. Therefore, the reputation blemish and losses caused are primary motivations for technologies and methodologies for fraud detection that have been applied successfully in some economic activities. The detection involves monitoring the behavior of users based on huge data sets such as the logged data and user behavior.

The aim of this contribution is to show some data mining techniques for fraud detection and prevention with applications in credit card and telecommunications, within a business of mining the data to achieve higher cost savings, and also in the interests of determining potential legal evidence.

The problem is very difficult because fraudsters takes many different forms and are adaptive, so they will usually look for ways to avoid every security measures.

BACKGROUND

The economic operations under security control can be classified into the class of genuine and into the class of fraudulent. A fraud is a criminal deception, use of false representations to obtain an unjust advantage, or to injure the rights and interests of another. The fraud is prevalent in insurance, credit card, telecommunications, health care, finance, etc. Diversity of fraud regards organisations, governments, and individuals such as external parties, internal employees, customers, service providers and suppliers.

It is important to analyze in detail the fraud scenario in order to establish: what is the fraudulent and normal behavior and what separates one individual from another, the degree of available knowledge about known fraud, the kind of available data exemplifying, types of fraud offenders and their modus operandi over time. It is difficult to provide precise estimates since some fraud may never be detected, and the operators are reluctant to reveal fraud losses due to show an appearance of reliability and security in business operations and to avoid reputation blemish.

It is necessary to take into account the cost of the fraud detection and the cost of fraudulent behavior, because stopping a fraud of few dollars can require a very expensive system. This is possible by introducing a decision layer on top of the system in order to decide the action taking into account factors like the amount of transaction and the risk associated to user doing the transaction.

The development of new detections methods is more difficult due to the severe limitation on privacy and on exchange of ideas. Moreover, data sets are not available and results are often not disclosed to the public.

The planning audit strategies is a posteriori fraud detection problem with prevention purpose of analyzing historical audit data and constructing models of planning effectively future audits. An application is fiscal and insurance domain, where audits are intended to detect tax evasion and fraudulent claims. A case study is presented by Bonchi (1999) which illustrates how techniques based on classification can be used to support the task of planning audit strategies.

The fraud detection methods in online auction (Shah, 2002) are based on statistical methods and association analysis in order to detect shilling, that occurs when the seller tries to hike up the prices in auction by placing buy bids under distinct aliases or through associates.

Apart fraud, the detection efforts may be further motivated by the need to understand the behavior of customers to enable provision of matching services and to improve operations.

DATA MINING APPROACH

Data mining analyzes the huge volumes of transactions and billing data and seeks out patterns, trends and clusters that reveal fraud. The main steps for implementing this approach for fraud detection within a business organization are:

1. Analyze the fraud objectives and the potential fraudsters, in order to converting them into data mining objectives;
2. Data collection and understanding;
3. Data cleaning and preparation for the algorithms;
4. Experiment design;
5. Evaluation results in order to review the process.

Relevant technical problems are due to:

1. Imperfect data not collected for purpose of data mining, so they are inaccurate, incomplete, and irrelevant data attributes;
2. Highly skewed data, there are many more legitimate than fraudulent examples, so by predicting all examples to be legal a very high success rate is achieved without detecting any fraud;
3. Higher chances of overfitting, that occurs when model high accuracy arises from fitting patterns in the training set that are not statistically reliable and not available in the score set.

To handle with skewed data the training set is divided into pieces where the distribution is less skewed (Chan, 1998).

A typical detection approach consists in outlier detection where the non-fraudulent behavior is assumed as normal and identify outliers that fall far outside the expected range should be evaluated more closely. Statistic techniques used for this approach are:

1. Predict and Classify
   - Regression algorithms: neural networks, CART, Regression, GLM;
   - Classification algorithms (predict symbolic outcome): CART, logistic regression;
2. Group and Find Associations
   - Clustering/Grouping algorithms: K-means, Kohonen, Factor analysis;
   - Association algorithms: GRI, Capri Sequence.

Many existing fraud detection systems operate by: supervised approaches on labelled data, hybrid approaches on labelled data, semi-supervised approaches with legal (non-fraud) data, unsupervised approaches with unlabelled data (Phua, 2005).

For a pattern recognition problem requiring great flexibility, adaptivity, and speed, neural networks techniques are suitable and the computational immunological systems, inspired by human immune system, might prove even more effective than neural networks in rooting out e-commerce fraud. (Weatherford, 2002). Unsupervised neural networks can mainly be used because they act on unlabelled data in order to extract an efficient internal representation of the data distribution structure.

The relational approach (Kovalerchuk, 2000) is applicables for discovering financial fraud, because overcome difficulties of traditional data mining in discovering patterns having only few relevant events in irrelevant data and insufficient statistics of relevant data.

The choice of three classification algorithms and one hybrid meta-learning was introduced by Phua (2004), to process the sampled data partitions, combined with straightforward cost model to evaluate the classifiers, so the best mix of classifiers can be picked.

Visualization techniques are based on the human capacity in pattern recognition in order to detect anomalies and are provided with real-time data. A machine-based detection method is static, the human visual system is dynamic and can easily adapt to the typical ever-changing techniques of the fraudsters. Visual data mining is a data mining approach that combine human detection and statistical analysis for greater computational capacity, is developed by building a user interface to manipulate the visual representation of data in fraud analysis.

Service providers use performance metric like the detection rate, false alarm rate, average time to detection after fraud starts, and average number of fraud or minutes until detection. As first step it is important to define a specific metric considering that misclassification costs can differ in each data set and can change over time. The false alarm rate is the percentage of legitimate that are incorrectly identified as fraudulent; fraud catching rate (or true positive rate or detection accuracy rate) is the percentage of transactions that are correctly identified as fraudulent; false negative rate is the percentage of transactions that are incorrectly identified as legitimate. The objective of this detection is to maximize correct fraud predictions and maintain incorrect predictions at an acceptable level. A realistic objective consists on balance of the performance criteria. A false negative error is usually more costly than

a false positive error. Other important considerations are: how fast the frauds can be detected and average time of detection, how many kind of fraud detected, on-line or off-line detection mode.

Five data mining tools was compared in Abbott (1998) with descriptions of their distinctive strenghts and weaknesses during the process of evaluating the tools. A list of software solutions is available on www.kdnuggets.com/solutions/fraud-detection.html

Credit Card Fraud

Improved fraud detection is an essential step to maintain the security and the suitability of the electronic payment system. There are two class: a stolen credit card number is used for making a purchase that appears on account statement, the cardholders used a legitimate credit card but deliberately denies the transaction upon receiving the service because a dishonest merchant use the card without permission from the cardholders (Leung, 2004).

Offline fraud is committed by using a stolen physical card and the institution issuing the card can lock it before it is used in a fraud. Online fraud is committed via web or phone shopping because only the card‘s details are needed and a manual signature and card imprint are not required (Lu).

Dorronsoro (1997) describe two characteristics: a very limited time span for decisions and huge amount of credit card operations to be processed that continue to grow in number.

Scalable techniques to analyze massive amounts of transaction data that efficiently compute fraud detectors in a timely manner is an important problem, especially for e-commerce (Chan, 1999).

Example of behaviour feature: value and kind of purchases in a specific time, number of charges made from specific postal codes. Behaviour analysis can also help uncover suspicious behaviors, such as a small gasoline purchase followed by an expensive purchase may indicate that someone was verifying that a charge card still worked before going after serious money. Departures from these norms may indicate fraud, expecially in case of two or three such instances ought to attract investigation.

Machine learning techniques such as backpropagation neural networks and Bayesian networks are compared for reasoning under uncertainty (Maes, 2002) showing that Bayesian networks are more accurate and much faster to train but they are slower when applied to new instances.

E-payment systems with internal logics that are capable of detecting fraud transaction are more powerful when combined with standard network security schemes, so there is a well user acceptance of credit card as payment solution. Leung (2004) designing issues on add-on module for detection in e-payment system, based on atomic transactions implemented in e-wallet accounts.

Telecommunications Fraud

The fraud in telecommunications, as any transmission of voice or data across a communications network, regards the intent of frauder to avoid or reduce legitimate call charges, so obtaining unbillable services, acquire free access, reselling the services. Significant loss are in wireless and international calls, because they are most expensive, so when fraud is committed the costs mount quickly. In this kind of application there are specific problems: callers are dissimilar, so calls that look like fraud for one account look like expected behavior for another, while all needles look the same. Sometime fraudsters create a new account without having the intention to pay for the used services. Moreover, fraud has to be found repeatedly, as fast as fraud calls are placed.

Due to legislation on privacy, the intentions of the mobile phone subscribers cannot be observed, but it is assumed that the intentions are reflected in the calling behavior and thus in the observed call data. The call data is subsequently used in describing behavioral patterns of users. Unfortunately, there is no specific sequence of communications that would be fraudulent with absolute certainty, because the same sequence of calls could as well be fraudulent or normal. Therefore, uncertainty in creating the model is needed. The calling activity of each mobile phone subscribers is recorded for billing in call records, which store attributes of calls like the identity of the subscriber, the number to call, time of the call, duration of the call, etc. Call data (or events input) are ordered in time, so it is possible to describe the daily usage formed by number and summed length of calls, and it is possible to separate them in sub-categories.

A common approach is to reduce the call records for an account to several statistics that are computed each period. For example, average call duration, longest call

duration, and numbers of calls to particular countries might be computed over the past hour, several hours, day, or several days. Account summaries can be compared to thresholds each period, and an account whose summary exceeds a threshold can be queued to be analyzed for fraud. The summaries that are monitored for fraud may be defined by subject matter experts,

It is possible to improve the thresholding (Fawcett, 1996) using an innovative method for choosing account-specific thresholds rather than universal thresholds that apply to all accounts. This approach detection has several disadvantages: thresholds may need to vary with time of day, type of account, and type of call to be sensitive to fraud without setting off too many false alarms for legitimate traffic, so it is necessary periodically to review the setting by an expert to accommodate changing traffic patterns. Moreover, accounts with high calling rates or unusual, but legitimate, calling patterns may setting off more false alarms. These problems lead to expensive multiplying the number of thresholds.

An efficient solution must be tailored to each account's own activity, based on historic memory of the use, and must be able to learn the pattern on an account and adapt to legitimate changes in user behavior. It is possible to define the user signature, in order to track legitimate behavior for an user, based on variables and values described by a multivariate probability distribution. The disadvantage consists in estimating the full multivariate distribution.

Cahill (2002) describes an approach based on tracking calling behavior on an account over time and scoring calls according to the extent that they deviate from that pattern and resemble fraud; signatures avoid the discontinuities inherent in most threshold-based systems that ignore calls earlier than the current time period.

The cloning fraud is a superimposition fraud upon the legitimate usage of an account. Fawcett (1997) describes a framework for automatically generating detectors for this cellular fraud, that is based on analysis of massive amounts of call data to determine patterns for a set of monitors watching customers' behavior with respect to one discovered pattern. A monitor profiles each customer behavior and measures the extent to which current behavior is abnormal with respect to the monitor particular pattern. Each monitor output is provided to a neural network, which weights the values and issues an alarm when the combined evidence for fraud is strong enough.

Ferreira (2006) describes the problem of superimposed fraud, that is the fraudsters make an illegitimate use of a legitimate account and some abnormal usage is blurred into the characteristic usage of the account. The approach is based on signature that corresponds to a set of information, or vector of feature variables, that captures the typical behavior of legitimate user during a certain period of time. In case of an user deviates from typical signature a statistical distance is evaluated to detect anomalies and to send an alarm.

Concerning visualization methods, it is possible to create a graphical representation of quantities of calls between different subscribers in various geographical locations, in order to detect international calling fraud (Cox, 1997). As example, in a simple representation the nodes correspond to the subscribers and the lines from the nodes to the countries encode the total number of calls, so investigations on the brightly colored nodes revealed that some of them were involved in fraud. In this way it is possible to show a complete set of information and several tools on a dashboard to facilitate the evaluation process.

FUTURE TRENDS

The available statistical models are unable to detect new types of fraud as they occur, because they must be aware of fraud methods such making a prevention effort, based on amounts of historical data, that can be implemented before the fraud occurred producing. Unfortunately, preventing fraud is an evolving and dynamic process and frauders creates new schemes daily, thus making not suitable this static solution. Future research is based on dynamic, self-correcting and self-adaptation in order to maintain continuous accuracy and adapt to identify and predict new scenarios. Another challenge is creating systems that work quickly enough to detect fraudulent activities as they occur. Moreover an useful feature is due to detailed results including the reason for suspicion of fraud, so the user can prioritizes the suspect transaction and related remedy.

CONCLUSION

The best strategy consists in: monitoring the behavior of populations of users, analyze contextual information and to avoid the examine of individual transactions

exclusively, good database with a large amount data on fraud behaviour, to combine the results from individual flags to create a score which raises a stop flag when it exceeds a threshold. Data mining based on machine learning techniques is suitable on economic data, in case of this approach is applied on a specific problem with a-priori analysis of the problem domain and a specific choice of performance metric. The papers of Bolton (2002) and Kou (2004) and the book of Wells (2004) present a survey of different techniques and more details to detect frauds in credit card, telecommunication, computer intrusion.

This work has been developed with the financial support of MIUR-PRIN funding "statistical models for e-business applications".

KEY TERMS

Credit Card Fraud: A stolen credit card number is used for making a purchase, or a dishonest merchant use the card without permission from the cardholders.

Fraud: A fraud is a criminal deception, use of false representations to obtain an unjust advantage, or to injure the rights and interests of another.

Fraud Detection: An automatic system based on description of user behaviour and fraud scenario, in order to detect a fraudulent activity as soon as possible to reduce loss.

Telecommunications Fraud: any transmission of voice or data across a communications network to avoid or reduce legitimate call charges.

Data Mining for Improving Manufacturing Processes

Lior Rokach
Ben-Gurion University, Israel

INTRODUCTION

In many modern manufacturing plants, data that characterize the manufacturing process are electronically collected and stored in the organization's databases. Thus, data mining tools can be used for automatically discovering interesting and useful patterns in the manufacturing processes. These patterns can be subsequently exploited to enhance the whole manufacturing process in such areas as defect prevention and detection, reducing flow-time, increasing safety, etc.

When data mining is directed towards improving manufacturing process, there are certain distinctions that should be noted compared to the classical methods employed in quality engineering, such as the experimental design. In data mining the primary purpose of the targeted database is not data analysis; the volume of the collected data makes it impractical to explore it using standard statistical procedures (Braha and Shmilovici, 2003).

BACKGROUND

This chapter focuses on mining performance-related data in manufacturing. The performance can be measured in many different ways, most commonly as a quality measure. A product is considered as faulty when it does not meet its specifications. Faults may come from sources such as, raw material, machines setup and many other sources.

The quality measure can either have nominal values (such as "good"/"bad") or continuously numeric values (Such as the number of good chips obtained from silicon wafer or the pH level in a cream cheese). Even if the measure is numeric, it can still be reduced to a sufficiently discrete set of interesting ranges. Thus we can use classification methods in order to find the relation between the quality measure (target attribute) and the input attributes (the manufacturing process data).

Classification methods can be used to improve the learning curve both in the learning pace, as well as in the target measure that is reached at the mature stage. The idea is to find a classifier that is capable of predicting the measure value of a certain product or batch, based on its manufacturing parameters. Subsequently, the classifier can be used to set up the most appropriate parameters or to identify the reasons for bad measures values.

The manufacturing parameters obviously include the characteristics of the production line (such as which machine has been used in each step, how each machine has been setup, operation sequence etc.), and other parameters (if available) relating to the raw material that is used in the process; the environment (moistness, temperature, etc); the human resources that operate the production line (the experience level of the worker which have been assigned on each machine in the line, the shift number) and other such significant factors.

The performance measure (target attribute) in manufacturing data tends to have imbalanced distribution. For instance, if the quality measure is examined, then most of the batches pass the quality assurance examinations and only a few are considered invalid. On the other hand, the quality engineer is more interested in identifying the invalid cases (the less frequent class).

Traditionally, the objective of the classification method is to minimize the misclassification rate. However, for the unbalanced class distribution, accuracy is not an appropriate metric. A classifier working on a population where one class ("bad") represents only 1% of the examples can achieve a significantly high accuracy of 99% by just predicting all the examples to be of the prevalent class ("good"). Thus, the goal is to identify as many examples of the "bad" class as possible (high recall) with as little false alarms (high precision). Traditional methods fail to obtain high values of recall and precision for the less frequent classes, as they are oriented toward finding global high accuracy.

Figure 1. Decision tree for quality assurance

```
CW_WASH_DUR <= 286
|  FINAL_COOLING_TEMP <= 5.9
|  |  AVG_COOLING_TEMP <= 10.1: Tasty (0.864,0.136)
|  |  AVG_COOLING_TEMP > 10.1: Sour (0.323,0.674)
|  FINAL_COOLING_TEMP > 5.9
|  |  AVG_COOLING_TEMP <= 12.3: Tasty (0.682,0.318)
|  |  AVG_COOLING_TEMP > 12.3: Sour (0.286,0.714)
CW_WASH_DUR > 286: Tasty (0.906,0.094)
```

Usually in manufacturing plants there are many input attributes that may affect performance measure and the required number of labelled instances for supervised classification increases as a function of dimensionality. In quality engineering mining problems, we would like to understand the quality patterns as soon as possible in order improve the learning curve. Thus, the training set is usually too small relative to the number of input features.

MAIN FOCUS

Classification Methods

Classification methods are frequently used in mining of manufacturing datasets. Classifiers can be used to control the manufacturing process in order to deliver high quality products.

Kusiak (2002) suggested a meta-controller seamlessly developed using neural network in order to control the manufacturing in the metal industries. While neural networks provide high accuracy, it is usually hard to interpret its predictions. Rokach and Maimon (2006) used a decision tree inducer in cheese manufacturing. As in every dairy product, there is a chance that a specific batch will be found sour when consumed by the customer, prior to the end of the product's shelf-life. During its shelf-life, the product's pH value normally drops. When it reaches a certain value, the consumer reacts to it as a spoiled product. The dairy department performs randomly tests for pH as well organoleptic (taste) at the end of the shelf-life.

Figure 1 demonstrates a typical decision tree induced from the manufacturing database. Each representing symptoms of a product quality, denoted here as features Cold Water Wash Duration, Final Cooling Temperature and Average Cooling Temperature. The leaves are labeled with the most frequent class together with their appropriate probability. For instance, the probability to get a tasty cheese is 0.906 if the Cold Water Wash Duration is greater than 286 seconds.

Ensemble of Classifiers

The main idea of ensemble methodology is to combine a set of models, each of which solves the same original task, in order to obtain a better composite global model, with more accurate estimates than can be obtained from using a single model.

Maimon and Rokach (2004) showed that ensemble of decision trees can be used in manufacturing datasets and significantly improve the accuracy. Similar results have been obtained by Braha and Shmilovici (2002) arguing that ensemble methodology is particularly important for semiconductor manufacturing environments where various physical and chemical parameters that affect the process exhibit highly complex interactions, and data is scarce and costly for emerging new technologies.

Because in many classification applications non-uniform misclassification costs are the governing rule, has led to a resurgence of interest in cost-sensitive classification. Braha et al. (in press) present a decision-theoretic classification framework that is based on a model for evaluating classifiers in terms of their value

in decision-making. The underlying assumption is that the predictions displayed by a classifier are 'effective' only insofar as the derived information leads to actions that increase the payoff for the decision-maker. They suggested two robust ensemble classification methods that construct composite classifiers which are at least as good as any of the existing component classifiers for all possible payoff functions and class distributions.

Decomposition Methods

When a problem becomes more complex, there is a natural tendency to try to break it down into smaller, distinct but connected pieces. This approach is generally referred to as decomposition. Several researchers have shown that the decomposition methodology can be appropriate for mining manufacturing data (Kusiak, 2000; Maimon and Rokach, 2001). Recently Rokach and Maimon (2006) suggested a new feature set decomposition algorithm called Breadth-Oblivious-Wrapper for manufacturing problems. Feature set decomposition decomposes the original set of features into several subsets, and builds a classifier for each subset. A set of classifiers are trained such that each classifier employs a different subset of the original features set. An unlabeled instance is classified by combining the classifications of all classifiers. This approach can be further improved by using genetic algorithms (Rokach, in press).

Association Rules Methods

Agard and Kusiak (2004) use data mining for selection of subassemblies in wire harness process that the automotive industry. By using association rules methods they construct a model for selection of subassemblies for timely delivery from the suppliers to the contractor. The proposed knowledge discovery and optimization framework integrates the concepts from product design and manufacturing efficiency.

da Cunha et al. (2006) analyzed the effect of the production sequence on the quality of the product using data mining techniques. The sequence analysis is particularly important for assemble-to-order production strategy. This strategy is useful when the basic components can be used as building blocks of a variety of end products. Manufactures are obligated to manage a growing product portfolio in order to meet customer needs. It is not feasible for the manufacturer to build all possible end products in advance, thus the assembly is performed only when the customer order is received. Because the quality tests of the components can be performed in advance, the quality of the final assembly operations should be the focus. da Cunha et al., (2006) provide an industrial example of electrical wire harnesses in the automobile industry. There are millions of different wire harnesses for a unique car model, mainly because wire harnesses control many functions (such as the electrical windows) and because every function has different versions depending on other parameters such as engine type.

In order to solve the problem using existing techniques the following encoding is proposed: Each column in the table represents a different sequence pair. By that "the precedence information is contained in the data itself". For instance Figure 2 illustrates a product route which consists of 5 operations followed by an inspection test targeted to identify faults. Because a fault was identified, rework of operation 9 has to be done. The rework is followed by an additional inspection test that indicates that the product fits the product specification.

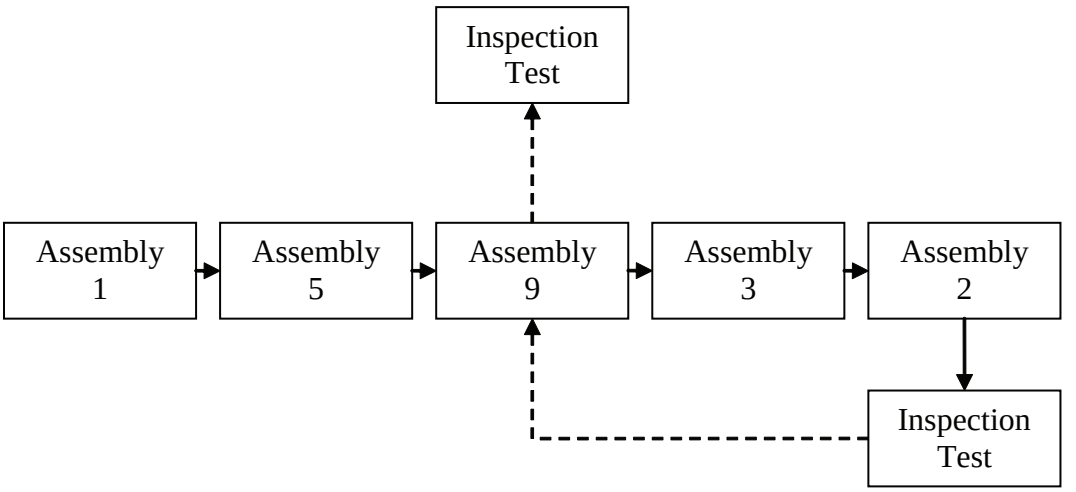
da Cunha et al., (2006) suggest to represent the sequence 1-5-9-3-2 by the following set of pairs: {B1, 1_5 , 5_9, 9_3, 3_2, 2F}. Note that B1 and 2F represent the fact that the sequence begin in operation 1 and that the final operation is 2. By proposing this encoding, it is possible to analyze the effect of the production sequence on the quality of the product using supervised association rules algorithms.

Applications in the Electronic Industry

Most of the data mining applications in manufacturing have been applied to the electronic industry. The reason for that is four-fold:

1. **Process Complexity:** The manufacturing process (such as semiconductor wafer fabrication) = contains many steps. It is very difficult to use standard statistical procedures to detect intricate relations between the parameters of different processing steps (Braha and Shmilovici, 2003).
2. **Process variations:** The process suffers from constant variations in the characteristics of the wafer manufacturing process (Braha et al., in press). It has been estimated that up to 80% of yield losses in high volume integrated circuits production can be attributed to random, equipment

Figure 2. Illustration of a product route



related process-induced defects. The manufacturing environments at different wafer producing plants may be similar, still some wafers obtain higher quality than other. Even within individual plants product quality varies (Kusiak, 2006).

3. **Data availability:** In leading fabs, large volume of data is collected from the production floor.
4. **Data Volume:** Semiconductor databases are characterized as having large amount of records, each of which contain hundreds of attributes, which need to be simultaneously considered in order to accurately model the system's behavior (Braha and Shmilovici, 2003, Rokach and Maimon, 2006).

The main performance measures that are often used to assess profitability in the semiconductor manufacturing process are yield and flow times of production batches (Cunningham et al 1995). Yield models are developed to automate the identification of out of control manufacturing conditions. This is used as feedback to improve and confirm top quality operation.

Last and Kandel (2001) applied the Info-Fuzzy Network (IFN) methodology of data mining and knowledge discovery to WIP (Work-in-Process) data obtained from a semiconductor plant. In this methodology, the recorded features of each manufacturing batch include its design parameters, process tracking data, line yield, etc.

Electronic product assembly lines face a quality problem with printed-circuit boards where assemblies rather than components fail the quality test (Kusiak, 2006). Classification methods can be used to predict circumstances under which an individual product might fail. Kusiak and Kurasek (2001) presents a an industrial case study in which data mining has been applied to solve a quality engineering problem in electronics assembly. During the assembly process, solder balls occur underneath some components of printed circuit boards. The goal is to identify the cause of solder defects in a circuit board using a rough set approach over the decision tree approach.

Braha and Shmilovici (2003) presented an application of decision tree induction to lithographic process. The work suggests that decision tree induction may be particularly useful when data is multidimensional, and the various process parameters and machinery exhibit highly complex interactions. Wu et al. (2004) suggested an intelligent CIM (computer integrated manufacturing) system which uses decision tree induction algorithm. The proposed system has been implemented in a semiconductor packaging factory and an improved yield is reported. Jothishankar et al. (2004) used data mining techniques for improving the soldering process of printed circuit boards. More specifically they looked for the reasons for a specific defect in which a chip component that has partially or completely lifted off one end of the surface of the pad.

Fountain et al. (2003) describe a data mining application to the problem of die-level functional tests (DLFT) in integrated circuit manufacturing. They

describe a decision-theoretic approach to DLFT in which historical test data is mined to create a probabilistic model of patterns of die failure. This model is combined with greedy value-of-information computations to decide in real time which die to test next and when to stop testing.

Braha and Shmilovici (2002) presented an application of refinement of a new dry cleaning technology that utilizes a laser beam for the removal of micro-contaminants which have a negative impact on the process yield. They examine two classification methods (decision tree induction and neural networks) showing that both of them can significantly improve the process. Gardner and Bieker (2000) suggested a combination of self-organizing neural networks and rule induction in order to identify the critical poor yield factors from normally collected wafer manufacturing data from Motorola manufacturing plant, showing that the proposed method efficiently identify lower yielding factor and in a much quicker way. Kim and Lee (1997) used explicit and implicit methods to predict nonlinear chaotic behavior of manufacturing process. They combined statistical procedures, neural networks and case based reasoning for prediction of manufacturing processed of optic fibers adulterated by various patterns of noise.

FUTURE TRENDS

There are several trends in the field of using data mining in manufacturing systems including:

- Preliminary applications have used existing data mining techniques to solve manufacturing problems. However data accumulated in manufacturing plants have unique characteristics, such as unbalanced distribution of the target attribute, and a small training set relative to the number of input features. Thus, data mining methods should be adapted accordantly.
- It seems that it is important to integrate the mining of manufacturing process with other entities such as equipment failure events.
- The creation of a unified knowledge discovery framework for manufacturing process.
- Developing a meta-data mining approach, in which knowledge about the organization will be used to improve the effectiveness of data mining methods.
- Developing a distributed data mining framework by sharing patterns among organizations while preserving privacy.

CONCLUSION

In this chapter, we surveyed data mining methods and their applications in intelligent manufacturing systems. Analysis of past performance of production systems is necessary in any manufacturing plan in order to improve manufacturing quality or throughput. The difficulty is in finding pertinent information as in the manufacturing databases. Data mining tools can be very beneficial for discovering interesting and useful patterns in complicated manufacturing processes. These patterns can be used, for example, to improve quality. We review several applications in the field especially in the electronic industry. We also analyzed how ensemble methods and decomposition methods can be used to improve prediction accuracy in this case. Moreover we show how association rules can be used in manufacturing applications. Finally future trends in this field have been presented.

KEY TERMS

Association Rules: Techniques that find in a database conjunctive implication rules of the form ``X and Y implies A and B''.

CIM (Computer Integrated Manufacturing): The complete automation of a manufacturing plant in which all processes are functioning under computer control.

Classifier: A structured model that maps unlabeled instances to finite set of classes.

Clustering: The process of grouping data instances into subsets in such a manner that similar instances are grouped together into the same cluster, while different instances belong to different clusters.

Ensemble of Classifiers: Combining a set of classifiers in order to obtain a better composite global

classifier, with more accurate and reliable estimates or decisions than can be obtained from using a single classifier.

Induction Algorithm: An algorithm that takes as input a certain set of instances and produces a model that generalizes these instances.

Intelligent Manufacturing Systems: A manufacturing system that aims to satisfy customer needs at the most efficient level for the lowest possible cost by using AI methods.

Quality Control: A set of measures taken to ensure that defective products or services are not produced, and that the design meets performance requirements.

Data Mining for Internationalization

Luciana Dalla Valle
University of Milan, Italy

INTRODUCTION

The term "internationalization" refers to the process of international expansion of firms realized through different mechanisms such as export, strategic alliances and foreign direct investments. The process of internationalization has recently received increasing attention mainly because it is at the very heart of the globalization phenomenon. Through internationalization firms strive to improve their profitability, coming across new opportunities but also facing new risks.

Research in this field mainly focuses on the determinants of a firms' performance, in order to identify the best entry mode for a foreign market, the most promising locations and the international factors that explain an international firms' performance. In this way, scholars try to identify the best combination of firms' resources and location in order to maximize profit and control for risks (for a review of the studies on the impact of internationalization on performance see Contractor et al., 2003).

The opportunity to use large databases on firms' international expansion has raised the interesting question concerning the main data mining tools that can be applied in order to define the best possible internationalization strategies.

The aim of this paper is to discuss the most important statistical techniques that have been implemented to show the relationship among firm performance and its determinants.

These methods belong to the family of multivariate statistical methods and can be grouped into *Regression Models* and *Causal Models*. The former are more common and easy to interpret, but they can only describe direct relationships among variables; the latter have been used less frequently, but their complexity allows us to identify important causal structures, that otherwise would be hidden.

BACKGROUND

We now describe the most basic approaches used for internationalization. Our aim is to give an overview of the statistical models that are most frequently applied in International Finance papers, for their easy implementation and the straightforwardness of their result interpretation. In this paragraph we also introduce the notation that will be used in the following sections.

In the class of *Regression Models*, the most common technique used to study internationalization is the *Multiple Linear Regression*. It is used to model the relationship between a continuous response and two or more linear predictors.

Suppose we wish to consider a database, with N observations, representing the enterprises, the response variable (firm performance) and the covariates (firm characteristics). If we name the dependent variable Y_i, with $i = 1, \ldots, N$, this is a linear function of H predictors $x_1, \ldots, x_H$, taking values $x_{i1}, \ldots, x_{iH}$, for the i–th unit. Therefore, we can express our model in the following way:

$$y_i = \beta_1 x_{i1} + \beta_2 x_{i2} + \ldots + \beta_H x_{iH} + \varepsilon_i, \qquad (1)$$

where $\beta_1, \ldots, \beta_i$ are the regression coefficients and ε_i is the error term, that we assume to be normally distributed with mean zero and variance σ^2 (Kutner et al., 2004).

Hitt, Hoskisson and Kim (1997), for example, applied the technique shown above to understand the influence of firm performance on international diversification, allowing not only for linear, but also for curvilinear and interaction effects for the covariates.

When our dependent variable is discrete, the most appropriate regression model is the *Logistic Regression* (Giudici, 2003).

The simplest case of Logistic Regression is when the response variable Y_i is binary, so that it assumes only the two values *0* and *1*, with probability p_i and $1\text{-}p_i$, respectively.

We can describe the Logistic Regression model for the *i*-th unit of interest by the logit of the probability p_i, linear function of the predictors:

$$\log it(p_i) = \log \frac{p_i}{1-p_i} = \eta_i = \underline{x}_i' \underline{\beta}, \qquad (2)$$

where $\underline{x}_i$ is the vector of covariates and $\underline{\beta}$ is the vector of regression coefficients.

For more details about Logit models the reader can consult, for example, Mardia, Kent and Bibby (1979) or Cramer (2003).

For an interesting application, the reader can consult the study by Beamish and Ruihua (2002), concerning the declining profitability from foreign direct investments by multinational enterprises in China. In their paper the authors used subsidiaries' performance as the response variable, with the value "1" indicating "profitable" and value "0" denoting "break-even" or "loss" firms. Beamish and Ruihua show that the most important determinants of profitability are subsidiaries-specific features, rather than macro-level factors.

Concerning *Causal models*, *Path Analysis* is one of the first techniques introduced in the internationalization field.

Path Analysis is an extension of the regression model, where causal links are allowed between the variables. Therefore, variables can be at the same time both dependent and independent (see Dillon and Goldstein, 1984 or Loehlin, 1998).

This approach could be useful in an analysis of enterprise internationalization, since, through a flexible covariate modeling, it shows even indirect links between the performance determinants.

Path Analysis distinguishes variables into two different types: *exogenous* and *endogenous*. The former are always independent and they do not have explicit causes; the latter can be dependent as well as independent and, since they are stochastic, they are characterized by a disturbance term as an uncertainty indicator.

The association between a couple of endogenous variables caused by an exogenous one is defined as *spurious correlation*. This particular correlation is depicted by an arrow in a circle-and-arrow figure, called a *path diagram* (see figure 1).

The object of Path Analysis is to find the best causal model through a comparison between the regression weights predicted by some models and the observed correlation matrix for the variables. Those regression weights are called *path coefficients* and they show the direct effect of an independent variable on a dependent variable in the path model.

For more details about Path Analysis, see, for example, Bollen (1989) or Deshpande and Zaltman (1982).

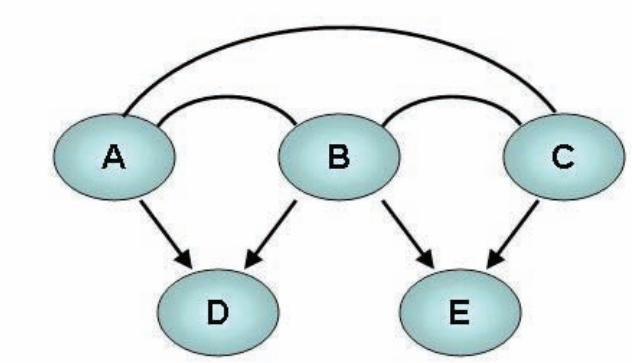
MAIN FOCUS

In this section we analyze the statistical methodologies most recently used for internationalization, with particular attention to the applications.

Regression Models

Logistic Regression is very useful when we deal with a binary response variable, but when we consider a

Figure 1: The path diagram. A, B and C are correlated exogenous variables; D and E are endogenous variables caused by A, B and C.



dependent variable with more than two response categories we need to consider a different type of model: the *Multinomial Logit Model* (see, for example, Hensher et al., 2005 or Mc Fadden, 1974).

Suppose to have a random variable Y_i, as the response variable, which takes values indexed by *1, 2, …, J*. Then,

$$p_{ij} = \Pr\{Y_i = j\} \qquad (3)$$

denotes the probability that the *i*-th response falls in the *j*-th category. Since the categories are mutually exclusive and exhaustive, we have only *J-1* parameters, because

$$\sum_{j=1}^{J} p_{ij} = 1. \qquad (4)$$

Typically, in the Multinomial Logit Model, the most common approach consists of nominating one of the categories of the response variable as the baseline (normally the last category), calculating the logit for all the other categories relative to the baseline and finally setting the logit as a linear function of the predictors:

$$\eta_{ij} = \log \frac{p_{ij}}{p_{iJ}} = \underline{x}_i \, ' \, \underline{\beta}_j, \qquad (5)$$

where $\underline{\beta}_j$ is the vector of regression coefficients, for *j = 1, …, J-1*.

If our aim is to understand the choice behavior of individuals, we introduce an extension of the Multinomial Logit model, where the explanatory variables may include attributes of the alternative behaviors as well as characteristics of the individuals: the *Conditional Logit Model*, proposed by Mc Fadden (1974).

Consider the random variable Y_i, representing the choice among *J* alternative behaviors. Suppose that U_{ij} represents the *i*-th individual's utility resulting from the *j*-th alternative, so that

$$U_{ij} = \eta_{ij} + \varepsilon_{ij}, \qquad (6)$$

where η_{ij} is the systematic component and ε_{ij} is the random component (for more details, see Greene (1997)). This disturbance term reflects the unique advantages of alternative *j* to individual *i*. It differs across alternatives for any one individual, and across individuals for any alternative.

Assuming that individuals act in a rational way, they tend to maximize their utility. Thus, the probability that subject *i* will choose alternative *j* is given by

$$p_{ij} = \Pr\{Y_i = j\} = \Pr\{U_{ij} > U_{ik}, k \neq j\}. \qquad (7)$$

It can be shown that if the random components ε_{ij} are distributed according to a Type I extreme value distribution, then we can express these probabilities as:

$$p_{ij} = \frac{\exp\{\eta_{ij}\}}{\sum_{k=1}^{J} \exp\{\eta_{ij}\}}. \qquad (8)$$

The previous equation can be obtained according to the *axiom of independence from irrelevant alternatives*, requiring that the odds of choosing alternative *j* over alternative *k* should be independent of the choice set for all pairs *j, k*. However, this requirement is not always reasonable for all the choices.

The main difference between the Conditional and the Multinomial Logit model is the fact that in the latter the expected utilities η_{ij} are a linear function of the individuals' characteristics. Instead, in the *Conditional Logit Model* the expected utilities are explained in terms of the alternative characteristics, rather than the individual attributes.

In International Business studies Conditional Logit models are applied when the main objective is to determine which factors are behind the multinational enterprises' location choices. Chang and Park (2005), for example, analyze a database of Korean firms investing in China. In their paper U_{ij} represents the utility a firm *i* derives from opening a manufacturing operation in region *j*. In particular, a firm decides to locate in region *j* if U_{ij} is the maximum among all the utilities. The model's response variable is expressed in terms of the random variable Y_i that indicates a choice made by firm *i*, assuming independence of irrelevant alternatives (the relative probability of choosing two alternatives does not depend on the availability of other alternatives).

The Conditional Logit model is also applied by Ford and Strange (1999) in their paper about Japanese firms locating affiliates in Western Europe. Each Japanese investor chooses to locate its affiliate *i* in country *j* if the expected profit (utility) is maximized. Since the random variable Y_i indicates the location chosen for

affiliate *i*, then the probability of choosing a specific country *j* depends upon the attributes of that country relative to the attributes of the other seven countries in the choice set.

Another interesting extension of the Logit model is the *Hierarchical Logit model,* which defines a hierarchy of nested comparisons between two subsets of responses, using a logit model for each comparison (see, for example, Louviere et al., 2000 or Train, 2003). This approach is particularly appropriate if we assume that individuals make decisions on a sequential basis.

An application of the Nested Logit Model is described in the paper by Basile, Castellani and Zanfei (2003). The database used is about 5761 foreign subsidiaries established in 55 regions in 8 EU countries. The authors' aim is to understand the determinants of multinational firms' location choices not only in European countries, but also in the regions within each country. The idea is to group alternatives (regions) into nests (countries). Let the *J* regions being grouped into *K* countries, then the probability of choosing region *j* is calculated as the product of two probabilities: the probability of choosing region *j* conditional on having chosen country *k* times the marginal probability of choosing country *k*. The final model expresses firm's utility in terms of country characteristics and of regional characteristics, which eventually vary across firms.

Causal Models

When the variables in the model are latent variables measured by multiple observed indicators, Path Analysis is termed *Structural Equation Modeling* (*SEM*). We can define such models according to Goldberger (1973): "by 'structural models' I refer to stochastic models in which each equation represents a causal link rather than an empirical association". Therefore this technique can be seen as an extension of Path Analysis (since each variable has not only a single but multiple indicators) and of Factor Analysis (since it permits direct effects connecting those variables).

Variables in SEM are grouped into observed and unobserved. The former are also called *indicators* and are used to measure the unobserved variables (*factors* or latent variables), that could be exogenous as well as endogenous (Mueller, 1996).

To determine the causal structure among the variables, first of all the null model (without direct effects connecting factors) is built. Then, this model is tested to evaluate the significance of the latent variables. Finally, more complex models are compared to the null model and are accepted or rejected, according to a goodness of fit measure. Once the final model is determined, the *direct structural standardized coefficients* are estimated via maximum likelihood estimation or generalized least squares. These coefficients are used to compare direct effects on an endogenous variable.

The factor *loadings* are the weights of the indicator variables on the respective factor and they can be used to interpret the meaning of the latent variable (Bollen, 1989).

The database analyzed by Goerzen and Beamish (2003) is about a sample of 580 large Japanese multinational enterprises. The authors' purpose is to discover the relationship between the endogenous latent variable representing firm's economic performance and the two independent exogenous latent variables "international asset dispersion (IAD)" and "country environment diversity (CED)", through the observed variables (firm-specific, country-specific and control variables). The endogenous variable is measured by three indicators: "Jensen's alpha", "Sharpe's measure" and "Market-to-book ratio". The exogenous latent variable IAD is measured by the "number of countries", the "asset dispersion entropy score" and the "number of foreign subsidiaries". Finally, the associated indicators of CED are the "global competitiveness entropy score", the "economic freedom entropy score", the "political constraint entropy score" and the "cultural diversity entropy score". The equations describing the model for each firm are:

$$\begin{cases} \eta = \gamma_1 \xi_1 + \gamma_2 \xi_2 + \gamma_3 \xi_1 \xi_2 + \varsigma \\ x_i = \lambda_i^x \xi_1 + \delta_i & i = 1,2,3 \\ x_i = \lambda_i^x \xi_2 + \delta_i & i = 4,5,6,7 \\ x_i = \lambda_i^x \xi_1 \xi_2 + \delta_i & i = 8,9,\ldots,19 \\ y_j = \lambda_j^y \eta + \varepsilon_j & j = 1,2,3 \end{cases}$$

where η denotes the economic performance, ξ_1 denotes the international asset dispersion, ξ_2 denotes the country environment diversity, ς is the error term and γ_1, γ_2, γ_3 are the parameters associated to the independent variables. The equation is nonlinear, for the presence of the interaction term $\xi_1 \xi_2$ between the latent variables. Results show a positive relationship between economic performance and international asset dispersion, but country environment diversity is negatively associated

with performance, with a positive interaction between the two independent latent variables.

FUTURE TRENDS

The main future trend for the analysis of internationalization is the exploitation and development of more complex statistical techniques. Bayesian methods represent a natural evolution in this field. Hansen, Perry and Reese (2004) propose a Bayesian Hierarchical methodology to examine the relationship between administrative decisions and economic performance over time, which have the advantage of accounting for individual firm differences. The performance parameter is expressed as a function of the firm, the industry in which the firm operates and the set of administrative decisions (actions) made by the firm. More formally, let Y_{it} indicate the economic performance for company i ($i=1,...,175$) in year t ($t=1,...,4$), the

$$Y_{it} \approx N(\mu_{it} \sigma_t^2) \qquad (10)$$

meaning that Y_{it} is normally distributed, with mean μ_{it} and variance σ_t^2.

If X_{itk} ($k=1,...,10$) denotes the actions, the model is:

$$\mu_{it} = \eta_{it} + \sum_{k=1}^{10} \beta_{tk} X_{itk} \qquad (11)$$

where each firm is given its own effect.

A *prior* distribution must be specified for the entire set of parameters and the joint *posterior* distribution is then estimated with Markov Chain Monte Carlo (MCMC).

In the applied Bayesian model, the firm effect on economic performance can be isolated and indicates if the focal firm possesses some competitive advantage that will allow that firm to achieve economic performance greater than what would be predicted by the actions taken by that firm.

The advantages of Bayesian models are also underlined by Hahn and Doh (2006), showing that these methodologies are highly relevant not only for strategic problems, but also to its extensions in the areas of dynamic capabilities and co-evolution of industries and firms. The advantages of Bayesian methods include the full estimation of the distribution of individual effect terms, a straightforward estimation of predictive results even in complex models and exact distributional results under skew and small samples.

Another expected future trend could be represented by Bayesian Networks, which have the advantages of the Bayesian Models and belong also to the class of causal models (for further details about Bayesian Networks, see Bernardo and Smith, 1994).

CONCLUSION

In the previous sections we have seen how we can apply statistical techniques such as regression and causal models to understand the determinants of firm performance.

Regression methods are easier to implement, since they categorize variables simply into dependent and independent and they do not allow causal links among them. On the other hand, causal methods are more complex, since the presence of causal links allows us to model more flexible relationships among exogenous and endogenous variables.

The common objective of these models is to show how the dependent variable is related to the covariates, but while regression aims to reduce the number of independent variables influencing the dependent variable, causal models aim to represent correlations in the most accurate way. Given the high level of complexity of the processes of firms' international expansion, these statistical techniques seem well-suited to understanding and explaining the complex web of factors that impact on a firms' international performance. Therefore, with causal models we do not only implement an explorative analysis, which characterize regression methods, but we can also show causal ties, distinguishing them from the spurious ones.

International Business represents a new field for Data Mining researchers, which so far focused their attention on classical methodologies. But there is space for innovative applications, as for example Bayesian models, to improve the results in this area.

KEY TERMS

Exogenous and Endogenous Variables: Exogenous variables are always independent variables without a causal antecedent; endogenous variables can be mediating variables (causes of other variables) or dependent variables.

Indicators: Observed variables, which determine latent variables in SEM.

Logistic Regression: Statistical method, belonging to the family of generalized linear models, whose principal aim is to model the link between a discrete dependent variable and some independent variables.

Multiple Regression: Statistical model that estimates the conditional expected value of one variable y given the values of some other variables x_i. The variable of interest, y, is conventionally called the *dependent variable* and the other variables are called the *independent variables*.

Path Analysis: Extension of the regression model belonging to the family of causal models. The most important characteristic of this technique is the presence of causal links among the variables.

Spurious Correlation: Association between two endogenous variables caused by an exogenous variable.

Structural Equation Modeling: Causal model that combines the characteristics of factor and path analysis, since it allows the presence of causal ties and latent variables.

Data Mining for Lifetime Value Estimation

Silvia Figini
University of Pavia, Italy

INTRODUCTION

Customer lifetime value (LTV, see e.g. Bauer et al. 2005 and Rosset et al. 2003), which measures the profit generating potential, or value, of a customer, is increasingly being considered a touchstone for administering the CRM (Customer relationship management) process. This in order to provide attractive benefits and retain high-value customers, while maximizing profits from a business standpoint. Robust and accurate techniques for modelling LTV are essential in order to facilitate CRM via LTV. A customer LTV model needs to be explained and understood to a large degree before it can be adopted to facilitate CRM. LTV is usually considered to be composed of two independent components: tenure and value. Though modelling the value (or equivalently, profit) component of LTV, (which takes into account revenue, fixed and variable costs), is a challenge in itself, our experience has revealed that finance departments, to a large degree, well manage this aspect. Therefore, in this paper, our focus will mainly be on modelling tenure rather than value.

BACKGROUND

A variety of statistical techniques arising from medical survival analysis can be applied to tenure modelling (i.e. semi-parametric predictive models, proportional hazard models, see e.g. Cox 1972). We look at tenure prediction using classical survival analysis and compare it with data mining techniques that use decision tree and logistic regression. In our business problem the survival analysis approach performs better with respect to a classical data mining predictive model for churn reduction (e.g. based on regression or tree models). In fact, the key challenge of LTV prediction is the production of segment-specific estimated tenures, for each customer with a given service supplier, based on the usage, revenue, and sales profiles contained in company databases. The tenure prediction models we have developed generate, for a given customer i, a hazard curve or a hazard function, that indicates the probability $h_i(t)$ of cancellation at a given time t in the future. A hazard curve can be converted to a survival curve or to a survival function which plots the probability $S_i(t)$ of "survival" (non-cancellation) at any time t, given that customer i was "alive" (active) at time (t-1), i.e., $S_i(t)=S_i(t-1) \times [1-h_i(t)]$ with $S_i(1)=1$. Once a survival curve for a customer is available, LTV for that specific customer i can be computed as:

$$\text{LTV} = \sum_{t=1}^{T} S_i(t) \times v_i(t), \qquad (1)$$

where $v_i(t)$ is the expected value of customer i at time t and T is the maximum time period under consideration. The approach to LTV (see e.g. Berger et. Al. 1998) computation provides customer specific estimates (as opposed to average estimates) of the total expected future (as opposed to past) profit based on customer behaviour and usage patterns. In the realm of CRM, modelling customer LTV has a wide range of applications including:

- Evaluating the returns of the investments in special offers and services.
- Targeting and managing unprofitable customers.
- Designing marketing campaigns and promotional efforts
- Sizing and planning for future market opportunities

Some of these applications would use a single LTV score computed for every customer. Other applications require a separation of the tenure and value component for effective implementation, while even others would use either the tenure or value and ignore the other component. In almost all cases, business analysts who use LTV are most comfortable when the predicted LTV score and/or hazard can be explained in intuitive terms.

Our case study concerns a media service company. The main objective of such a company is to maintain

its customers, in an increasingly competitive market; and to evaluate the lifetime value of such customers, to carefully design appropriate marketing actions. Currently the company uses a data mining model that gives, for each customer, a probability of churn (score).

The churn model used in the company to predict churn is currently a classification tree (see e.g. Giudici 2003). Tree models can be defined as a recursive procedure, through which a set of n statistical units is progressively divided in groups, according to a divisive rule which aims to maximize a homogeneity or purity measure of the response variable in each of the obtained groups. Tree models may show problems in time-dependent applications, such as churn applications.

MAIN FOCUS

The use of new methods is necessary to obtain a predictive tool which is able to consider the fact that churn data is ordered in calendar time. To summarize, we can sum up at least four main weaknesses of traditional models in our set-up, which are all related to time-dependence:

- excessive influence of the contract deadline date
- redundancies of information
- presence of fragmentary information, depending on the measurement time
- excessive weight of the different temporal perspectives

The previous points explain why we decided to look for a novel and different methodology to predict churn.

Future Survival Analysis Models to Estimate Churn

We now turn our attention towards the application of methodologies aimed at modelling survival risks (see e.g. Klein and Moeschberger 1997). In our case study the risk concerns the value that derives from the loss of a customer. The objective is to determine which combination of covariates affect the risk function, studying specifically the characteristics and the relation with the probability of survival for every customer.

Survival analysis (see e.g. Singer and Willet 2003) is concerned with studying the time between entry to a study and a subsequent event (churn). All of the standard approaches to survival analysis are probabilistic or stochastic. That is, the times at which events occur are assumed to be realizations of some random processes. It follows that T, the event time for some particular individual, is a random variable having a probability distribution. A useful, model-free approach for all random variables is nonparametric (see e.g. Hougaard 1995), that is, using the cumulative distribution function. The cumulative distribution function of a variable T, denoted by F(t), is a function that tell us the probability that the variable will be less than or equal to any value t that we choose. Thus, $F(t) = P\{T \leq t\}$. If we know the value of F for every value of t, then we know all there is to know about the distribution of T. In survival analysis it is more common to work with a closely related function called the survivor function defined as $S(t) = P\{T > t\} = 1 - F(t)$. If the event of interest is a death (or, equivalently, a churn) the survivor function gives the probability of surviving beyond t. Because S is a probability we know that it is bounded by 0 and 1 and because T cannot be negative, we know that S(0) =1. Finally, as t gets larger, S never increases. Often the objective is to compare survivor functions for different subgroups in a sample (clusters, regions…). If the survivor function for one group is always higher than the survivor function for another group, then the first group clearly lives longer than the second group.

When variables are continuous, another common way of describing their probability distributions is the probability density function. This function is defined as:

$$f(t) = \frac{dF(t)}{dt} = -\frac{dS(t)}{dt}, \qquad (2)$$

that is, the probability density function is just the derivative or slope of the cumulative distribution function. For continuous survival data, the hazard function is actually more popular than the probability density function as a way of describing distributions. The hazard function (see e.g. Allison 1995) is defined as:

$$h(t) = \lim \varepsilon t \to 0 \frac{\Pr\{t \leq T < t + \varepsilon t \mid T \geq t\}}{\varepsilon t}, \qquad (3)$$

The aim of the definition is to quantify the instantaneous risk that an event will occur at time t. Since time

is continuous, the probability that an event will occur at exactly time t is necessarily 0. But we can talk about the probability that an event occurs in the small interval between t and t+εt and we also want to make this probability conditional on the individual surviving to time t. For this formulation the hazard function is sometimes described as a conditional density and, when events are repeatable, the hazard function is often referred to as the intensity function. The survival function, the probability density function and the hazard function are equivalent ways of describing a continuous probability distribution. Another formula expresses the hazard in terms of the probability density function:

$$h(t) = \frac{f(t)}{S(t)}, \qquad (4)$$

and together equations (4) and (2) imply that

$$h(t) = -\frac{d}{dt}\log S(t) \quad (5),$$

Integrating both sides of equation (5) gives an expression for the survival function in terms of the hazard function:

$$S(t) = \exp\left(-\int_0^t h(u)du\right), \qquad (6)$$

With regard to numerical magnitude, the hazard is a dimensional quantity that has the form: number of events per interval of time. The database available for our analysis contain information that can affect the distribution of the event time, as the demographic variables, variables about the contract, the payment, the contacts and geo-marketing.

We remind the readers that the target variable has a temporal nature and, for this reason, it is preferable to build predictive models through survival analysis.

The actual advantages of using a survival analysis approach with respect to a traditional one can be reassumed in following:

- to correctly align the customers regarding their cycle of life;
- to analyze the real behaviour of the customers churn, without having to distinguish between EXIT and SUSPENSION payers.

In order to build a survival analysis model, we have constructed two variables: one variable of status (distinguish between active and non active customers) and one of duration (indicator of customer seniority). The first step in the analysis of survival data (for the descriptive study) consists in a plot of the survival function and the risk. The survival function is estimated through the methodology of Kaplan Meier (see e.g. Kaplan Meier 1958). Suppose there are K distinct event times, $t_1 < t_2 < \ldots < t_k$. At each time t_j there are n_j individuals who are said to be at risk of an event. At risk means they have not experienced an event not have they been censored prior to time t_j. If any cases are censored at exactly t_j, there are also considered to be at risk at t_j. Let d_j be the number of individuals who die at time t_j. The KM estimator is defined as:

$$\hat{S}(t) = \prod_{j:t_j \le t} [1 - \frac{d_j}{n_j}] \ (5.7) \text{ for } t_1 \le t \le t_k, \qquad (7)$$

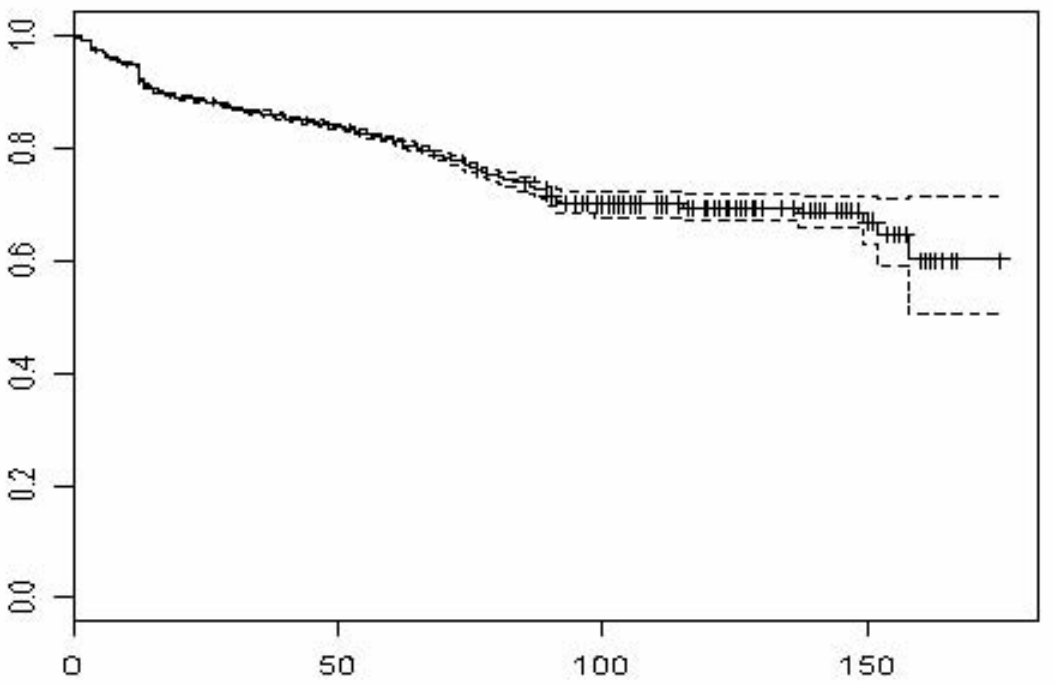
This formula says that, for a given time t, take all the event times that are less than or equal to t. For each of those event times, compute the quantity in brackets, which can be interpreted as the conditional probability of surviving to time t_{j+1}, given that one has survived to time t_j. Then multiply all of these survival probabilities together.

We now consider our application to the company data. Figure 1 shows the survival function for the whole customer database. On the x-axis there is the survival time (in months) and in the vertical axis we can see the probability of survival.

From Figure 1 note that the survival function has varying slopes, corresponding to different periods. When the curve decreases rapidly we have time periods with high churn rates; when the curve decreases softly we have periods of "loyalty". We remark that the final jump is due to a distortion caused by a few data, in the tail of the lifecycle distribution.

A very useful information, in business terms, is the calculation of the life expectancy of the customers. This can be obtained as a sum over all observed event times: $\hat{S}(t_{(j)})(t_{(j)} - t_{(j-1)})$, where $\hat{S}(t_{(j)})$ is the estimate of the survival function at the j-th event time, obtained using Kaplan-Meier method, and *t* is a duration indicator. ($t_{(0)}$ is by assumption equal to 0). We remark that life expectancy tends to be underestimated if most observed event types are censored (i.e., no more observable).

Figure 1. Descriptive survival function



Survival Predictive Model

We have chosen to implement Cox's model (see e.g. Cox 1972). Cox proposed a model that is a proportional hazards model and also he proposed a new estimation method that was later named partial likelihood or more accurately, maximum partial likelihood. We will start with the basic model that does not include time-dependent covariate or non proportional hazards. The model is usually written as:

$$h(t_{ij}) = h_0(t_j)\exp[\beta_1 X_{1ij} + b_2 X_{2ij} + ... + \beta_P X_{Pij}], \quad (8)$$

Equation 8 says that the hazard for individual i at time t is the product of two factors: a baseline hazard function that is left unspecified, and a linear combination of a set of p fixed covariates, which is then exponentiated. The baseline function can be regarded as the hazard function for an individual whose covariates all have values 0. The model is called proportional hazard model because the hazard for any individual is a fixed proportion of the hazard for any other individual. To see this, take the ratio of the hazards for two individuals i and j:

$$\frac{h_i(t)}{h_j(t)} = \exp\{\ \beta_1 (x_{i1} - x_{j1}) + \ldots + \beta_p (x_{ip} - x_{jp})\ \}, \quad (9)$$

What is important about this equation is that the baseline cancels out of the numerator and denominator. As a result, the ratio of the hazards is constant over time.

In Cox model building the objective is to identify the variables that are more associated with the churn event. This implies that a model selection exercise, aimed at choosing the statistical model that best fits the data, is to be carried out. The statistical literature presents many references for model selection (see e.g. Giudici 2003, Anderson 1991).

Most models are based on the comparison of model scores. The main score functions to evaluate models are related to the Kullback-Leibler principle (see e.g. Spiegelhalter et al. 2006).

This occurs for criteria that penalize for model complexity, such as AIC (Akaike Information Criterion, see e.g. Akaike et al., 1974) and BIC (Bayesian Information Criterion). In formal terms the AIC criterion is defined by the following equation:

$$AIC = -2\log L(\hat{\vartheta}; x_1,...,x_n) + 2q, \quad (10)$$

where $\log L(\hat{\vartheta}; x_1,...,x_n)$ is the logarithm of the likelihood function, calculated in the maximum likelihood parameter estimate and q is the number of parameters of the model. Notice that the AIC score essentially penalises the log-likelihood score with a term that increases linearly with model complexity.

The AIC criterion is based on the implicit assumption that q remains constant when the size of the sample increases. However this assumption is not always valid and therefore the AIC criterion does not lead to a consistent estimate of the dimension of the unknown model.

An alternative, and consistent, scoring function is the BIC criterion, also called SBC. It was formulated by Schwarz (1978) and is defined by the following expression:

$$BIC = -2\log L(\hat{\vartheta}; x_1,...,x_n) + q\log(n), \quad (11)$$

As is easily seen the BIC differs from the AIC (see e.g. Burnham et. al., 2004) only in the second part which now also depends on the sample size n. To conclude, the scoring function criteria for selecting models which we have examined are easy to calculate and lead to a total ordering of the models.

In our case we have compared all models and chose the one with the lowest value of AIC and BIC. The obtained model presents a good fit, as shown in Table 1.

From Table 1 note that both AIC and BIC present lower values with the inclusion of covariates: this means that adding covariates lead to a better fit (see e.g. Spitzner, 2006).

The result of the procedure is a set of about twenty explanatory variables. Such variables can be grouped in three main categories, according to the sign of their association with the churn rate, represented by the hazard ratio:

Table 1. Goodness of fit statistics

Model Fit Statistics		
Criterion	Without Covariates	With Covariates
-2 LOG L	1124678.6	943660.62
AIC	1124678.6	943788.62
BIC	1124678.6	944347.95

- variables that show a positive association (e.g. related to the wealth of the geographic region, the quality of the call center service, the sales channel)
- variables that show a negative association (e.g. number of technical problems, cost of service bought, status of payment method)
- variables that have no association (e.g. equipment rental cost, age of customer, number of family components).

More precisely, to calculate the previous associations we have considered the values of the hazard ratio under different covariate values. For example, for the variables indicating number of technical problems we compare the hazard function for those that have called at least once with those that have not made such calls. As the resulting ratio turns out to be equal to 0.849, the risk of becoming churner is lower for the "callers" than for the "non callers".

FUTURE TRENDS

Our results show that survival analysis modelling is a much powerful tool for lifetime value analysis and, consequently, for the actual planning of a range of marketing actions that impact on both perspective and actual customers. We believe that survival analysis is a very promising tool in the area, and that further research is indeed needed, both in applied and methodological terms. From an applied viewpoint, directions to be further investigated concern the application of

the methodology to a wider range of companies (we have studies in progress in the banking sector). From a methodological viewpoint further research is needed on the robustification of Cox model which, being semi-parametric and highly structured, may lead to variable results.

CONCLUSION

In the paper we have presented a comparison between classical and novel data mining techniques to predict rates of churn of customers. Our conclusions show that the novel approach we have proposed, based on survival analysis modelling, leads to more robust conclusions. In particular, although the lift of the best models are substantially similar, survival analysis modelling gives more valuable information, such as a whole predicted survival function, rather than a single predicted survival probability.

KEY TERMS

Customer Lifetime Value: (also variously referred to as lifetime customer value or just lifetime value, and abbreviated CLV, LCV, or LTV) is a marketing metric that projects the value of a customer over the entire history of that customer's relationship with a company.

Customer Relationship Management (CRM): includes the methodologies, technology and capabilities that help an enterprise manage customer relationships. The general purpose of CRM is to enable organizations to better manage their customers through the introduction of reliable systems, processes and procedures.

Geomarketing: A set of scientific methods, which is capable of collecting and working out data, allowing the evaluation of the customer's impact before opening a new sales point, the exact definition of the interested territory and the identification of ideal users for the distribution of advertising material based on specified

times and distances, avoiding superimpositions with neighboring user basins.

Hazard Risk: The hazard rate (the term was first used by Barlow, 1963) is defined as the probability per time unit that a case that has survived to the beginning of the respective interval will fail in that interval.

Robustification: Robust statistics have recently emerged as a family of theories and techniques for estimating the parameters of a parametric model while dealing with deviations from idealized assumptions. There are a set of methods to improve robustification in statistics, as: M-estimator, Least Median of Squares Estimator, W-estimators.

Data Mining for Model Identification

Diego Liberati
Italian National Research Council, Italy

INTRODUCTION

In many fields of research, as well as in everyday life, it often turns out that one has to face a huge amount of data, without an immediate grasp of an underlying simple structure, often existing. A typical example is the growing field of bio-informatics, where new technologies, like the so-called Micro-arrays, provide thousands of gene expressions data on a single cell in a simple and fast integrated way. On the other hand, the everyday consumer is involved in a process not so different from a logical point of view, when the data associated to his fidelity badge contribute to the large data base of many customers, whose underlying consuming trends are of interest to the distribution market.

After collecting so many variables (say gene expressions, or goods) for so many records (say patients, or customers), possibly with the help of wrapping or warehousing approaches, in order to mediate among different repositories, the problem arise of reconstructing a synthetic mathematical model capturing the most important relations between variables. To this purpose, two critical problems must be solved:

1 To select the most salient variables, in order to reduce the dimensionality of the problem, thus simplifying the understanding of the solution
2 To extract underlying rules implying conjunctions and/or disjunctions between such variables, in order to have a first idea of their even non linear relations, as a first step to design a representative model, whose variables will be the selected ones

When the candidate variables are selected, a mathematical model of the dynamics of the underlying generating framework is still to be produced. A first hypothesis of linearity may be investigated, usually being only a very rough approximation when the values of the variables are not close to the functioning point around which the linear approximation is computed.

On the other hand, to build a non linear model is far from being easy: the structure of the non linearity needs to be a priori known, which is not usually the case. A typical approach consists in exploiting a priori knowledge to define a tentative structure, and then to refine and modify it on the training subset of data, finally retaining the structure that best fits a cross-validation on the testing subset of data. The problem is even more complex when the collected data exhibit hybrid dynamics, i.e. their evolution in time is a sequence of smooth behaviors and abrupt changes.

BACKGROUND

Such tasks may be sequentially accomplished with various degree of success in a variety of ways. Principal components (O'Connel 1974) orders the variables from the most salient to the least one, but only under a linear framework (Liberati et al., 1992a).

Partial least squares (Dijkstra 1983) allow to extend to non linear models, provided that one has some a priori information on the structure of the involved non linearity: in fact, the regression equation needs to be written before identifying its parameters. Clustering may operate in an unsupervised way, without the a priori correct classification of a training set (Booley 1998).

Neural networks are known to learn the embedded rules, with the indirect possibility (Taha and Ghosh 1999) to make rules explicit or to underline the salient variables. Decision trees (Quinlan 1994) are a popular framework providing a satisfactory answer to both questions.

Systems identification (Söderström and Stoica, 1989) is widely and robustly addressed even in calculus tools like Matlab from Matworks.

MAIN FOCUS

More recently, a different approach has been suggested, named Hamming Clustering (Muselli & Liberati 2000). It is related to the classical theory exploited in minimizing the size of electronic circuits, with the additional

care to obtain a final function able to generalize from the training data set to the most likely framework describing the actual properties of the data. Such approach enjoys the following remarkable two properties:

a) It is fast, exploting, after proper binary coding, just logical operations instead of floating point multiplications

b) It directly provides a logical understandable expression (Muselli & Liberati 2002), being the final synthesized function directly expressed as the OR of ANDs of the salient variables, possibly negated.

An alternative approach is to infer the model directly from the data via an identification algorithm capable to reconstruct a very general class of piece-wise affine models (Ferrari-Trecate et al., 2003). This method can be also exploited for the data-driven modeling of hybrid dynamical systems where logic phenomena interact with the evolution of continuous-valued variables.. Such approach will be concisely described later in the following, after a little more detailed drawing of the rules-oriented mining procedure. The last section will briefly discuss some applications.

HAMMING CLUSTERING: BINARY RULE GENERATION AND VARIABLE SELECTION WHILE MINING DATA

The approach followed by Hamming Clustering (HC) in mining the available data to select the salient variables and to build the desired set of rules consists of the three steps in Table 1.

- **Step 1:** A critical issue is the partition of a possibly continuous range in intervals, whose number and limits may affect the final result. The thermometer code may then be used to preserve ordering and distance (in case of nominal input variables, for which a natural ordering cannot be defined, the only-one code may instead be adopted). The metric used is the Hamming distance, computed as the number of different bits between binary strings: the training process does not require floating point computation, but only basic logic operations, for the sake of speed and insensitivity to precision.
- **Step 2:** Classical techniques of logical synthesis, such as ESPRESSO (Brayton at al 1984) or MINI (Hong 1997), are specifically designed to obtain the simplest AND-OR expression able to satisfy all the available input-output pairs, without an explicit attitude to generalize. To generalize and infer the underlying rules, at every iteration HC groups together, in a competitive way, binary strings having the same output and close to each other. A final pruning phase does simplify the resulting expression, further improving its generalization ability. Moreover, the minimization of the involved variables do intrinsically exclude the redundant ones, thus enhancing the very salient variables for the investigated problem. The quadratic computational cost allows to manage quite large datasets.
- **Step 3:** Each logical product directly provides an intelligible rule synthesizing a relevant aspect of the searched underlying system that is believed to generate the available samples.

Table 1. The tree steps executed by Hamming clustering to build the set of rules embedded in the mined data

1.	The input variables are converted into binary strings via a coding designed to preserve distance and, if relevant, ordering.
2.	The 'OR of ANDs' expression of a logical function is derived from the training examples coded in the binary form of step 1
3.	In the OR final expression, each logical AND provides intelligible conjunctions or disjunctions of the involved variables, ruling the analyzed problem

IDENTIFICATION OF PIECEWISE AFFINE SYSTEMS THROUGH A CLUSTERING TECHNIQUE

Once the salient variables have been selected, it may be of interest to capture a model of their dynamical interaction. Piecewise affine (PWA) identification exploits *K-means* clustering that associates data points in multivariable space in such a way to jointly determine a sequence of linear sub-models and their respective regions of operation, without even imposing continuity at each change in the derivative. In order to obtain such result, the five steps reported in Table 2 are executed:

- **Step 1:** The model is locally linear: small sets of data points close to each other likely belong to the same sub-model. For each data point, a local set is built, collecting the selected point together with a given number of its neighbours (whose cardinality is one of the parameters of the algorithm). Each local set will be *pure* if made of points really belonging to the same single linear subsystem, otherwise *mixed.*
- **Step 2:** For each local data set, a linear model is identified through least squares procedure. *Pure* sets, belonging to the same sub-model, give similar parameter sets, while *mixed* sets yield isolated vectors of coefficients, looking as outliers in the parameter space. If the signal to noise ratio is good enough, and there are not too many mixed sets (i.e. the number of data points are enough more than the number of sub-models to be identified, and the sampling is fair in every region), the vectors will cluster in the parameter space around the values pertaining to each sub-model, apart from a few outliers.
- **Step 3:** A modified *K-means* (Ferrari-Trecate et al., 2003), whose convergence is guaranteed in a finite number of steps, takes into account the confidence on pure and mixed local sets, in order to cluster the parameter vectors.
- **Step 4:** Data points are then classified, being each local data set one-to-one related to its generating data point, which is thus classified according to the cluster to which its parameter vector belongs.
- **Step 5:** Both the linear sub-models and their regions are estimated from the data in each subset. The coefficients are estimated via weighted least squares, taking into account the confidence measures. The shape of the polyhedral region characterizing the domain of each model may be obtained either via Linear Support Vector Machines (Vapnik, 1998), easily solved via linear/quadratic programming, or via Multi-category Robust linear Programming (Bennet & Mangasarian, 1992).

FUTURE TRENDS

The field of application of the proposed approaches is wide, being both tools general and powerful, especially if combined together. A few suggestions will be drawn, with reference to the field of life science because of its relevance to science and society. Systems Biology, the edge of Bio-informatics, starts from analyzing data from Micro-arrays, where thousands of gene expressions may be obtained from the same cell material, thus providing a huge amount of data whose handling with the usual approaches is not conceivable, fault to obtain not significant synthetic information. Thus, matrices of subjects, possibly grouped in homogeneous categories for supervised training, each one carrying his luggage of thousands of gene expressions, are the natural input

Table 2. The five steps for piecewise affine identification

1.	Local data sets are built neighbouring each sample
2.	Local linear models are identified through least squares
3.	Parameters vectors are clustered through a modified *K-means*
4.	Data points are classified accordingly to the clustered parameter vectors
5.	Sub-models are estimated via least squares; their regions are estimated via support vector machines or multi-category robust linear programming

to algorithms like HC. A desired output is to extract rules classifying, for instance, patients affected by different tumors from healthy subjects, on the basis of a few identified genes (Garatti et al.,., 2007), whose set is the candidate basis for the piecewise linear model describing their complex interaction in such a particular class of subjects. Also without such a deeper inside in the cell, the identification of the prognostic factors in oncology is already at hand with HC (Paoli et al., 2000), also providing a hint about their interaction, which is not explicit in the outcome of a neural network (Drago et al., 2002). Drug design does benefit form the a priori forecasting provided by HC about hydrophilic behavior of the not yet experimented pharmacological molecule, on the basis of the known properties of some possible radicals, in the track of Manga et al., (2003), within the frame of computational methods for the prediction of 'drug-likeness' (Clark & Pickett, 2000). Such in silico predictions, is relevant to Pharmaceutical Companies in order to save money in designing minimally invasive drugs whose kidney metabolism would less affect the liver the more hydrophilic they are.

Compartmental behaviour of drugs may then be analysed via piece-wise identification by collecting in vivo data samples and clustering them within the more active compartment at each stage, instead of the classical linear system identification that requires non linear algorithms (Maranzana et al., 1986). The same happens for metabolism, like glucose in diabetes or urea in renal failure: dialysis can be modelled as a compartmental process in a sufficiently accurate way (Liberati et al., 1993). A piece-wise linear approach is able to simplify the identification even on a single patient, when population data are not available to allow a simple linear de-convolution approach (Liberati & Turkheimer 1999) (whose result is anyway only an average knowledge of the overall process, without taking into special account the very subject under analysis). Compartmental model are such pervasive, like in ecology, wildlife and population studies, that potential applications in such direction are almost never ending.

Many physiological processes are switching form active to quiescent state, like Hormone pulses, whose identification (De Nicolao & Liberati 1993) is useful in growth and fertility diseases among others, as well as in doping assessment. In that respect, the most fascinating human organ is probably the brain, whose study may be undertaken today either in the sophisticated frame of functional Nuclear Magnetic Imaging or in the simple way of EEG recording. Multidimensional (3 space variables plus time) images or multivariate time series provide lot of raw data to mine in order to understand which kind of activation is produced in correspondence with an event or a decision (Baraldi et al., 2007). A brain computer interfacing device may then be built, able to reproduce one's intention to perform a move, not directly possible for the subject in some impaired physical conditions, and command a proper actuator. Both HC and PWA Identification do improve the already interesting approach based on Artificial Neural Networks (Babiloni et al., 2000). A simple drowsiness detector based on the EEG can be designed, as well as an anaesthesia/hypotension level detector more flexible than the one in (Cerutti et al., 85), without needing the time-varying more precise, but more costly, identification in (Liberati et al., 91a). A psychological stress indicator can be inferred, outperforming (Pagani et al., 1991). The multivariate analysis (Liberati et al., 1997), possibly taking into account also the input stimulation (Liberati et al., 1989, 1991b, 1992b,c), useful in approaching not easy neurological tasks like modelling Electro Encephalographic coherence in Alzheimer's disease patients (Locatelli et al., 1998) or non linear effects in muscle contraction (Orizio et al., 1996), can be outperformed by PWA identification even in time-varying contexts like epilepsy, aiming to build an implantable defribillator.

Industrial applications are of course not excluded from the field of possible interests. In (Ferrari-Trecate et al., 2003), for instance, the classification and identification of the dynamics of an industrial transformer are performed via the piece-wise approach, with a much simpler cost, not really paid in significant reduction of performances, with respect to the non linear modelling described in (Bittanti et al., 2001).

CONCLUSION

The proposed approaches are very powerful tools for quite a wide spectrum of applications, providing an answer to the quest of formally extracting knowledge from data and sketching a model of the underlying process.

Table 3. Summary of selected applications of the proposed approaches

System Biology and Bioinformatics	To identify the interaction of the main proteins involved in cell cycle
Drug design	To forecast the behavior of the final molecule from components
Compartmental modeling	To identify number, dimensions and exchange rates of communicating reservoirs
Hormone pulses detection	To detect true pulses among the stochastic oscillations of the baseline
Sleep detector	To forecast drowsiness, as well as to identify sleep stages and transitions
Stress detector	To identify the psychological state from multivariate analysis of biological signals
Prognostic factors	To identify the interaction between selected features, for instance in oncology
Pharmaco-kinetics and Metabolism	To identify diffusion and metabolic time constants from time series sampled in blood
Switching processes	To identify abrupt or possibly smoother commutations within the process duty cycle
Brain Computer Interfacing	To identify and propagate directly form brain waves a decision
Anesthesia detector	To monitor the level of anesthesia and provide close-loop control
Industrial applications	Wide spectrum of dynamic-logical hybrid problems, like tracking a transformer

ACKNOWLEDGMENT

Marco Muselli had a key role in conceiving and developing the clustering algorithms, while Giancarlo Ferrari-Trecate has been determinant in extending them to model identification

KEY TERMS

Bio-Informatics: The processing of the huge amount of information pertaining biology.

Hamming Clustering: A fast binary rule generator and variable selector able to build understandable logical expressions by analyzing the Hamming distance between samples.

Hybrid Systems: Their evolution in time is composed by both smooth dynamics and sudden jumps.

Micro-Arrays: Chips where thousands of gene expressions may be obtained from the same biological cell material.

Model Identification: Definition of the structure and computation of its parameters best suited to mathematically describe the process underlying the data.

Rule Generation: The extraction from the data of the embedded synthetic logical description of their relationships.

Salient Variables: The real players among the many apparently involved in the true core of a complex business.

Systems Biology: The quest of a mathematical model of the feedback regulation of proteins and nucleic acids within the cell.

Data Mining for Obtaining Secure E-Mail Communications

INTRODUCTION

Email is now an indispensable communication tool and its use is continually growing. This growth brings with it an increase in the number of electronic threats that can be classified into five categories according to their inner behavior: virus, trojans, pharming, spam, and phishing. Viruses, trojans and pharming threats represent an attack to the user's computer while the focus of attack of spam and phishing threats is mainly the user, that is, these last two threats involve a kind of intellectual attack.

A virus is a small program that replicates itself and inserts copies into other executable code or documents using e-mails as a means of transport. Trojans can not replicate themselves and they are used to open a network port giving other users a means of controlling the infected computer. Other more dangerous trojans are called spy programs (spyware) which wait until users visit some websites and then capture all the keys typed and mouse movements and make screenshots to obtain information. Pharming is a technique used to redirect users to illegitimate websites. These three threats, in spite of being present in e-mails, can be solved by an anti virus program.

The next two threats need e-mail filters to be solved and this chapter focuses on them: spam and phishing. Spam consists on the massive sending of unsolicited commercial e-mail to a large number of recipients. Unlike legitimate commercial e-mail, spam is sent without the explicit permission of the recipients. Spammers obtain e-mail addresses by different ways such as guessing common names at known domains or searching addresses in web pages. A report from the Commission of European Communities ("Communication from", 2004) shows that more than 25 percent of all e-mail currently received is spam. More recent reliable data shows that spam represents 60-80 percent of e-mail volume. Spam is widely recognized as one of the most significant problems facing the Internet today.

Spam has evolved to a new and dangerous form known as 'phishing'. Phishing differs from spam in that it is generated by a criminal intent on stealing personal data for financial gain ("Spyware", 2007). Phishing is the term used to describe emails which trick recipients into revealing their personal or their company's confidential information such as social security and financial account numbers, account passwords and other identity or security information.

According to Anti-Phishing Working Group ("June Phishing", 2006) the number of phishing reports has increased from 20,109 in May 2006 to 28,571 in June 2006 and it is the most ever recorded. Phishing attacks increase despite of the efforts of e-mail filters. Although only 0.001 percent of e-mail sent is responded to, this percentage is enough to return on the investment and keep the phishing industry alive. Further research has estimated that the costs of these phishing attacks on consumers in 2003 ranged from $500 million to an amazing $2.4 billion.

The early phishing attempts consisted on a link to a website which looked like a legitimate website, but in fact was an illegitimate website. The website address usually was not a domain, but simply an IP address, and the e-mails were often very poorly written, with bad grammar and spelling, and little attention to detail. Needless to say that phishing attacks have evolved with more convincing content and became harder to recognize. While a non-professional appearance such as a spelling error, a dubious URL, or a non-secure website are sure signs of a fraudulent phishing website, the lack of these features can no longer be used as a sure sign of a legitimate site (Green, 2005).

It is hard to successfully obtain bibliographical information in the scientific and marketing literature about techniques that aim to avoid spam and electronic fraud. This could be due to the features of these security systems, which should not be revealed in public documents for security reasons. This lack of information prevents improvements of criminals' attacks because spammers/phishers just do not know the methods used to detect and eliminate their attacks. It is also necessary to emphasize that there is little available commercial technology that shows an actual and effective solution for users and businesses.

Spam and phishing filters process e-mail messages and then choose where these messages have to be delivered. These filters can deliver spurious messages to a defined folder in the user's mailbox or throw messages away.

BACKGROUND

Filtering can be classified into two categories, origin-based filtering or content-based filtering, depending on the part of the message chosen by the filter as the focus for deciding whether e-mail messages are valid or illegitimate (Cunningham, 2003). Origin-based filters analyse the source of the e-mail, i.e. the domain name and the address of the sender (Mertz, 2002) and check whether it belongs to white (Randazzese, 2004) or black (Pyzor, 2002) verification lists.

Content-based filters aim to classify the content of e-mails: text and links. Text classifiers automatically assign document to a set of predefined categories (legitimate and illegitimate). They are built by a general inductive process that learns, from a set of preclassified messages, the model of the categories of interest (Sebastiani, 2002). Textual content filters may be differentiated depending on the inductive method used for constructing the classifier in a variety of ways:

Rule-based filters. Rules obtained by an inductive rule learning method consist of a premise denoting the absence or presence of keywords in textual messages and a consequent that denotes the decision to classify the message under a category. Filters that use this kind of filtering assign scores to messages based on fulfilled rules. When a message's score reaches a defined threshold, it is flagged as illegitimate. There are several filters using rules (Sergeant, 2003).

Bayesian filters. First, the probabilities for each word conditioned to each category (legitimate and illegitimate) are computed by applying the Bayes theorem, and a vocabulary of words with their associated probabilities is created. The filter classifies a new text into a category by estimating the probability of the text for each possible category C_j, defined as $P(C_j \mid text) = P(C_j) \cdot \Pi_i P(w_i \mid C_j)$, where w_i represents each word contained in the text to be classified. Once these computations have been carried out, the Bayesian classifier assigns the text to the category that has the highest probability value. Filter shown in ("Understanding Phishing", 2006) uses this technique.

Memory-based filters. These classifiers do no build a declarative representation of the categories. E-mail messages are represented as feature or word vectors that are stored and matched with every new incoming message. These filters use e-mail comparison as their basis for analysis. Some examples of this kind of filter are included in (Daelemans, 2001). In (Cunningham, 2003), case-based reasoning techniques are used.

Other textual content filters. Some of the content-based approaches adopted do not fall under the previous categories. Of these, the most noteworthy are the ones based on support vector machines, neural networks, or genetic algorithms. SVMs are supervised learning methods that look, among all the n-dimensional hyperplanes that separate the positive from the negative messages training, the hyperplane that separates the positive from the negative by the widest margin (Sebastiani, 2002). Neural network classifiers are nets of input units representing the words of the message to be classified, output units representing categories, and weighted edges connecting units represent dependence relations that are learned by backpropagation (Vinther, 2002). Genetic algorithms represent textual messages as chromosomes of a population that evolves by copy, crossover and mutation operators to obtain the textual centroid or prototypical message of each category (Serrano, 2007).

Non textual content-based filters or link-based filters detect illegitimate schemes by examining the links embedded in e-mails. This filtering can be done by using white-link and black-link verification lists (GoDaddy, 2006) or by appearance analysis (NetCraft, 2004) looking for well known illegitimate features contained in the name of the links.

Origin-based filters as well as link-based filters do not perform any data mining task from e-mails samples.

MAIN FOCUS

Most current filters described in the previous section achieve an acceptable level of classification performance, detecting 80%-98% of illegitimate e-mails. The main difficulty of spam filters is to detect false positives, i.e., the messages that are misidentified as illegitimate. Some filters obtain false positives in nearly 2% of the tests run on them. Although these filters are used commercially, they show two key issues for which there is no solution at present: 1) Filters are tested on standard sets of examples that are specifically designed for evaluating filters and these sets become obsolete within a short period of time, and 2) In response to the acceptable performance of some filters, spammers study the techniques filters use, and then create masses of e-mails intended to be filtered out, so that the content-based filters with the ability to evolve over time will learn from them. Next, the spammers/phishers generate new messages that are completely different in terms of content and format.

The evolution ability of some filters presents a double side: they learn from past mistakes but learning can lead to upgrade their knowledge base (words, rules or stored mesages) in an undirected manner so that the classification phase of the filter for incoming e-mails becomes inefficient due to the exhaustive search of words, rules or examples that would match the e-mail.

In order to design effective and efficient filtering systems, that overcome the drawbacks of the current filters, it is necessary to adopt an integrating approach that can make use of all possible patterns found by analysing all types of data present in e-mails: senders, textual content, and non textual content as images, code, links as well as the website content addressed by such links. Each type of data must be tackled by the mining method or methods most suitable for dealing with this type of data. This multistrategy and integrating approach can be applied to filtering both spam and phishing e-mails.

In (Castillo, 2006) a multistrategy system to identify spam e-mails is described. The system is composed of a heuristic knowledge base and a Bayesian filter that classifies the three parts of e-mails in the same way and then integrates the classification result of each part. The vocabulary used by the Bayesian filter for classifying the textual content is not extracted after a training stage but it is learned incrementally starting from a previously heuristic vocabulary resulting from mining invalid words (for example: vi@gra, v!agra, v1agra). This heuristic vocabulary includes word patterns that are invalid because their morphology does not meet the morphological rules of all the languages belonging to the Indo-European family. Invalid words are primarily conceived to fool spam filters. A finite state automata is created from a set of examples of well-formed words collected randomly from a set of dictionaries of several languages. Words taken from e-mails labelled as spam are not recognized by the automata as valid words, and are thus identified as misleading words. Then, an unsupervised learning algorithm is used to build a set of invalid word patterns and their descriptions according to different criteria. So, this spam system performs two textual data mining tasks: on the words by a clustering method and on the full content by a Bayesian filter.

Phishing filters use verification list (for origin and links) which are combined with the anti spam technology developed until now. Phishing filters based on the source and/or on the links contained in the body of the e-mail are very bounded. The sole possible way of filter evolution implies that the white or black lists used have to be continuously updated. However, phishers can operate between one updating and the following one and the user can receive a fraudulent mail. So, in this type of attacks and due to its potential danger, the analysis of the filter has to be focused on minimizing the number of false negatives, i.e., the messages erroneously assigned to the legitimate class, produced by the filter. Anyway, building a phishing filter actually effective means that the filter should take advantage of a multistrategy data mining on all kind of data included in e-mails. Usually, phishing e-mails contain forms, executable code or links to websites. The analysis of these features can give arise to patterns or rules that the filtering system can look up in order to make a classification decision. These mined rules can complement a Bayesian filter devoted to classify the textual content.

A key issue missed in any phishing filter is the analysis of the textual content of the websites addressed by the links contained in e-mails. Data and information present in these websites, and the way in which the fraudulent websites ask the client for his/her

personal identification data and then process these data, clearly reveals the fraudulent or legitimate nature of the websites. Choosing a data mining method that extracts the regularities found in illegitimate websites leads the filtering system to discriminate between legitimate and illegitimate websites and so, between legitimate and illegitimate e-mais in a more accurate way. In (Castillo, 2007) a hybrid phishing filter consisting of the integrated application of three classifiers is shown. The first classifier deals with patterns extracted from textual content of the subject and body and it is based on a probabilistic paradigm. The second classifier based on rules analyses the non grammatical features contained in the body of e-mails (forms, executable code, and links). The third classifier focuses on the content of the websites addressed by the links contained in the body of e-mails. A finite state automata identifies the answers given by these websites when a fictitious user introduces false confidential data in them. The final decision of the filter about the e-mail nature integrates the local decisions of the three classifiers.

FUTURE TRENDS

Future research in the design and development of e-mail filters should be mainly focused on the following five points:

1. Finding an effective representation of attributes or features used in textual and non textual data contained in e-mails and in the websites addressed by links present in the body of e-mails.
2. The methods used to deal with these new data. It would be necessary to improve or adapt well known data mining methods for analysing the new information or to develop new classification methods suitable to the features of the new data.
3. Reducing the dependence between the classification performance and the size of the training sample used in the training phase of filters.
4. Learning capabilities. Many current filters are not endowed with the ability of learning from past mistakes because the chosen representation of the information does not allow evolution at all.
5. The integration of different methods of analysis and classification in order to design and develop hybrid systems that use different strategies cooperating to enhance the classification performance.

CONCLUSION

The classification performance of e-mail filters mainly depends on the representation chosen for the e-mail content and the methods working over the representation. Most current spam and phishing filters fail to obtain a good classification performance since the analysis and processing rely only on the e-mail source and the words in the body. The improvement of filters would imply to design and develop hybrid systems that integrate several sources of knowledge (textual content of emails, links contained in emails, addressed websites and heuristic knowledge) and different data mining techniques. A right representation and processing of all available kinds of knowledge will lead to optimize classification effectiveness and efficiency.

KEY TERMS

Classification Efficiency: Time and resources used to build a classifier or to classify a new e-mail.

Classification Effectiveness: Ability of a classifier to take the right classification decisions.

Data Mining: Application of algorithms for extracting patterns from data.

Hybrid System: System that processes data, information and knowledge taking advantage of the combination on individual data mining paradigms.

Integrated Approach: Approach that takes into account different sources of data, information and knowledge present in e-mails.

Phishing E-Mail: Unsolicited e-mail intending on stealing personal data for financial gain.

Spam E-Mail: Unsolicited commercial e-mail.

Data Mining for Structural Health Monitoring

Ramdev Kanapady
University of Minnesota, USA

Aleksandar Lazarevic
United Technologies Research Center, USA

INTRODUCTION

Structural health monitoring denotes the ability to collect data about critical engineering structural elements using various sensors and to detect and interpret adverse "changes" in a structure in order to reduce life-cycle costs and improve reliability. The process of implementing and maintaining a structural health monitoring system consists of operational evaluation, data processing, damage detection and life prediction of structures. This process involves the observation of a structure over a period of time using continuous or periodic monitoring of spaced measurements, the extraction of features from these measurements, and the analysis of these features to determine the current state of health of the system. Such health monitoring systems are common for bridge structures and many examples are citied in (Maalej et al., 2002).

The phenomenon of damage in structures includes localized softening or cracks in a certain neighborhood of a structural component due to high operational loads, or the presence of flaws due to manufacturing defects. Damage detection component of health monitoring system are useful for non-destructive evaluations that are typically employed in agile manufacturing systems for quality control and structures, such as turbine blades, suspension bridges, skyscrapers, aircraft structures, and various structures deployed in space for which structural integrity is of paramount concern (Figure 1). With the increasing demand for safety and reliability of aerospace, mechanical and civilian structures damage detection techniques become critical to reliable prediction of damage in these structural systems.

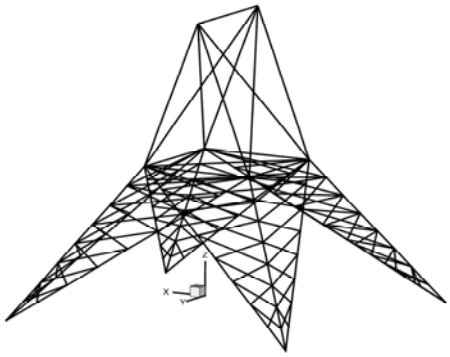
Most currently used damage detection methods are manual such as tap test, visual or specially localized measurement techniques (Doherty, 1997). These techniques require that the location of the damage have to be on the surface of the structure. In addition, location of the damage has to be known a priori and these locations have to be readily accessible. This makes current maintenance procedure of large structural systems very time consuming and expensive due to its heavy reliance on human labor.

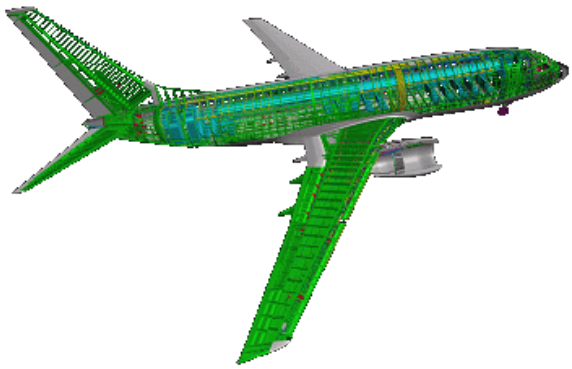
BACKGROUND

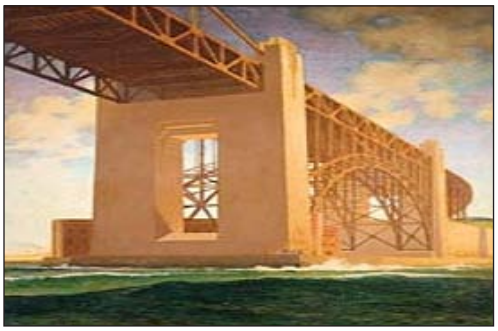
The damage in structures and structural systems is defined through comparison between two different states of the system, where the first one is the initial undamaged state, and the second one is damaged state. Emerging continuous monitoring of an instrumented structural system often results in the accumulation of a large amount of data that need to be processed, analyzed and interpreted for damage detection. However, the rate of accumulating such data sets far outstrips the ability to analyze them manually. As a result, there is a need to develop an intelligent data processing component that can significantly improve current damage detection systems. Since damage in changes in the properties of the structure or quantities derived from these properties, the process of health monitoring eventually reduces to a form of data mining problem. Design of data mining techniques that can enable efficient, real-time and robust (without false alarm) prediction of damage presents one of key challenging technological opportunity.

In recent years, various data mining techniques such as artificial neural networks (ANNs) (Anderson et al., 2003; Lazarevic et al., 2004; Ni et al., 2002; Sandhu et al., 2001; Yun & Bahng, 2000; Zhao, Ivan & DeWolf, 1998;), support vector machines (SVMs) (Mita & Hagiwara 2003), decision trees (Sandhu et al., 2001) have been successfully applied to structural damage detection problems. This success can be attributed to numerous disciplines integrated with data mining such as pattern recognition, machine learning and statistics. In addition, it is well known that data mining techniques can effectively handle noisy, partially incomplete and

Figure 1. Examples of engineering structures that require structural health monitoring systems







faulty data, which is particularly useful, since in damage detection applications, measured data are expected to be incomplete, noisy and corrupted.

The intent of this chapter is to provide a survey of emerging data mining techniques for structural health monitoring with particular emphasis on damage detection. Although the field of damage detection is very broad and consists of vast literature that is not based on data mining techniques, this survey will be predominantly focused on data-mining techniques for damage detection based on changes in properties of the structure.

CATEGORIZATION OF STRUCTURAL DAMAGE

The damage in structures can be classified as linear or nonlinear. Damage is considered as linear if the undamaged structure remains elastic after damage. However, if the initial structure behaves in a nonlinear manner after the damage initiation, then the damage is considered as nonlinear. However, it is possible that the damage is linear at the damage initiation phase, but after prolonged growth in time, it may become nonlinear. For example, loose connections between the structures at the joints or the joints that rattle (Sekhar, 2003) are considered non-linear damages. Examples of such non-linear damage detection systems are described in (Adams & Farrar, 2002; Kerschen & Golinval, 2004).

The most of the damage detection techniques in the literature are proposed for linear case. They are based on the following three levels of damage identification: 1. Recognition—qualitative indication that damage might be present in the structure, 2. Localization—information about the probable location of the damage in the structure, 3. Assessment—estimate of the extent of severity of the damage in the structure. Such damage detection techniques can be found in several approaches (Yun & Bahng, 2000; Ni et al., 2002; Lazarevic et al., 2004).

CLASSIFICATION OF DAMAGE DETECTION TECHNIQUES

We provide several different criteria for classification of damage detection techniques based on data mining.

In the first classification, damage detection techniques can be categorized into continuous (Keller & Ray, 2003) and periodic (Patsias & Staszewski, 2002) damage detection systems. While continuous techniques are mostly employed for real-time health monitoring, periodic techniques are employed for time-to-time health monitoring. Feature extraction from large amount of data collected from real time sensors can be a key distinction between these two techniques.

In the second classification, we distinguish between application-based and application-independent techniques. Application-based techniques are generally applicable to a specific structural system and they typically assume that the monitored structure responds in some predetermined manner that can be accurately modeled by (i) numerical techniques such as finite element (Sandhu et al., 2001) or boundary element analysis (Anderson et al., 2003) and/or (ii) behavior of the response of the structures that are based on physics based models (Keller & Ray, 2003). Most of damage detection techniques that exist in literature belong to application-based approach, where the minimization of the residue between the experimental and the analytical model is built into the system. Often, this type of data is not available and can render application-based methods impractical for certain applications particularly for structures that are designed and commissioned without such models. On the other hand, application-independent techniques do not depend on specific structure and they are generally applicable to any structural system. However, the literature on these techniques is very sparse and the research in this area is at very nascent stage (Bernal & Gunes, 2000; Zang et. al 2004).

In the third classification, damage detection techniques are split into signature based and non-signature based methods. Signature–based techniques extensively use signatures of known damages in the given structure that are provided by human experts. These techniques commonly fall into the category of recognition of damage detection, which only provides the qualitative indication that damage might be present in the structure (Friswell et al., 1994) and to certain extent the localization of the damage (Friswell et al., 1997). Non-signature methods are not based on signatures of known damages and they do not only recognize but also localize and assess extent of damage. Most of the damage detection techniques in the literature fall into this category (Lazarevic et al., 2004; Ni et al., 2002; Yun & Bahng 2000).

In the fourth classification, damage detection techniques are classified into local (Sekhar 2003; Wang, 2003) and global (Fritzen & Bohle 2001) techniques. Typically, the damage is initiated in a small region of the structure and hence it can be considered as local phenomenon. One could employ a local or global damage detection features that are derived from local or global response or properties of the structure. Although local features can detect the damage effectively, these features are very difficult to obtain from the experimental data such as higher natural frequencies and mode shapes of structure (Ni, Wang & Ko, 2002). In addition, since the vicinity of damage is not known a priori, the global methods that can employ only global damage detection features such lower natural frequencies of the structure (Lazarevic et al., 2004) are preferred.

Finally, damage detection techniques can be classified as traditional and emerging data-mining techniques. Traditional analytical techniques employ mathematical models to approximate the relationships between specific damage conditions and changes in the structural response or dynamic properties. Such relationships can be computed by solving a class of so-called inverse problems. The major drawbacks of the existing approaches are as follows: i) the more sophisticated methods involve computationally cumbersome system solvers which are typically solved by singular value decomposition techniques, non-negative least squares techniques, bounded variable least squares techniques, etc.; and, ii) all computationally intensive procedures need to be repeated for any newly available measured test data for a given structure. Brief survey of these methods can be found in (Doebling et al., 1996). On the other hand, data mining techniques consist of application techniques to model an explicit inverse relation between damage detection features and damage by minimization of the residue between the experimental and the analytical model at the training level. For example, the damage detection features could be natural frequencies, mode shapes, mode curvatures, etc. It should be noted that data mining techniques are also applied to detect features in large amount of measurement data. In the next few sections we will provide a short description of several types of data-mining algorithms used for damage detection.

Classification

Data mining techniques based on classification were successfully applied to identify the damage in the structures. For example, decision trees have been applied to detect damage in an electrical transmission tower (Sandhu et al., 2001). It has been found that in this approach decision trees can be easily understood, while many interesting rules about the structural damage were found. In addition, a method using SVMs has been proposed to detect local damages in a building structure (Mita & Hagiwara, 2003). The method is verified to have capability to identify not only the location of damage but also the magnitude of damage with satisfactory accuracy employing modal frequency patterns as damage features.

Pattern Recognition

Pattern recognition techniques are also applied to damage detection by various researchers. For example, the statistical pattern recognition is applied to damage detection employing relatively few measurements of modal data collected from three scale model-reinforced concrete bridges (Haritos & Owen, 2004), but the method could only be able to indicate that damage had occurred. In addition, independent component analysis, a multivariate statistical method also known as proper orthogonal decomposition, has been applied to damage detection problem on time history data to capture essential pattern of the measured vibration data (Zang et al., 2004).

Regression

Regression techniques such as radial basis functions (Önel et. al, 2006) and neutral networks (Lazarevic et al., 2004; Ni, Wang & Ko, 2002; Zhao et al., 1998) have been successfully applied to detect the existence, location and quantification of the damage in the structure employing modal data. Neural networks have been extremely popular in recent years due to their capabilities as universal approximators.

In damage detection approaches based on neural networks, the damage location and severity are simultaneously identified using one-stage scheme, as also called the direct method (Zhao et al., 1998), where the neural network is trained with different damage levels at each possible damage location. However, these studies were restricted to very small models with a small number of target variables (order of 10), and the development of a predictive model that could correctly identify the location and severity of damage in practical large-scale complex structures using this direct approach was a considerable challenge. Increased geometric complexity of the structure caused increase in the number of target variables thus resulting in data sets with large number of target variables. Since the number of prediction models that needs to be built for each continuous target variable increases, the number of training data records required for effective training of neural networks also increases, thus requiring more computational time for training neural networks but also more time for data generation, since each damage state (data record) requires an eigen solver to generate natural frequency and mode shapes of the structure. The earlier direct approach, employed by numerous researchers required the prediction of the material property, namely, the Young's modulus of elasticity considering all the elements in the domain individually or simultaneously. However, this approach does not scale to situations in which thousands of elements are present in the complex geometry of the structure or when multiple elements in the structure have been damaged simultaneously.

To reduce the size of the system under consideration, several substructure-based approaches have been proposed (Sandhu et al., 2002; Yun & Bahng, 2000). These approaches partition the structure into logical sub-structures, and then predict the existence of the damage in each of them. However, pinpointing the location of damage and extent of the damage is not resolved completely in these approaches. Recently, these issues have been addressed in two hierarchical approaches (Lazarevic et al., 2004; Ni et al., 2002). Ni (Ni et al., 2002) have proposed the approach where neural networks are hierarchically trained using one-level damage samples to first locate the position of the damage and then the network is re-trained by an incremental weight update method using additional samples corresponding to different damage degrees but only at the identified location at the first stage. The input attributes of neural networks are designed to depend only on damage location, and they consisted of several natural frequencies and a few incomplete modal vectors. Since measuring mode shapes are difficult, global method based only on natural frequencies are highly preferred. However, employing natural frequencies as

features traditionally has many drawbacks (e.g. two symmetric damage locations cannot be distinguished using only natural frequencies). To overcome these drawbacks, (Lazarevic et. al, 2004; Lazarevic et al., 2007) proposed an effective and scalable data mining technique based only on natural frequencies as features where symmetrical damage locations of damage, as well as spatial characteristics of structural systems are integrated in building the model. The proposed localized clustering-regression based approach consists of two phases: (*i*) finding the most similar training data records to a test data record of interest and creating a cluster from these data records; and (*ii*) predicting damage intensity only in those structure elements that correspond to data records from the built cluster, assuming that all other structure elements are undamaged. In the first step, for each test data record, they build a local cluster around that specific data record. The cluster contains the most similar data records from the training data set. Then, in the second step, for all identified similar training data records that belong to created cluster, they identify corresponding structure elements assuming that the failed element is one of these identified structure elements. By identifying corresponding structure elements the focus is only on prediction of the structure elements that are highly possible to be damaged. Therefore, instead of predicting an intensity of damage in all structure elements, a prediction model is built for each of these identified corresponding structure elements in order to determine which of these structure elements has really failed. Prediction model for a specific structure element is constructed using only those data records from the entire training data set that correspond to different intensities of its failure and using only a specific set of relevant natural frequencies. Experiments performed on the problem of damage prediction in a large electric transmission tower frame indicate that this hierarchical and localized clustering-regression based approach is more accurate than previously proposed hierarchical partitioning approaches as well as computationally more efficient.

Other Techniques

Other data mining based approaches have also been applied to different problems in structural health monitoring. For example, outlier based analysis techniques (Worden et al., 2000, Li, et al., 2006,) have been used to detect the existence of damage and wavelet based approaches (Wang, 2003; Bulut et. al., 2005) have been used to detect damage features or for data reduction component of structural heath monitoring system.

Hybrid Data Mining Models

For efficient, robust and scalable large-scale health monitoring system, that addresses all the three levels of damage detection, it is imperative data mining models include combination of classification, pattern recognition and/or regression type of methods. Combination of independent component analysis and artificial neural networks (Zang et al., 2004) has also been successfully applied to detect damages in structures. Recently, a hybrid local and global damage detection model employing SVM with the design of smart sensors (Hayano & Mita 2005) was also used. (Bulut et. al., 2005) presented a real-time prediction technique with wavelet based data reduction and SVM based classification of data at each sensor location and clustering based data reduction and SVM based classification at the global level for wireless network of sensors. For network of sensors architecture, an information fusion methodology that deals with data processing, feature extraction and damage decision techniques such as voting scheme, Bayesian inference, Dempster-Shafer rule and fuzzy inference integration in a hierarchical setup was recently presented (Wang et al. 2006).

FUTURE TRENDS

Damage detection is increasingly becoming an indispensable and integral component of any comprehensive structural health monitoring programs for mechanical and large-scale civilian, aerospace and space structures. Although a variety of techniques have been developed for detecting damages, there are still a number of research issues concerning the prediction performance and efficiency of the techniques that need to be addressed (Auwerarer & Peeters, 2003; De Boe & Golinval, 2001). In addition to providing three levels of damage identification, namely recognition, localization and assessment, future data mining research should also focus on providing another level of damage identification to include estimating the remaining service life of a structure.

CONCLUSION

In this chapter a survey of emerging data mining techniques for damage detection in structures is provided. This survey reveals that the existing data-mining techniques are predominantly based on changes in properties of the structure to classify, localize and predict the extent of damage.

KEY TERMS

Damage: Localized softening or cracks in a certain neighborhood of a structural component due to high operational loads, or the presence of flaws due to manufacturing defects.

High Natural Frequency: Natural Frequency which measurement requires sophisticated instrumentation and it characterizes local response or properties of an engineering structure.

Low Natural Frequency: Natural Frequency that can be measured with simple instrumentation and it characterizes global response or properties of an engineering structure.

Modal Properties: Natural frequency, mode shapes and mode curvatures constitutes modal properties.

Mode Shapes: Eigen vectors associated with the natural frequencies of the structure.

Natural Frequency: Eigen values of the mass and stiffness matrix system of the structure.

Smart Structure: A structure with a structurally integrated fiber optic sensing system.

Structures and Structural System: The word structure used has been employed loosely in the chapter. The structure is referred to the continuum material and whereas the structural system consists of structures which are connected at joints.

Data Mining for the Chemical Process Industry

Ng Yew Seng

Rajagopalan Srinivasan
National University of Singapore and Institute of Chemical & Engineering Sciences, Singapore

INTRODUCTION

Advancements in sensors and database technologies have resulted in the collection of huge amounts of process data from chemical plants. A number of process quantities such as temperature, pressure, flow rates, level, composition, and pH can be easily measured. Chemical processes are dynamic systems and are equipped with hundreds or thousands of sensors that generate readings at regular intervals (typically seconds). In addition, derived quantities that are functions of the sensor measurements as well as alerts and alarms are generated regularly. Several commercial data warehouses, referred to as plant historians in chemical plants, such as the DeltaV Continuous Historian (from Emerson Process Management), InfoPlus.21™ (from AspenTech), Uniformance® PHD (from Honeywell), and Industrial SQL (from Wonderware) are in common use today around the world. These historians store large amount (weeks) of historical process operation data at their original resolution and an almost limitless amount (years) in compressed form. This data is available for mining, analysis and decision support – both real-time and offline.

Process measurements can be classified based on their nature as binary (on/off) or continuous. However, both are stored in discrete form in the historians. Measurements can also be classified based on their role during operation as controlled, manipulated, and non-control related variables. Controlled variables are directly or indirectly related to the plant's quality, production, or safety objectives and are maintained at specified setpoints, even in the face of disturbances, by analog or digital controllers. This regulation is achieved by altering manipulated variables such as flow-rates. Chemical plants are typically well-integrated – a change in one variable would propagate across many others. Non-control related variables do not have any role in plant control, but provide information to plant personnel regarding the state of the process.

In general, a plant can operate in a number of states which can be broadly classified into steady-states and transitions (Srinivasan *et al.*, 2005b). Large scale plants such as refineries typically run for long periods in steady-states but undergo transition if there is a change in feedstock or product grades. Transitions also result due to large process disturbances, maintenance activities, and abnormal events. During steady-states, the process variables vary within a narrow range. In contrast, transitions correspond to large changes / discontinuities in the plant operations; *i.e.*, change of set points, turning on or idling of equipments, valve manipulations, etc. A number of decisions are needed on the part of the plant personnel to keep the plant running safely and efficiently during steady states as well as transitions. Data mining and analysis tools that facilitate humans to uncover information, knowledge, patterns, trends, and relationships from the historical data are therefore crucial.

BACKGROUND

Numerous challenges bedevil the mining of data generated by chemical processes. These arise from the following general characteristics of the data:

1. *Temporal*: Since the chemical process is a dynamic system, all measurements vary with time.
2. *Noisy*: The sensors and therefore the resulting measurements can be significantly noisy.
3. *Non-stationarity*: Process dynamics can change significantly, especially across states because of structural changes to the process. Statistical properties of the data such as mean and variance can therefore change significantly between states.
4. *Multiple time-scales*: Many processes display multiple time scales with some variables varying quickly (order of seconds) while others respond over hours.

5. *Multi-rate sampling*: Different measurements are often sampled at different rates. For instance, online measurements are often sampled frequently (typically seconds) while lab measurements are sampled at a much lower frequency (a few times a day).
6. *Nonlinearity*: The data from chemical processes often display significant nonlinearity.
7. *Discontinuity:* Discontinuous behaviors occur typically during transitions when variables change status – for instance from inactive to active or no flow to flow.
8. *Run-to-run variations*: Multiple instances of the same action or operation carried out by different operators and at different times would not match. So, signals from two instances could be significantly different due to variation in initial conditions, impurity profiles, exogenous environmental or process factors. This could result in deviations in final product quality especially in batch operations (such as in pharmaceutical manufacturing).

Due to the above, special purpose approaches to analyze chemical process data are necessary. In this chapter, we review these data mining approaches.

MAIN FOCUS

Given that large amounts of operational data are readily available from the plant historian, data mining can be used to extract knowledge and improve process understanding – both in an offline and online sense. There are two key areas where data mining techniques can facilitate knowledge extraction from plant historians, namely (i) process visualization and state-identification, and (ii) modeling of chemical processes for process control and supervision.

Visualization techniques use graphical representation to improve human's understanding of the structure in the data. These techniques convert data from a numeric form into a graphic form that facilitates human understanding by means of the visual perception system. This enables post-mortem analysis of operations towards improving process understanding or developing process models or online decision support systems. A key element in data visualization is dimensionality reduction. Subspace approaches such as principal components analysis and self-organizing maps have been popular for visualizing large, multivariate process data. For instance, an important application is to identify and segregate the various operating regimes of a plant. Figure 1 shows the various periods over a course of two weeks when a refinery hydrocracker was operated in steady-states or underwent transitions. Such information is necessary to derive operational statistics of the operation. In this example, the states have been identified using two principal components that summarize the information in over 50 measurements. As another illustration, oscillation of process variables during steady-state operations is common but undesirable. Visualization techniques and dimensionality reduction can be applied to detect oscillations (Thornhill and Hagglund, 1997). Other applications include process automation and control (Amirthalingam *et al*., 2000; Samad *et al.*, 2007), inferential sensing (Fortuna *et al.*, 2005), alarm management (Srinivasan *et al.*, 2004a), control loop performance analysis (Huang, 2003) and preventive maintenance (Harding *et al*., 2007).

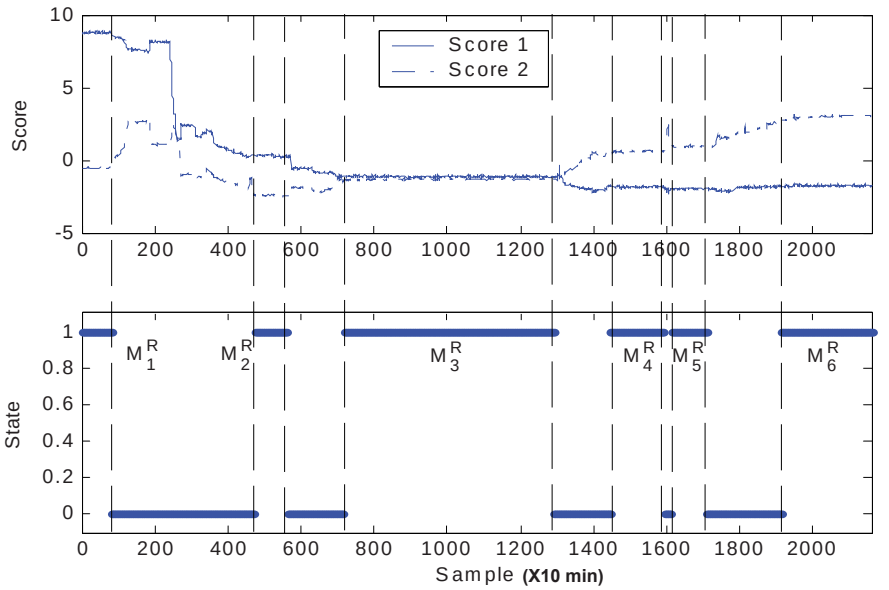
Data-based models are also frequently used for process supervision – fault detection and identification (FDI). The objective of FDI is to decide in real-time the condition – normal or abnormal – of the process or its constituent equipment, and (ii) in case of abnormality, identify the root cause of the abnormal situation. It has been reported that approximately 20 billion dollars are lost on an annual basis by the US petrochemical industries due to inadequate management of abnormal situations (Nimmo, 1995). Efficient data mining algorithms are hence necessary to prevent abnormal events and accidents. In the chemical industry, pattern recognition and data classification techniques have been the popular approaches for FDI. When a fault occurs, process variables vary from their nominal ranges and exhibit patterns that are characteristic of the fault. If the patterns observed online can be matched with known abnormal patterns stored in a database, the root cause of a fault can generally be identified.

In the following, we review popular data mining techniques by grouping them into machine-learning, statistical, and signal processing approaches.

Machine Learning Methods

Neural-network (NN) is a popular machine learning technique that exhibits powerful classification and func-

Figure 1. Classification of process steady-states and transitions



tion approximation capability. It has been shown to be robust to noise and able to model nonlinear behaviors. It has hence become popular for process control, monitoring, and fault diagnosis. Reviews of the applications of neural-networks in the chemical process industry have been presented in Hussain (1999) and Himmelblau (2000). Although in theory, artificial neural-networks can approximate any well-defined non-linear function with arbitrary accuracy, the construction of an accurate neural classifier for complex multivariate, multi-class, temporal classification problems such as monitoring transient states suffers from the "curse of dimensionality". To overcome this, new neural-network architectures such as one-variable-one-network (OVON) and one-class-one-network (OCON) have been proposed by Srinivasan *et al.* (2005a). These decompose the original classification problem into a number of simpler classification problems. Comparisons with traditional neural networks indicate that the new architectures are simpler in structure, faster to train, and yield substantial improvement in classification accuracy.

The Self-Organizing Map (SOM) is another type of neural-network based on unsupervised learning. It is capable of projecting high-dimensional data to a two dimensional grid, and hence provides good visualization facility to data miners. Ng *et al.* (2006) demonstrated that data from steady-state operations are reflected as clusters in the SOM grid while those from transitions are shown as trajectories. Figure 2 depicts four different transitions that were commonly carried out in the boiler unit in a refinery. The SOM can therefore serve as a map of process operations and can be used to visually identify the current state of the process.

Classical PCA approaches cannot be directly applied to transitions data because they do not satisfy the statistical stationarity condition. An extension of PCA called Multiway-PCA was proposed by Nomikos and MacGregor (1994) that reorganizes the data into time-ordered blocks. A time-based scaling is applied to different samples based on the nominal operation of the transition. This leads to a normalized variable that is stationary and can be analyzed by PCA. However, this requires every run of data to have equal length, and each time point to be synchronized. An alternate approach is the so called dynamic PCA (DPCA) where each time instant is modeled using the samples at that point as well as additional time-lagged ones (Ku *et al.*, 1995). Srinivasan *et. al.* (2004b) used DPCA to classify transitions as well as steady states. Multi-model approaches, where different PCA models are developed for different states, offer another way to model such complex operations (Lu and Gao, 2005; Doan and Srinivasan, 2008). The extent of resemblance between the different models can be compared using PCA similarity factors. Comparison

of different instances of the same transition can also be performed to extract best practices (Ng *et al.*, 2006).

Signal Processing Methods

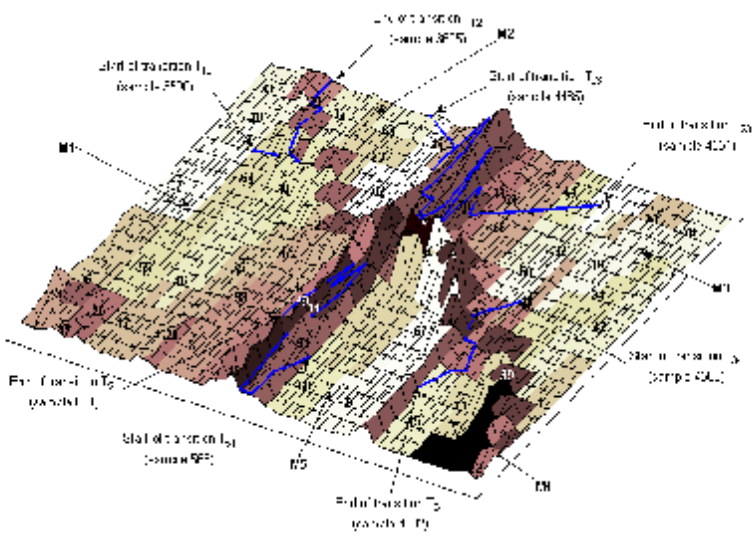
The above data mining methods abstract information from the data in the form of a model. Signal comparison methods on the other hand rely on a direct comparison of two instances of signals. Signal comparison methods thus place the least constraint on the characteristics of the data that can be processed, however they are computationally more expensive. The comparison can be done at a low level of resolution – comprising process trends – or at a high level of resolution, i.e., the sensor measurements themselves. Trend analysis is based on the granular representation of process data through a set of qualitative primitives (Venkatasubramanian *et al.*, 2003), which qualitatively describe the profile of the evolution. Different process states – normal and abnormal, map to different sequences of primitives. So a characteristic trend signature can be developed for each state, hence allowing a fault to be identified by template matching. A review of trend analysis in process fault diagnosis can be found in Maurya *et al.* (2007), where various approaches for online trend extraction and comparison are discussed.

Signal comparison at the process measurement level has been popular when non-stationary data, with different run lengths, have to be compared. Time synchronization between the signals is required in such cases. Dynamic time warping (DTW) has been frequently used for this purpose (Kassidas *et al.*,1998). As DTW is computationally expensive for long, multi-variate signals, several simplifications have been proposed. One such simplification relies on landmarks in the signal (such as peaks or local minima) to decompose a long signal into multiple shorter segments which are in turn compared using time warping (Srinivasan and Qian, 2005; 2007). However, one key requirement of DTW is that the starting and ending points of the signals to be compared should coincide. This obviates its direct use for online applications since the points in the historical database that should be matched with the starting and ending points of the online signal are usually unknown. A technique called dynamic locus analysis, based on dynamic programming, has been recently proposed for such situations (Srinivasan and Qian, 2006).

FUTURE TRENDS

Data analysis tools are necessary to aid humans visualize high dimensional data, analyze them, and extract actionable information to support process operations. A variety of techniques with differing strengths and weaknesses have been developed to date. The ideal data mining method would (i) adapt to changing operating and environmental conditions, and be tolerant to noise and uncertainties over a wide range, (ii) provide

Figure 2. Visualization of multi-state, multivariate temporal data with SOM



explanation on the patterns observed, their origin and propagation among the variables, (iii) simultaneously analyze many process variables, (iv) detect and identify novel patterns, (v) provide fast processing with low computational requirement, and (vi) be easy to implement and maintain. As shown in Table 1, no one technique has all these features necessary for large-scale problems (Srinivasan, 2007). Additional insights from human knowledge of process principles and causality can resolve some of the uncertainties that mere data cannot. Since no single method can completely satisfy all the important requirements, effective integration of different data mining methods is necessary. Multi-agent approaches (Wooldridge, 2002) could pave the way for such integration (Davidson *et al.*, 2006) and collaboration between the methods (Ng and Srinivasan, 2007). When multiple methods are used in parallel, a conflict resolution strategy is needed to arbitrate among the contradictory decisions generated by the various methods. Decision fusion techniques such as voting, Bayesian, and Dempster-Shafer combination strategies hold much promise for such fusion (Bossé *et al.*, 2006).

CONCLUSION

Data in the process industry exhibit characteristics that are distinct from other domains. They contain rich information that can be extracted and used for various purposes. Therefore, specialized data mining tools that account for the process data characteristics are required. Visualization and clustering tools can uncover good operating practices that can be used to improve plant operational performance. Data analysis methods for FDI can reduce the occurrence of abnormal events and occupational injuries from accidents. Collaborative multi-agent based methodology holds promise to integrate the strengths of different data analysis methods and provide an integrated solution.

KEY TERMS

Data Mining: The process of discovering meaningful information, correlations, patterns, and trends from databases, usually through visualization or pattern recognition techniques.

Fault Detection and Identification: The task of determining the health of a process (either normal or abnormal) and locating the root cause of any abnormal behavior.

Plant Historian: The data warehouse in a chemical plant. They can store large number of process variables such as temperature, pressure, and flow rates, as well as a history of the process operation, such as equipment settings, operator logs, alarms and alerts.

Process Industry: An industry in which raw materials are mixed, treated, reacted, or separated in a series of stages using chemical process operations. Examples of process industries include oil refining, petrochemicals, pharmaceuticals, water and sewage treatment, food processing, etc.

Process Supervision: The task of monitoring and overseeing the operation of a process. It involves monitoring of the process as well as of the activities carried out by operators.

Root Cause: The main reason for any variation in the observed patterns from an acceptable set corresponding to normal operations

Visualization: A technique that uses graphical representation to improve human's understanding of patterns in data. It converts data from a numeric form into a graphic that facilitates human understanding by means of the visual perception system.

Data Mining in Genome Wide Association Studies

Tom Burr
Los Alamos National Laboratory, USA

INTRODUCTION

The genetic basis for some human diseases, in which one or a few genome regions increase the probability of acquiring the disease, is fairly well understood. For example, the risk for cystic fibrosis is linked to particular genomic regions. Identifying the genetic basis of more common diseases such as diabetes has proven to be more difficult, because many genome regions apparently are involved, and genetic effects are thought to depend in unknown ways on other factors, called covariates, such as diet and other environmental factors (Goldstein and Cavalleri, 2005).

Genome-wide association studies (GWAS) aim to discover the genetic basis for a given disease. The main goal in a GWAS is to identify genetic variants, single nucleotide polymorphisms (SNPs) in particular, that show association with the phenotype, such as "disease present" or "disease absent" either because they are causal, or more likely, because they are statistically correlated with an unobserved causal variant (Goldstein and Cavalleri, 2005). A GWAS can analyze "by DNA site" or "by multiple DNA sites. " In either case, data mining tools (Tachmazidou, Verzilli, and De Lorio, 2007) are proving to be quite useful for understanding the genetic causes for common diseases.

BACKGROUND

A GWAS involves genotyping many cases (typically 1000 or more) and controls (also 1000 or more) at a large number (10^4 to 10^6) of markers throughout the genome. These markers are usually SNPs. A SNP occurs at a DNA site if more than one nucleotide (A, C, T, or G) is found within the population of interest, which includes the cases (which have the disease being studied) and controls (which do not have the disease). For example, suppose the sequenced DNA fragment from subject 1 is AAGC**C**TA and from subject 2 is AAGC**T**TA. These contain a difference in a single nucleotide. In this case there are two alleles ("alleles" are variations of the DNA in this case), C and T. Almost all common SNPs have only two alleles, often with one allele being rare and the other allele being common.

Assume that measuring the DNA at millions of sites for thousands of individuals is feasible. The resulting measurements for n_1 cases and n_2 controls are partially listed below, using arbitrary labels of the sites such as shown below. Note that DNA site 3 is a candidate for an association, with T being the most prevalent state for cases and G being the most prevalent state for controls.

	123	456	789 ...
Case 1:	AA**T**	CT**A**	TAT ...
Case 2:	A* **T**	CT**C**	TAT …
...			
Case n_1:	AA**T**	CT**G**	TAT ...
Control 1:	AA**G**	CT**A**	TTA ...
Control 2:	AA**G**	CT**A**	TTA ...
...			
Control n_2:	AA**G**	CT**A**	TTA ...

Site 6 is also a candidate for an association, with state A among the controls and considerable variation among the cases. The * character (case 2) can denote missing data, an alignment character due to a deletion mutation, or an insertion mutation, etc. (Toivonen et al., 2000).

In this example, the eye can detect such association candidates "by DNA site." However, suppose the collection of sites were larger and all n_1 cases and n_2 controls were listed, or that the analysis were "by haplotype." In principle, the haplotype (one "half" of the genome of a paired-chromosome species such as humans) is the entire set of all DNA sites in the entire genome. In practice, haplotype refers to the sequenced sites, such as those in a haplotype mapping (HapMap,

2005) involving SNPs as we focus on here. Both a large "by DNA site" analysis and a haplotype analysis, which considers the joint behavior of multiple DNA sites, are tasks that are beyond the eye's capability.

Using modern sequencing methods, time and budget constraints prohibit sequencing all DNA sites for many subjects (Goldstein and Cavalleri, 2005). Instead, a promising shortcut involves identifying haplotype blocks (Zhang and Jin, 2003; Zhang et al., 2002). A haplotype block is a homogeneous region of DNA sites that exhibit high linkage disequilibrium. Linkage disequilibrium between two DNA sites means there is negligible recombination during reproduction, thus "linking" the allelic states far more frequently than if the sites evolved independently. The human genome contains regions of very high recombination rates and regions of very low recombination rates (within a haplotype block). If a haplotype block consists of approximately 10 sites, then a single SNP marker can indicate the DNA state (A, C, T, or G) for each site in the entire block for each subject, thus reducing the number of sequenced sites by a factor of 10.

The HapMap project (HapMap, 2005) has led to an increase from approximately 2 million known SNPs to more than 8 million. Many studies have reported low haplotype diversity with a few common haplotypes capturing most of the genetic variation. These haplotypes can be represented by a small number of haplotype-tagging SNPs (htSNPs). The presence of haplotype blocks makes a GWAS appealing, and summarizes the distribution of genetic variation throughout the genome. SNPs are effective genetic markers because of their abundance, relatively low mutation rate, functional relevance, ease of automating sequencing, and role as htSNPs. The HapMap project is exploiting the concept that if an htSNP correlates with phenotype, then some of the SNPs in its "association block" are likely to be causally linked to phenotype.

MAIN THRUST

Data Mining

Data mining involves the extraction of potentially useful information from data. Identifying genomic regions related to phenotype falls within the scope of data mining; we will limit discussion to a few specific data mining activities, which can all be illustrated using the following example. Consider the 10 haplotypes (rows) below (Tachmazidou et al., 2007) at each of 12 SNPs (columns). The rare allele is denoted "1," and the common allele is denoted "0." By inspection of the pattern of 0s and 1s, haplotypes 1 to 4 are somewhat distinguishable from haplotypes 5 to 10. Multidimensional scaling (Figure 1) is a method to display the distances between the 45 pairs of haplotypes (Venables and Ripley, 1999). Although there are several evolutionary-model-based distance definitions, the Manhattan distance (the number of differences between a given pair of haplotype) is defensible, and was used to create all three plots in Figure 1. The top plot in Figure 1 suggests that there are two or three genetic groups. Ideally, if there are only two phenotypes (disease present or absent), then there would be two genetic groups that correspond to the two phenotypes. In practice, because common diseases are proving to have a complex genetic component, it is common to have more than two genetic groups, arising, for example, due to racial or geographic subdivision structures in the sampled population (Liu et al., 2004).

haplotype1	1	0	0	0	1	0	1	0	0	0	1	0
haplotype2	1	0	0	0	1	0	1	0	0	0	0	0
haplotype3	1	0	0	0	0	0	1	0	0	0	0	0
haplotype4	1	0	0	0	0	0	0	0	0	1	0	0
haplotype5	0	1	0	0	0	1	0	0	0	0	0	1
haplotype6	0	1	0	0	0	1	0	0	0	0	0	0
haplotype7	0	0	0	1	0	1	0	0	0	0	0	0
haplotype8	0	0	0	1	0	1	0	0	1	0	0	0
haplotype9	0	0	0	1	0	1	0	1	1	0	0	0
haplotype10	0	0	1	0	0	1	0	0	0	0	0	0

The data mining activities described below include: defining genetics-model-based distance measures; selecting features; control of the false alarm rate; clustering in the context of phylogenetic tree building, and genomic control using genetic model fitting to protect against spurious association between halplotype and disease status.

Defining Genetics-Model-Based Distance Measures

Effective haplotype blocks in a GWAS requires small "within-block" variation relative to "between-block" variation. Variation can be defined and measured in several ways. One way is the Manhattan distance be-

tween pairs of corresponding haplotype blocks from two subjects. In cases, a more appropriate distance measure can accommodate missing data, insertion mutations, deletion mutations. and weights DNA differences by an evolutionary model under which, for example, an A to G mutation ("transition") is more likely than an A to T or A to C ("transversions") (Burr, 2006; Burr et al., 2002). As with most distance-based analyses, the choice of distance measure can impact the conclusions. A reasonable approach to choosing a distance measure is to select the most defensible evolutionary model for the genome region under study and then choose the corresponding distance measure. The GWAS concept is then to search for excess similarity among haplotypes from affected individuals (the "disease present" phenotype).

Feature Selection

One-SNP-site-at-a-time screening as previously illustrated is common, and often uses a statistical measure of association between allele frequency and phenotype (Stram, 2004). One such measure is Pearson's χ^2 test statistic that tests for independence between phenotype and genotype. This leads to an efficient preliminary screening for candidate association sites by requiring the minimum allele frequency to be above a threshold that depends on the false alarm rate (Hannu et al., 2000). This screening rule immediately rejects most candidate SNPs, thus greatly reducing the number of required calculations of the χ^2 statistic.

Defining and finding haplotype blocks is a data mining activity for which several methods have been proposed. Finding effective blocks is a specialized form of "feature selection," which is a common data mining activity. The task with the GWAS context is to find partition points and associated blocks such that the blocks are as large and as homogeneous as possible, as defined by block size and homogeneity specifications. Liu et al. (2004) describe a dynamic programming method to find effective blocks and show that the block structure within each of 16 particular human subpopulations is considerably different, as is the block structure for the entire set of 16 subpopulations. This implies that most if not all subpopulations will need to be deliberately included for an effective GWAS. A second feature selection approach (Stram, 2004) is based on choosing htSNPs in order to optimize the predictability of unmeasured SNPs. The concept is that the haplotype should be increasingly well predicted as more SNPs are genotyped, and leads to a different search strategy than the ones described by Liu et al. (2004).

A third feature selection approach invokes the well-known scan statistic. There are many versions of the scan statistic, but any scan statistic (Sun et al., 2006) scans a "window" of fixed or variable length to find regions of interest, based for example on elevated count rates within the window, or in the GWAS context, based on regions showing a strong clustering of low "*p*"-values associated with large values of the χ^2 statistic. The "*p*" value in this context is the probability of observing a χ^2 statistic as large as or larger than what is actually observed in the real (phenotype, genotype) data.

Controlling the False Alarm Rate

As with many data mining analyses, the false alarm rate in searching for SNPs that are associated with phenotype can be quite high; however, suitable precautions such as a permutation test reference distribution are straightforward, although they are computationally intensive (Toivonen et al., 2000). The permutation test assumes the hypothesis "no association between the SNP and phenotype," which would imply that the "case" and "control" labels are meaningless labels that can be randomly assigned (permuted). This type of random reassignment is computed many times, and in each random reassignment, the test statistic such as the χ^2 test is recalculated, producing a reference distribution of χ^2 values that can be compared with the χ^2 value computed using the actual case and control labels.

Clustering

Clustering involves partitioning sampled units (haplotypes in our case) into groups and is one of the most commonly-used data mining tools (Tachmazidou et al., 2007). Finding effective ways to choose the number of groups and the group memberships is a large topic in itself. Consider the aforementioned example with 10 subjects, each measured at 12 SNP sites. The top plot in Figure 1 is a two-dimensional scaling plot (Venables and Ripley, 1999) of the matrix of pairwise Manhattan distances among the 10 example haplotypes. Haplotypes {1,2,3,4}, {5,6,10}, and {7,8,9} are candidate clusters. Methods to choose the number of clusters are beyond our scope here; however, another reasonable clustering appears to be {1,2,3,4} and {5,6,7,8,9,10}. Burr (2006)

considers options for choosing the number of clusters for phylogenetic trees which describe the evolutionary history (branching order) of a group of taxa such as those being considered here.

The 12 SNP sites would typically be a very small fraction of the total number of sequenced sites. Suppose there are an additional 38 sites in the near physical vicinity on the genome but the SNP states are totally unrelated to the phenotype (disease present or absent) of interest. The middle plot of Figure 1 is based on all 50 SNP sites, and the resulting clustering is very ambiguous. The bottom plot is based on only SNP sites 1 and 6, which together would suggest the grouping {1,2,3,4} and {5,6,7,8,9,10}. The plotting symbols 1 to 10 are jittered slightly for readability.

Spurious Association

In many data mining applications, spurious associations are found, arising, for example, simply because so many tests for association are conducted, making it difficult to maintain a low false discovery rate. Spurious associations can also arise because effect A is linked to effect B only if factor C is at a certain level. For example, soft drink sales might link to sun poisoning incidence rates, not because of a direct causal link between soft drink sales and sun poisoning, but because both are linked to the heat index.

In GWAS, is it known that population subdivision can lead to spurious association between haplotype and phenotype (Liu et al., 2004). Bacanu et al. (2000) and Schaid (2004) show the potential power of using "genomic control" (GC) in a GWAS. The GC method adjusts for the nonindependence of subjects arising from the presence of subpopulations and other types of spurious associations. Schaid (2004) models the probability p that disease is present as a function of haplotype and covariates (possibly including subpopulation information), using, for example, a generalized linear model such as $y = \log(p/(1-p)) = f(X\beta) + \text{error}$, where haplotype and covariate information is captured in the X matrix, and β is estimated in order to relate X to y.

One common data mining activity is to evaluate many possible models relating predictors X to a scalar response y. Issues that arise include overfitting, error in X, nonrepresentative sampling of X (such as ignoring population substructure in a GWAS), feature selection, and selecting a functional form for $f()$. Standard data mining techniques such as cross validation or the use of held-out test data can help greatly in the general task of selecting an effective functional form for $f()$ that balances the tension between model complexity chosen to fit the training data well, and generalizability to new test data.

FUTURE TRENDS

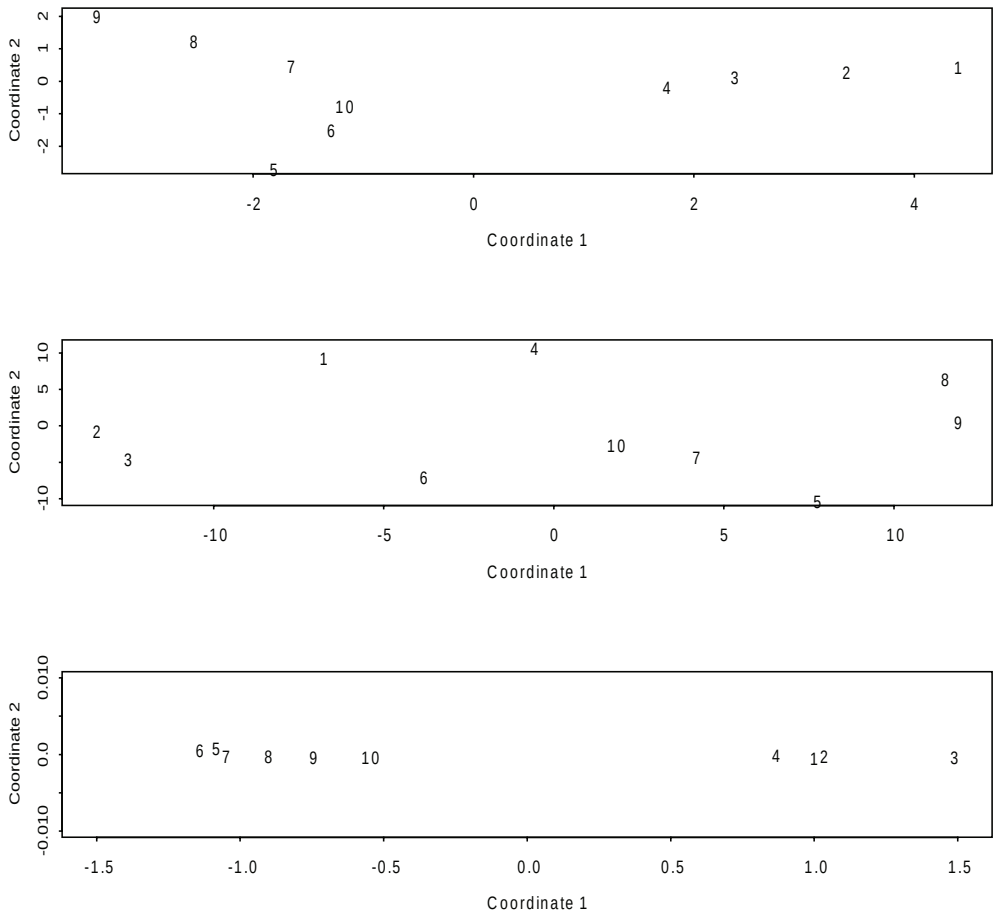
Searching for relations among multiple SNPs and phenotype will continue to use the techniques described. It is likely that evolutionary-model-based measures of haplotype similiarity will be increasingly invoked, and corresponding measures of genetic diversity in a sample will be developed.

Because it is now recognized that subpopulation structure can lead to spurious relations between phenotype (case or control, diseased or not, etc.) and allele frequency, genotype, and/or SNP state. Therefore, there is likely to be increasing attention to statistical sampling issues. For example, recent diabetes 2 literature has identified susceptibility loci on chromosomes 1q, 6, 11, and 14. However, Fingerlin et al. (2002) contradicts Hanis et al. (1996) regarding a susceptibility locus on chromosome 2. Such contradictions are not unusual, with many purported phenotype-genotype associations failing to be replicated. Resolving such a contradiction is related to the challenges previously described regarding finding effective haplotype "blocks" that can be replicated among samples. This particular contradiction appears to be explained by differences between Mexican-Americans and Finnish population samples.

Most common haplotypes occur in all human subpopulations; however, their frequencies differ among subpopulations. Therefore, data from several populations are needed to choose tag SNPs.

Pilot studies for the HapMap project found non-negligible differences in haplotype frequencies among population samples from Nigeria, Japan, China and the U.S. It is currently anticipated that GWAS using these four subpopulations should be useful for all subpopulations in the world. However, a parallel study is examining haplotypes in a set of chromosome regions in samples from several additional subpopulations. Several options to model subdivision and genetic exchange among partially subdivided populations are available and worth pursuing.

Figure 1. (top) Two-dimensional scaling plot of the matrix of pairwise Manhattan distances among the 10 example haplotypes. Haplotypes {1,2,3,4}, {5,6,10}, and {7,8,9} are candidate clusters. (middle) Same as top plot, except 0-1 values for each of an additional 38 SNP marker sites (a total of 50 SNP marker sites) are randomly added, rendering a very ambiguous clustering. (bottom) Same as top plot, except only marker sites 1 and 6 are used, resulting in a clear division into two clusters (the coordinate values are jittered slightly so the plotting symbols 1-10 can be read).



CONCLUSION

High throughput genomic technologies such as gene expression microarrays, SNP haplotype mapping as discussed here, array-based comparative genomic hybridization, etc., all involve genomic rather than single gene features of common human diseases.

Searching for relations among multiple SNPs and phenotype will continue to use the techniques described, including: genetics-model-based distance measures; feature selection; control of the false alarm rate; clustering in the context of phylogenetic tree building, and genomic control using genetic model fitting to protect against spurious association between halplotype and disease status.

Despite the challenges described here, GWAS successes have been reported, for example, for genotype-phenotype associations related to type 2 diabetes by Silander et al. (2005) and replicated by Zeggini et al. (2007).

KEY TERMS

Allele: A viable DNA (deoxyribonucleic acid) coding that occupies a given locus (site) on a chromosome.

Dynamic Programming: A method of solving problems that consist of overlapping subproblems by exploiting optimal substructure. Optimal substructure means that optimal solutions of subproblems can be used to find the optimal solution to the overall problem.

Haplotype: A haplotype is a set of single nucleotide polymorphisms (SNPs) on a single chromatid that are statistically associated.

Pearson χ^2 Test: A commonly-used statistical test used to detect association between two categorical variables, such as phenotype and allele type in our context.

Permutation Test: Is a statistical significance test in which a reference distribution is obtained by calculating many values of the test statistic by rearranging the labels (such as "case" and "control") on the observed data points.

Phenotype: The physical appearance of an organism, as opposed to its genotype**.** In our context, phenotype refers to whether the subject has the disease ("case") or does not ("control").

Phylogenetic Tree: A representation of the branching order and branch lengths of a collection of taxa, which, in its most common display form, looks like the branches of a tree.

Data Mining in Protein Identification by Tandem Mass Spectrometry

Haipeng Wang
Institute of Computing Technology & Graduate University of Chinese Academy of Sciences, China

INTRODUCTION

Protein identification (sequencing) by tandem mass spectrometry is a fundamental technique for proteomics which studies structures and functions of proteins in large scale and acts as a complement to genomics. Analysis and interpretation of vast amounts of spectral data generated in proteomics experiments present unprecedented challenges and opportunities for data mining in areas such as data preprocessing, peptide-spectrum matching, results validation, peptide fragmentation pattern discovery and modeling, and post-translational modification (PTM) analysis. This article introduces the basic concepts and terms of protein identification and briefly reviews the state-of-the-art relevant data mining applications. It also outlines challenges and future potential hot spots in this field.

BACKGROUND

Amino Acids, Peptides, and Proteins

An amino acid is composed of an amino group (NH_2), a carboxylic acid group (COOH), and a differentiating side chain (*R*). Each amino acid is represented by a letter from the English alphabet except B, J, O, U, X, and Z. A peptide or a protein is a chain that consists of amino acids linked together by peptide bonds. In this context, we refer to the products of enzymatic digestion of proteins as peptides.

Tandem Mass Spectrometry

Mass spectrometry (MS) is an analytical technique used to separate molecular ions and measure their mass-to-charge ratios (*m*/*z*). Tandem mass spectrometry (MS/MS), which can additionally fragment ionized molecules into pieces in a collision cell and measure the *m*/*z* values and ion current intensities of the pieces, is becoming increasingly indispensable for identifying complex protein mixtures in high-throughput proteomics.

MS-Based Protein Identification

According to the MS or MS/MS instrument adopted, there are two strategies for protein identification: peptide mass fingerprinting (PMF) and peptide fragment fingerprinting (PFF). The PFF approach is the focus of this article.

In a typical high-throughput PFF experiment, protein mixtures are digested with a site-specific protease (often trypsin) into complex peptide mixtures (e.g., the protein [AFCEFIVKLEDSE] digested into peptides [AFCEFIVK] and [LEDSE]). The resulted peptides are separated typically by liquid chromatography (LC) and sequentially fed into a MS/MS instrument. In this instrument the separated peptides are ionized with one or more units of charges, selected according to their *m*/*z* values, and broken into pieces by low-energy collision-induced dissociation (CID) resulting in various types of fragment ions (Figure 1). The fragment ions are measured to obtain a bundle of spectral peaks each comprising an *m*/*z* and an intensity values. Peaks plus the *m*/*z* value and charge state of a peptide ion constitutes a peptide MS/MS spectrum (Figure 2). It is not necessary that every possible fragment ion appear in the spectrum.

Figure 1. The nomenclature for various types of fragment ions

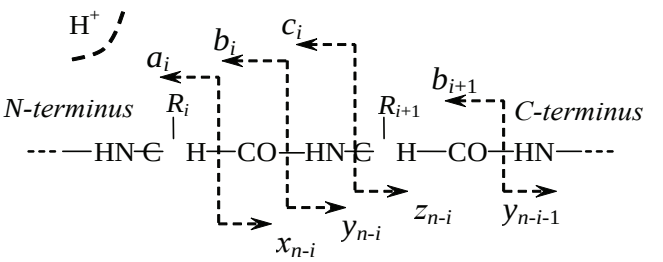

Figure 2. An example of a MS/MS spectrum and its annotation

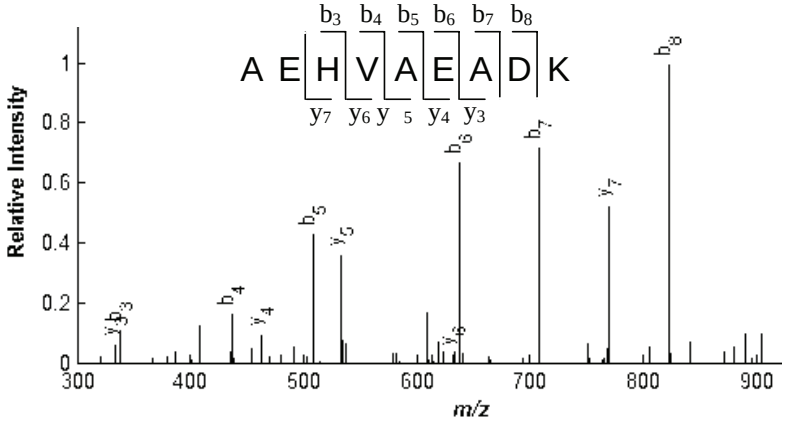

Peptide identification is the core of protein sequencing in that a protein sequence is identified from its constituent peptides with the help of protein databases. There are three different approaches for PFF peptide identification: database searching, *de novo* sequencing, and sequence tagging.

Database searching is the most widely used method in high-throughput proteomics. It correlates an experimental MS/MS spectrum with theoretical ones generated from a list of peptides digested *in silicon* from proteins in a database. As annotated MS/MS spectra increase, a spectrum library searching method which compares an experimental spectrum to previously identified ones in the reference library has recently proposed (Craig et al., 2006; Frewen et al., 2006). *De novo* sequencing tries to infer the complete peptide sequence directly from the *m*/*z* differences between peaks in a MS/MS spectrum without any help of databases. Sequence tagging yields one or more partial sequences by *de novo* sequencing, then finds homologous sequences in the protein database and finally scores the homologous candidate sequences to obtain the true peptide.

Robust data preprocessing, scoring scheme, validation algorithm, and fragmentation model are the keys to all of the above three approaches.

MAIN FOCUS

Preprocessing of MS/MS Spectra

The purpose of data preprocessing is to retain the potentially contributing data while removing the noisy or misleading ones as many as possible to improve the reliability and efficiency of protein identification. In general, only a relatively small fraction (say, <30%) of a large MS/MS spectra set is identified confidently due to some reasons. First, there exist some chemical or electronical noises in a spectrum resulting in random matches to peptides. Second, the peptide ion charge state of a spectrum is usually ambiguous due to the inability of instruments. Third, there are considerable duplicate spectra most likely representing a unique peptide. Four, many poor-quality spectra often have no results which can be filtered in advance using classification or regression methods. Clustering algorithms (Tabb et al., 2003; Beer et al., 2004), linear discriminant analysis (LDA) (Nesvizhskii et al., 2006), quadratic discriminant function (Xu et al., 2005), SVM (Bern et al., 2004; Klammer et al., 2005), linear regression (Bern et al., 2004), Bayesian rules (Colinge et al., 2003a; Flikka et al., 2006), decision tree and random forest (Salmi et al., 2006) have been widely used to address the above problems.

Scoring Scheme for Peptide Candidates

The goal of scoring is to find the true peptide-spectrum match (PSM). In principle there are two implementation frameworks for this goal: descriptive or probabilistic.

In descriptive frameworks, an experimental and a theoretical MS/MS spectra are represented as vectors $\mathbf{S} = (s_1,s_2,...,s_n)$ and $\mathbf{T} = (t_1,t_2,...,t_n)$, respectively, where n denotes the number of predicted fragments, s_i and t_i are binary values or the observed and predicted intensity

values of the *i*th fragment, respectively. The similarity between experimental and theoretical spectrum can be measured using shared peak count, spectral dot product (SDP) (Field et al., 2002) or cross-correlation (Eng et al., 1994). Fu et al. (2004) extends the SDP method by using kernel tricks to incorporate the information of consecutive fragment ions. SEQUEST and pFind are two representative software programs in this category.

In probabilistic frameworks, one strategy is to calculate a probability $P(\mathbf{S} \mid p, \ random)$ under the null hypothesis that the match between a peptide p and an experimental spectrum **S** is a random event (Perkins et al., 1999; Sadygov & Yates, 2003; Geer et al., 2004; Narasimhan et al., 2005). The hypergeometric distribution (Sadygov & Yates, 2003), Poisson distribution (Geer et al., 2004), and multinomial distribution (Narasimhan et al., 2005) was used to model the random matches. In another strategy, a probability $P(\mathbf{S} \mid p, correct)$ under the alternative hypothesis that a peptide p correctly generates a spectrum **S** is derived using certain fragmentation models (Bafna & Edwards, 2001; Zhang et al., 2002; Havilio et al., 2003; Wan et al., 2006). Wan et al. (2006) combined information on mass accuracy, peak intensity, and correlation among ions into a hidden Markov model (HMM) to calculate the probability of a PSM. As a combination of the above two ideas, a likelihood-ratio score can be obtained for assessing the relative tendency of peptide identifications being true or random (Colinge et al., 2003b; Elias et al., 2004). Elias et al. (2004) used probabilistic decision trees to model the random and true peptide matches respectively based on many features constructed from peptides and spectra and achieved significant improvement in suppressing false positive matches. Mascot and Phynex are two representative software programs in this framework (Perkins et al., 1999; Colinge et al., 2003b).

Validation of Peptide Identifications

Any of the scoring schemes sorts candidate peptides according to the score reflecting the similarity between the spectrum and the peptide sequence. Even if a peptide score is ranked at the first place, the score is not always sufficient for evaluating the correctness of a PSM. As a result, peptide identifications need to be carefully scrutinized manually (Chen et al., 2005) or automatically.

The common validation method is to use a threshold to filter peptide identifications (Elias et al., 2005). Its straightforward and operable features have facilitated proteomics experiments but it can not well balance the tradeoff between sensitivity and precision of peptide identification.

Some methods report the significance of peptide identifications by the E-value proposed in Fenyo & Beavis (2003). Keller et al. (2002) first used an LDA to separate true matches from random ones based on SEQUEST outputs and then derive a probability by applying an expectation-maximization (EM) algorithm to fit the Gaussian and gamma distributions of the LDA scores of true and random matches respectively.

Actually the LDA method in Keller et al. (2002) is just one kind of validation algorithms based on pattern classification methods such as SVM (Anderson et al., 2003), neural network (Baczek et al., 2004), decision tree and random forest (Ulintz et al., 2006), in which features were all extracted from SEQUEST outputs. Wang et al. (2006) developed an SVM scorer combining together the scoring and the validation processes of peptide identification. It can not only serve as a post-processing module for any peptide identification algorithm but also be an independent system. Robust feature extraction and selection form the basis of this method.

Peptide Fragmentation Models Under CID

The study of the mechanisms underlying peptide fragmentation will lead to more accurate peptide identification algorithms. Its history can be traced back to 1980's when the physicochemical methods were popular (Zhang, 2004; Paizs & Suhuai 2005). Recently, statistical methods have been applied to fragmentation pattern discovery (Wysocki et al. 2000; Kapp et al. 2003). The mobile-proton model, currently a most comprehensive model, was formed, improved, justified, and reviewed in the above references. Kapp et al. (2003) and Zhang (2004) are two representative methods based on two respective different strategies: top-down statistical and bottom-up chemical methods. The former explored the fragmentation trends between any two amino acids from a large database of identified PSMs and then applied a linear regression to fit the spectral peak intensities. The latter made an assumption that a certain spectrum is the result of the

competition of many different fragmentation pathways for a peptide under CID and a kinetic model based on the knowledge from the physicochemical domain was learnt from a training set of PSMs.

As Paizs & Suhai (2005) stated, the chemical and statistical methods will respectively provide a necessary framework and a quantitative description for the simulation of peptide fragmentation. Some databases of validated PSMs have been established to provide training data sets for discovery and modeling of peptide fragmentation mechanisms (Martens et al., 2005; McLaughlin et al., 2006).

FUTURE TRENDS

An ensemble scorer that combines together different types of scoring scheme will bring more confident identifications of MS/MS spectra. A peptide identification result with the corresponding estimated false positive rate is imperative. To assign peptides to proteins, there is an increased need for reliable protein inference algorithms with probability scores (Feng et al., 2007).

The algorithms combining database searching and *de novo* sequencing will be prevailing for reducing time complexity and improving robustness of current protein identification algorithms (Bern et al., 2007).

Peptide fragmentation modeling is still an open problem for data mining, proteomics and mass spectrometry communities. Nowadays, there is relatively little work involving this study. With more and more exposure to the mechanisms of peptide fragmentation from the physicochemical domain and intensively increased identified MS/MS spectra, the fragmentation model will be disclosed in a quantitative way.

Effective, efficient, practicable, especially unrestrictive PTM identification algorithms (Tanner et al., 2006; Havilio & Wool, 2007) are coming into focus in that most proteins undergo modification after being synthesized and PTM plays an extremely important role in protein function.

CONCLUSION

Protein identification based on MS/MS spectra is an interdisciplinary subject challenging both biologists and computer scientists. More effective data preprocessing, sensitive PSM scoring, and robust results validation are still the central tasks of protein identification, while the fields of peptide fragmentation modeling and PTM identification are making new opportunities for the development and application of data mining methods.

KEY TERMS

Bioinformatics: An interdisciplinary field that studies how to apply informatics to explore biological data.

Classification: A process that divides samples into several homogeneous subsets according to a model learnt from a training set of samples with known class labels.

Clustering: A process that groups samples into several subsets based on similarity (often distance measure).

Feature Extraction: A process of constructing features for describing a sample as characteristic as possible for clustering, classification or regression.

Feature Selection: A process of choosing an optimal subset of features from the existing features according to a specific purpose.

Precision: A ratio of the number of true positive samples to the total number of both false positive and true positive samples in a binary classification task.

Proteomics: A complement to genomics to study all the levels of proteins in a cell or a tissue under various physiological conditions in a high-throughput way.

Regression: A statistical method to determine the relationship between two variables.

Sensitivity (Recall): A ratio of the number of true positive samples to the total number of both false negative and true positive samples in a binary classification task.

Data Mining in Security Applications

Aleksandar Lazarevic
United Technologies Research Center, USA

INTRODUCTION

In recent years, research in many security areas has gained a lot of interest among scientists in academia, industry, military and governmental organizations. Researchers have been investigating many advanced technologies to effectively solve acute security problems. Data mining has certainly been one of the most explored technologies successfully applied in many security applications ranging from computer and physical security and intrusion detection to cyber terrorism and homeland security. For example, in the context of homeland security, data mining can be a potential means to identify terrorist activities, such as money transfers and communications, and to identify and track individual terrorists themselves, such as through travel and immigration records (Seifert, 2007). In another data mining's success story related to security, credit card fraud detection, all major credit card companies mine their transaction databases, looking for spending patterns that indicate a stolen card. In addition, data mining has also effectively been utilized in many physical security systems (e.g. in efficient system design tools, sensor fusion for false alarm reduction) and video surveillance applications, where many data mining based algorithms have been proposed to detect motion or intruder at monitored sites or to detect suspicious trajectories at public places.

This chapter provides an overview of current status of data mining based research in several security applications including cyber security and intrusion detection, physical security and video surveillance.

BACKGROUND

As the cost of the information processing and Internet accessibility falls, more and more organizations are becoming vulnerable to a wide variety of cyber threats. It has become increasingly important recently to make our information systems, especially those used for critical functions in the military and commercial sectors, resistant to and tolerant of such attacks. The conventional security mechanisms, such as firewalls, authentication mechanisms, Virtual Private Networks (VPN) almost always have inevitable vulnerabilities and they are usually insufficient to ensure complete security of the infrastructure and to ward off attacks that are continually being adapted to exploit the system's weaknesses. This has created the need for security technology, called intrusion detection that includes identifying malicious actions that compromise the integrity, confidentiality, and availability of information resources.

MAIN THRUST OF THE CHAPTER

Cyber Security and Intrusion Detection

Traditional intrusion detection systems (IDSs) are based on extensive knowledge of signatures (rule descriptions) of known attacks. However, the signature database has to be manually revised for each new type of intrusion that is discovered. In addition, signature-based methods cannot detect emerging cyber threats, since by their very nature these threats are launched using previously unknown attacks. These limitations have led to an increasing interest in intrusion detection techniques based upon data mining. Data mining techniques for cyber security and intrusion detection generally fall into one of two categories: misuse detection, and anomaly detection.

Misuse Detection

In misuse detection techniques, each instance in a data set is labeled as 'normal' or 'attack/intrusion' and a learning algorithm is trained over the labeled data. Unlike signature-based IDSs, data mining based misuse detection models are created automatically, and can be more sophisticated and precise than manually created signatures. In spite of the fact that misuse detection models have high degree of accuracy in detecting known attacks and their variations, their obvious drawback is

the inability to detect attacks whose instances have not yet been observed. In addition, labeling data instances as normal or intrusive may require enormous time for many human experts.

Since standard data mining techniques are not directly applicable to the problem of intrusion detection due to skewed class distribution (attacks/intrusions correspond to a much smaller, i.e. rarer class, than the class representing normal behavior) and streaming nature of data (attacks/intrusions very often represent sequence of events), a number of researchers have developed specially designed data mining algorithms suitable for intrusion detection. Research in misuse detection has focused mainly on classifying network intrusions using various standard data mining algorithms (Barbara, 2001; Lee, 2001), rare class predictive models (Joshi, 2001) and association rules (Barbara, 2001; Lee, 2000; Manganaris, 2000).

MADAM ID (Lee, 2000; Lee, 2001) was one of the first projects that applied data mining techniques to the intrusion detection problem. In addition to the standard features that were available directly from the network traffic (e.g. duration, start time, service), three groups of constructed features (content-based features that describe intrinsic characteristics of a network connection (e.g. number of packets, acknowledgments, data bytes from source to destination), time-based traffic features that compute the number of connections in some recent time interval and connection based features that compute the number of connections from a specific source to a specific destination in the last *N* connections) were also used by the RIPPER algorithm to learn intrusion detection rules. Other classification algorithms that are applied to the intrusion detection problem include standard decision trees (Bloedorn, 2001), modified nearest neighbor algorithms (Ye, 2001b), fuzzy association rules (Bridges, 2000), neural networks (Dao, 2002; Kumar, 2007; Zhang, 2005), support vector machines (Chen, 2005; Kim, 2005), naïve Bayes classifiers (Bosin, 2005; Schultz, 2001), genetic algorithms (Bridges, 2000; Kim, 2005; Li, 2004), genetic programming (Mukkamala, 2003), etc. Most of these approaches attempt to directly apply specified standard techniques to publicly available intrusion detection data sets (Lippmann, 1999; Lippmann, 2000), assuming that the labels for normal and intrusive behavior are already known. Since this is not realistic assumption, misuse detection based on data mining has not been very successful in practice.

Anomaly Detection

Anomaly detection creates profiles of normal "legitimate" computer activity (e.g. normal behavior of users (regular e-mail reading, web browsing, using specific software), hosts, or network connections) using different techniques and then uses a variety of measures to detect deviations from defined normal behavior as potential anomaly. Anomaly detection models often learn from a set of "normal" (attack-free) data, but this also requires cleaning data from attacks and labeling only normal data records. Nevertheless, other anomaly detection techniques detect anomalous behavior without using any knowledge about the training data. Such models typically assume that the data records that do not belong to the majority behavior correspond to anomalies.

The major benefit of anomaly detection algorithms is their ability to potentially recognize unforeseen and emerging cyber attacks. However, their major limitation is potentially high false alarm rate, since detected deviations may not necessarily represent actual attacks, but new or unusual, but still legitimate, network behavior.

Anomaly detection algorithms can be classified into several groups: (i) statistical methods; (ii) rule based methods; (iii) distance based methods (iv) profiling methods and (v) model based approaches (Lazarevic, 2005b). Although anomaly detection algorithms are quite diverse in nature, and thus may fit into more than one proposed category, most of them employ certain artificial intelligence techniques.

Statistical methods. Statistical methods monitor the user or system behavior by measuring certain variables over time (e.g. login and logout time of each session). The basic models keep averages of these variables and detect whether thresholds are exceeded based on the standard deviation of the variable. More advanced statistical models compute profiles of long-term and short-term user activities by employing different techniques, such as Chi-square (χ^2) statistics (Ye, 2001a), probabilistic modeling (Yamanishi, 2000), Markov-chain models (Zanero, 2006) and likelihood of data distributions (Eskin, 2000).

Distance based methods. Most statistical approaches have limitation when detecting outliers in higher dimensional spaces, since it becomes increasingly difficult and inaccurate to estimate the multidimensional distributions of the data points. Distance based approaches attempt to overcome these limitations by

detecting outliers using computed distances among points. Several distance based outlier detection algorithms (Lazarevic, 2003; Wang, 2004) as well as ensemble of outlier detection methods (Lazarevic, 2005a) that have been recently proposed for detecting anomalies in network traffic are based on computing the full dimensional distances of points from one another using all the available features, and on computing the densities of local neighborhoods. MINDS (Minnesota Intrusion Detection System) (Chandola 2006) employs outlier detection algorithms to routinely detect various intrusions that could not be detected using widely used traditional IDSs. These detected intrusions include various suspicious behavior and policy violations (e.g. identifying compromised machines, covert channels, illegal software), variations of worms (e.g., variations of slapper and slammer worms), as well as scanning activities (e.g., scans for unknown vulnerable ports, distributed scans). Many of these detected intrusions (scanning for Microsoft DS service on port 445/TCP) could not be detected using widely used traditional IDSs.

Several clustering based techniques, such as fixed-width and canopy clustering (Eskin, 2002), as well as density-based and grid-based clustering (Leung, 2005), have also been used to detect network intrusions as small clusters comparing to the large ones that corresponded to the normal behavior. In another interesting approach (Fan, 2001), artificial anomalies in the network intrusion detection data are generated around the edges of the sparsely populated "normal" data regions, thus forcing the learning algorithm to discover the specific boundaries that distinguish these "anomalous" regions from the "normal" data.

Rule based systems. Rule based systems were used in earlier anomaly detection based IDSs to characterize normal behavior of users, networks and/or computer systems by a set of rules. Examples of such rule based IDSs include ComputerWatch (Dowell, 1990) and Wisdom & Sense (Liepins, 1992). Recently, there were also attempts to automatically characterize normal behavior using association rules (Lee, 2001).

Profiling methods. In profiling methods, profiles of normal behavior are built for different types of network traffic, users, programs etc., and deviations from them are considered as intrusions. Profiling methods vary greatly ranging from different data mining techniques to various heuristic-based approaches.

For example, ADAM (Audit Data and Mining) (Barbara, 2001) is a hybrid anomaly detector trained on both attack-free traffic and traffic with labeled attacks. The system uses a combination of association rule mining and classification to discover novel attacks in tcpdump data by using the pseudo-Bayes estimator. Recently reported PHAD (packet header anomaly detection) (Mahoney, 2002) monitors network packet headers and builds profiles for 33 different fields (e.g., IP protocol, IP src/dest, IP/TCP src/dest ports) from these headers by observing attack free traffic and building contiguous clusters for the values observed for each field. ALAD (application layer anomaly detection) (Mahoney, 2002) uses the same method for calculating the anomaly scores as PHAD, but it monitors TCP data and builds TCP streams when the destination port is smaller than 1024.

Finally, there have also been several recently proposed commercial products that use profiling based anomaly detection techniques, such as Mazu Network Behavior Analysis system (Mazu Networks, 2007) and Peakflow X (Arbor Networks, 2007).

Model based approaches. Many researchers have used different types of data mining models such as replicator neural networks (Hawkins, 2002) or unsupervised support vector machines (Eskin, 2002; Lazarevic, 2003) to characterize the normal behavior of the monitored system. In the model-based approaches, anomalies are detected as deviations from the model that represents the normal behavior. Replicator four-layer feed-forward neural network reconstructs input variables at the output layer during the training phase, and then uses the reconstruction error of individual data points as a measure of outlyingness, while unsupervised support vector machines attempt to find a small region where most of the data lies, label these data points as a normal behavior, and then detect deviations from learned models as potential intrusions.

Physical Security and Video Surveillance

New types of intruder and terrorist threats around the world are accelerating the need for new, integrated security technologies that combine video and security analytics to help responders act faster during emergencies and potentially preempt attacks. This integrated vision of security is transforming the industry, revitalizing traditional surveillance markets and creating new opportunities for IT professionals. Networked video

surveillance systems apply powerful analytics to the video data and are known as intelligent video. Integration of many data sources into a common analytical frame of reference provides the grist for sophisticated forensic data mining techniques and unprecedented real-time awareness that can be used to quickly see the whole picture of what is occurring and trigger appropriate action.

There has been a surge of activity on using data mining techniques in video surveillance, based on extension of classification algorithms, similarity search, clustering and outlier detection techniques. Classification techniques for video surveillance include support vector machines to classify objects in far-field video images (Bose, 2002), Bhattacharya coefficients for automatic identification of events of interest, especially of abandoned and stolen objects in a guarded indoor environment (Ferrando 2006), and Mahalanobis classifiers for detecting anomalous trajectories as time series modeled using orthogonal basis function representations (Naftel 2006). In addition, non-metric similarity functions based on the Longest Common Subsequence (LCSS) have been used to provide an intuitive notion of similarity between video object trajectories in two or three dimensional space by giving more weight to the similar portions of the sequences (Vlachos 2002). The new measure has been demonstrated to be superior comparing to widely used Euclidean and Time Warping distance functions.

In clustering-based video surveillance techniques, trajectory clustering has been often active area of investigation. In (Foresti, 2005), a trajectory clustering method suited for video surveillance and monitoring systems was described, where the clusters are dynamic and built in real-time as the trajectory data is acquired. The obtained clusters have been successfully used both to give proper feedback to the low-level tracking system and to collect valuable information for the high-level event analysis modules. Yanagisawa and Satoh (Yanagisawa, 2006) have proposed using clustering to perform similarity queries between the shapes of moving object trajectories. Their technique is an extension of similarity queries for time series data, combined with velocities and shapes of objects.

Finally, detecting outliers from video data has gained a lot of interest recently. Researchers have been investigating various techniques including point distribution models and Hotteling's T2 statistics to detect outliers in trajectory data (De Meneses, 2005), Ullman and Basri's linear combination (LC) representation for outlier detection in motion tracking with an affine camera (Guo, 2005), and principal component analysis of 3D trajectories combined with incremental outlier detection algorithms to detect anomalies in simulated and real life experimental videos (Pokrajac, 2007).

FUTURE TRENDS

Along the changes around the world, the weapons and tools of terrorists and intruders are changing as well, thus leaving an opportunity for many artificial intelligence technologies to prove their capabilities in detecting and deterring criminals. Supported by FBI in the aftermath of September 11, data mining will start to be immensely involved in many homeland security initiatives. In addition, due to recent trend of integrating cyber and physical security, data from different monitoring systems will be integrated as well thus making a fruitful ground for various data mining techniques. There are an increasing number of government organizations and companies interested in using data mining techniques to detect physical intrusions, identify computer and network attacks, and provide video content analysis.

CONCLUSION

Data mining techniques for security application have improved dramatically over time, especially in the past few years, and they increasingly become an indispensable and integral component of any comprehensive enterprise security program, since they successfully complement traditional security mechanisms. Although a variety of techniques have been developed for many applications in security domain, there are still a number of open research issues concerning the vulnerability assessment, effectiveness of security systems, false alarm reduction and prediction performance that need to be addressed.

KEY TERMS

Intrusion: Malicious, externally induced, operational fault in the computer system.

Intrusion Detection: Identifying a set of malicious actions that compromise the integrity, confidentiality, and availability of information resources.

Misuse Detection: Analysis strategy that looks for events or sets of events that match a predefined pattern of a known attack.

Anomaly Detection: Analysis strategy that identifies intrusions as unusual behavior that differs from the normal behavior of the monitored system.

Signature-based Intrusion Detection: Analysis strategy where monitored events are matched against a database of attack signatures to detect intrusions.

Worms: Self-replicating programs that aggressively spread through a network, by taking advantage of automatic packet sending and receiving features found on many computers.

Physical / Electronic Security System: System consisting of tens or hundred of sensors (e,g., passive infrared, magnetic contacts, acoustic glass break, video cameras) that prevent, detect or deter attackers from accessing a facility, resource, or information stored on physical media.

Video Surveillance: Use of video cameras to transmit a signal to a specific, limited set of monitors where it is used for inspection of safety, possible crimes, traffic, etc.

Data Mining in the Telecommunications Industry

Gary Weiss
Fordham University, USA

INTRODUCTION

The telecommunications industry was one of the first to adopt data mining technology. This is most likely because telecommunication companies routinely generate and store enormous amounts of high-quality data, have a very large customer base, and operate in a rapidly changing and highly competitive environment. Telecommunication companies utilize data mining to improve their marketing efforts, identify fraud, and better manage their telecommunication networks. However, these companies also face a number of data mining challenges due to the enormous size of their data sets, the sequential and temporal aspects of their data, and the need to predict very rare events—such as customer fraud and network failures—in real-time.

The popularity of data mining in the telecommunications industry can be viewed as an extension of the use of expert systems in the telecommunications industry (Liebowitz, 1988). These systems were developed to address the complexity associated with maintaining a huge network infrastructure and the need to maximize network reliability while minimizing labor costs. The problem with these expert systems is that they are expensive to develop because it is both difficult and time-consuming to elicit the requisite domain knowledge from experts. Data mining can be viewed as a means of automatically generating some of this knowledge directly from the data.

BACKGROUND

The data mining applications for any industry depend on two factors: the data that are available and the business problems facing the industry. This section provides background information about the data maintained by telecommunications companies. The challenges associated with mining telecommunication data are also described in this section.

Telecommunication companies maintain data about the phone calls that traverse their networks in the form of *call detail* records, which contain descriptive information for each phone call. In 2001, AT&T long distance customers generated over 300 million call detail records per day (Cortes & Pregibon, 2001) and, because call detail records are kept online for several months, this meant that billions of call detail records were readily available for data mining. Call detail data is useful for marketing and fraud detection applications.

Telecommunication companies also maintain extensive customer information, such as billing information, as well as information obtained from outside parties, such as credit score information. This information can be quite useful and often is combined with telecommunication-specific data to improve the results of data mining. For example, while call detail data can be used to identify suspicious calling patterns, a customer's credit score is often incorporated into the analysis before determining the likelihood that fraud is actually taking place.

Telecommunications companies also generate and store an extensive amount of data related to the operation of their networks. This is because the network elements in these large telecommunication networks have some self-diagnostic capabilities that permit them to generate both status and alarm messages. These streams of messages can be mined in order to support network management functions, namely fault isolation and prediction.

The telecommunication industry faces a number of data mining challenges. According to a Winter Corporation survey (2003), the three largest databases all belong to telecommunication companies, with France Telecom, AT&T, and SBC having databases with 29, 26, and 25 Terabytes, respectively. Thus, the scalability of data mining methods is a key concern. A second issue is that telecommunication data is often in the form of transactions/events and is not at the proper semantic level for data mining. For example, one typically wants to mine call detail data at the customer (i.e., phone-

line) level but the raw data represents individual phone calls. Thus it is often necessary to *aggregate* data to the appropriate semantic level (Sasisekharan, Seshadri & Weiss, 1996) before mining the data. An alternative is to utilize a data mining method that can operate on the transactional data directly and extract sequential or temporal patterns (Klemettinen, Mannila & Toivonen, 1999; Weiss & Hirsh, 1998).

Another issue arises because much of the telecommunications data is generated in real-time and many telecommunication applications, such as fraud identification and network fault detection, need to *operate* in real-time. Because of its efforts to address this issue, the telecommunications industry has been a leader in the research area of mining data streams (Aggarwal, 2007). One way to handle data streams is to maintain a *signature* of the data, which is a summary description of the data that can be updated quickly and incrementally. Cortes and Pregibon (2001) developed signature-based methods and applied them to data streams of call detail records. A final issue with telecommunication data and the associated applications involves rarity. For example, both telecommunication fraud and network equipment failures are relatively rare. Predicting and identifying rare events has been shown to be quite difficult for many data mining algorithms (Weiss, 2004) and therefore this issue must be handled carefully in order to ensure reasonably good results.

MAIN FOCUS

Numerous data mining applications have been deployed in the telecommunications industry. However, most applications fall into one of the following three categories: marketing, fraud detection, and network fault isolation and prediction.

Telecommunications Marketing

Telecommunication companies maintain an enormous amount of information about their customers and, due to an extremely competitive environment, have great motivation for exploiting this information. For these reasons the telecommunications industry has been a leader in the use of data mining to identify customers, retain customers, and maximize the profit obtained from each customer. Perhaps the most famous use of data mining to acquire new telecommunications customers was MCI's Friends and Family program. This program, long since retired, began after marketing researchers identified many small but well connected subgraphs in the graphs of calling activity (Han, Altman, Kumar, Mannila & Pregibon, 2002). By offering reduced rates to customers in one's calling circle, this marketing strategy enabled the company to use their own customers as salesmen. This work can be considered an early use of social-network analysis and link mining (Getoor & Diehl, 2005). A more recent example uses the interactions between consumers to identify those customers likely to adopt new telecommunication services (Hill, Provost & Volinsky, 2006). A more traditional approach involves generating customer profiles (i.e., signatures) from call detail records and then mining these profiles for marketing purposes. This approach has been used to identify whether a phone line is being used for voice or fax (Kaplan, Strauss & Szegedy, 1999) and to classify a phone line as belonging to a either business or residential customer (Cortes & Pregibon, 1998).

Over the past few years, the emphasis of marketing applications in the telecommunications industry has shifted from identifying new customers to measuring customer value and then taking steps to retain the most profitable customers. This shift has occurred because it is much more expensive to acquire new telecommunication customers than retain existing ones. Thus it is useful to know the *total lifetime value* of a customer, which is the total net income a company can expect from that customer over time. A variety of data mining methods are being used to model customer lifetime value for telecommunication customers (Rosset, Neumann, Eick & Vatnik, 2003; Freeman & Melli, 2006).

A key component of modeling a telecommunication customer's value is estimating how long they will remain with their current carrier. This problem is of interest in its own right since if a company can predict when a customer is likely to leave, it can take proactive steps to retain the customer. The process of a customer leaving a company is referred to as *churn*, and *churn analysis* involves building a model of customer attrition. Customer churn is a huge issue in the telecommunication industry where, until recently, telecommunication companies routinely offered large cash incentives for customers to switch carriers. Numerous systems and methods have been developed to predict customer churn (Wei & Chin, 2002; Mozer, Wolniewicz, Grimes, Johnson, & Kaushansky, 2000; Mani, Drew, Betz & Datta, 1999; Masand, Datta, Mani,

& Li, 1999). These systems almost always utilize call detail and contract data, but also often use other data about the customer (credit score, complaint history, etc.) in order to improve performance. Churn prediction is fundamentally a very difficult problem and, consequently, systems for predicting churn have been only moderately effective—only demonstrating the ability to identify some of the customers most likely to churn (Masand et al., 1999).

Telecommunications Fraud Detection

Fraud is very serious problem for telecommunication companies, resulting in billions of dollars of lost revenue each year. Fraud can be divided into two categories: subscription fraud and superimposition fraud (Fawcett and Provost, 2002). *Subscription fraud* occurs when a customer opens an account with the intention of never paying the account and *superimposition fraud* occurs when a perpetrator gains illicit access to the account of a legitimate customer. In this latter case, the fraudulent behavior will often occur in parallel with legitimate customer behavior (i.e., is superimposed on it). Superimposition fraud has been a much more significant problem for telecommunication companies than subscription fraud. Ideally, both subscription fraud and superimposition fraud should be detected immediately and the associated customer account deactivated or suspended. However, because it is often difficult to distinguish between legitimate and illicit use with limited data, it is not always feasible to detect fraud as soon as it begins. This problem is compounded by the fact that there are substantial costs associated with investigating fraud, as well as costs if usage is mistakenly classified as fraudulent (e.g., an annoyed customer).

The most common technique for identifying superimposition fraud is to compare the customer's current calling behavior with a profile of his past usage, using deviation detection and anomaly detection techniques. The profile must be able to be quickly updated because of the volume of call detail records and the need to identify fraud in a timely manner. Cortes and Pregibon (2001) generated a signature from a data stream of call-detail records to concisely describe the calling behavior of customers and then they used anomaly detection to "measure the unusualness of a new call relative to a particular account." Because new behavior does not necessarily imply fraud, this basic approach was augmented by comparing the new calling behavior to profiles of generic fraud—and fraud is only signaled if the behavior matches one of these profiles. Customer level data can also aid in identifying fraud. For example, price plan and credit rating information can be incorporated into the fraud analysis (Rosset, Murad, Neumann, Idan, & Pinkas, 1999). More recent work using signatures has employed dynamic clustering as well as deviation detection to detect fraud (Alves et al., 2006). In this work, each signature was placed within a cluster and a change in cluster membership was viewed as a potential indicator of fraud.

There are some methods for identifying fraud that do not involve comparing new behavior against a profile of old behavior. Perpetrators of fraud rarely work alone. For example, perpetrators of fraud often act as brokers and sell illicit service to others—and the illegal buyers will often use different accounts to call the same phone number again and again. Cortes and Pregibon (2001) exploited this behavior by recognizing that certain phone numbers are repeatedly called from compromised accounts and that calls to these numbers are a strong indicator that the current account may be compromised. A final method for detecting fraud exploits human pattern recognition skills. Cox, Eick & Wills (1997) built a suite of tools for visualizing data that was tailored to show calling activity in such a way that unusual patterns are easily detected by users. These tools were then used to identify international calling fraud.

Telecommunication Network Fault Isolation and Prediction

Monitoring and maintaining telecommunication networks is an important task. As these networks became increasingly complex, expert systems were developed to handle the alarms generated by the network elements (Weiss, Ros & Singhal, 1998). However, because these systems are expensive to develop and keep current, data mining applications have been developed to identify and predict network faults. Fault identification can be quite difficult because a single fault may result in a cascade of alarms—many of which are not associated with the root cause of the problem. Thus an important part of fault identification is alarm correlation, which enables multiple alarms to be recognized as being related to a single fault.

The Telecommunication Alarm Sequence Analyzer (TASA) is a data mining tool that aids with fault identification by looking for frequently occurring temporal patterns of alarms (Klemettinen, Mannila & Toivonen, 1999). Patterns detected by this tool were then used to help construct a rule-based alarm correlation system. Another effort, used to predict telecommunication switch failures, employed a genetic algorithm to mine historical alarm logs looking for predictive sequential and temporal patterns (Weiss & Hirsh, 1998). One limitation with the approaches just described is that they ignore the structural information about the underlying network. The quality of the mined sequences can be improved if topological proximity constraints are considered in the data mining process (Devitt, Duffin and Moloney, 2005) or if substructures in the telecommunication data can be identified and exploited to allow simpler, more useful, patterns to be learned (Baritchi, Cook, & Lawrence, 2000). Another approach is to use Bayesian Belief Networks to identify faults, since they can reason about causes and effects (Sterritt, Adamson, Shapcott & Curran, 2000).

FUTURE TRENDS

Data mining should play an important and increasing role in the telecommunications industry due to the large amounts of high quality data available, the competitive nature of the industry and the advances being made in data mining. In particular, advances in mining data streams, mining sequential and temporal data, and predicting/classifying rare events should benefit the telecommunications industry. As these and other advances are made, more reliance will be placed on the knowledge acquired through data mining and less on the knowledge acquired through the time-intensive process of eliciting domain knowledge from experts—although we expect human experts will continue to play an important role for some time to come.

Changes in the nature of the telecommunications industry will also lead to the development of new applications and the demise of some current applications. As an example, the main application of fraud detection in the telecommunications industry used to be in cellular cloning fraud, but this is no longer the case because the problem has been largely eliminated due to technological advances in the cell phone authentication process. It is difficult to predict what future changes will face the telecommunications industry, but as telecommunication companies start providing television service to the home and more sophisticated cell phone services become available (e.g., music, video, etc.), it is clear that new data mining applications, such as recommender systems, will be developed and deployed.

Unfortunately, there is also one troubling trend that has developed in recent years. This concerns the increasing belief that U.S. telecommunication companies are too readily sharing customer records with governmental agencies. This concern arose in 2006 due to revelations—made public in numerous newspaper and magazine articles—that telecommunications companies were turning over information on calling patterns to the National Security Agency (NSA) for purposes of data mining (Krikke, 2006). If this concern continues to grow unchecked, it could lead to restrictions that limit the use of data mining for legitimate purposes.

CONCLUSION

The telecommunications industry has been one of the early adopters of data mining and has deployed numerous data mining applications. The primary applications relate to marketing, fraud detection, and network monitoring. Data mining in the telecommunications industry faces several challenges, due to the size of the data sets, the sequential and temporal nature of the data, and the real-time requirements of many of the applications. New methods have been developed and existing methods have been enhanced to respond to these challenges. The competitive and changing nature of the industry, combined with the fact that the industry generates enormous amounts of data, ensures that data mining will play an important role in the future of the telecommunications industry.

KEY TERMS

Bayesian Belief Network: A model that predicts the probability of events or conditions based on causal relations.

Call Detail Record: Contains the descriptive information associated with a single phone call.

Churn: Customer attrition. Churn prediction refers to the ability to predict that a customer will leave a company before the change actually occurs.

Signature: A summary description of a subset of data from a data stream that can be updated incrementally and quickly.

Subscription Fraud: Occurs when a perpetrator opens an account with no intention of ever paying for the services incurred.

Superimposition Fraud: Occurs when a perpetrator gains illicit access to an account being used by a legitimate customer and where fraudulent use is "superimposed" on top of legitimate use.

Total Lifetime Value: The total net income a company can expect from a customer over time.

Data Mining Lessons Learned in the Federal Government

Les Pang
National Defense University, USA

INTRODUCTION

Data mining has been a successful approach for improving the level of business intelligence and knowledge management throughout an organization. This article identifies lessons learned from data mining projects within the federal government including military services. These lessons learned were derived from the following project experiences:

- Defense Medical Logistics Support System Data Warehouse Program
- Department of Defense (DoD) Defense Financial and Accounting Service (DFAS) "Operation Mongoose"
- DoD Computerized Executive Information System (CEIS)
- Department of Homeland Security's Analysis, Dissemination, Visualization, Insight, and Semantic Enhancement (ADVISE) Program
- Department of Transportation (DOT) Executive Reporting Framework System
- Federal Aviation Administration (FAA) Aircraft Accident Data Mining Project
- General Accountability Office (GAO) Data Mining of DoD Purchase and Travel Card Programs
- U.S. Coast Guard Executive Information System
- Veteran Administrations (VA) Demographics System

BACKGROUND

Data mining involves analyzing diverse data sources in order to identify relationships, trends, deviations and other relevant information that would be valuable to an organization. This approach typically examines large single databases or linked databases that are dispersed throughout an organization. Pattern recognition technologies and statistical and mathematical techniques are often used to perform data mining. By utilizing this approach, an organization can gain a new level of corporate knowledge that can be used to address its business requirements.

Many agencies in the federal government have applied a data mining strategy with significant success. This chapter aims to identify the lessons gained as a result of these many data mining implementations within the federal sector. Based on a thorough literature review, these lessons were uncovered and selected by the author as being critical factors which led toward the success of the real-world data mining projects. Also, some of these lessons reflect novel and imaginative practices.

MAIN THRUST

Each lesson learned (indicated in **boldface**) is listed below. Following each practice is a description of illustrative project or projects (indicated in *italics*), which support the lesson learned.

Avoid the Privacy Trap

DoD Computerized Executive Information System: Patients as well as the system developers indicate their concern for protecting the privacy of individuals -- their medical records need safeguards. "Any kind of large database like that where you talk about personal info raises red flags," said Alex Fowler, a spokesman for the Electronic Frontier Foundation. "There are all kinds of questions raised about who accesses that info or protects it and how somebody fixes mistakes" (Hamblen, 1998).

Proper security safeguards need to be implemented to protect the privacy of those in the mined databases. Vigilant measures are needed to ensure that only authorized individuals have the capability of accessing, viewing and analyzing the data. Efforts should also

be made to protect the data through encryption and identity management controls.

Evidence of the public's high concern for privacy was the demise of the Pentagon's $54 million Terrorist Information Awareness (originally, Total Information Awareness) effort -- the program in which government computers were to be used to scan an enormous array of databases for clues and patterns related to criminal or terrorist activity. To the dismay of privacy advocates, many government agencies are still mining numerous databases (General Accounting Office, 2004; Gillmor, 2004). "Data mining can be a useful tool for the government, but safeguards should be put in place to ensure that information is not abused," stated the chief privacy officer for the Department of Homeland Security (Sullivan, 2004). Congressional concerns on privacy are so high that the body is looking at introducing legislation that would require agencies to report to Congress on data mining activities to support homeland security purposes (Miller, 2004). Privacy advocates have also expressed concern over Analysis, Dissemination, Visualization, Insight, and Semantic Enhancement (ADVISE), a data mining research and development program within the Department of Homeland Security (DHS). (Clayton, 2006).

The Center for Democracy and Technology calls for three technical solutions to address privacy: apply anonymization techniques so that data mining analysts can share information with authorities without disclosing the identity of individuals; include authorization requirements into government systems for reviewing data to ensure that only those who need to see the data do, and utilize audit logs to identify and track inappropriate access to data sources.

Steer Clear of the "Guns Drawn" Mentality if Data Mining Unearths a Discovery

DoD Defense Finance & Accounting Service's Operation Mongoose was a program aimed to discover billing errors and fraud through data mining. About 2.5 million financial transactions were searched to locate inaccurate charges. This approach detected data patterns that might indicate improper use. Examples include purchases made on weekends and holidays, entertainment expenses, highly frequent purchases, multiple purchases from a single vendor and other transactions that do not match with the agency's past purchasing patterns. It turned up a cluster of 345 cardholders (out of 400,000) who had made suspicious purchases.

However, the process needs some fine-tuning. As an example, buying golf equipment appeared suspicious until it was learned that a manager of a military recreation center had the authority to buy the equipment. Also, casino-related expense revealed to be a commonplace hotel bill. Nevertheless, the data mining results have shown sufficient potential that data mining will become a standard part of the Department's efforts to curb fraud.

Create a Business Case Based on Case Histories to Justify Costs

FAA Aircraft Accident Data Mining Project involved the Federal Aviation Administration hiring MITRE Corporation to identify approaches it can use to mine volumes of aircraft accident data to detect clues about their causes and how those clues could help avert future crashes (Bloedorn, 2000). One significant data mining finding was that planes with instrument displays that can be viewed without requiring a pilot to look away from the windshield were damaged a smaller amount in runway accidents than planes without this feature.

On the other hand, the government is careful about committing significant funds to data mining projects. "One of the problems is how do you prove that you kept the plane from falling out of the sky," said Trish Carbone, a technology manager at MITRE. It is difficult to justify data mining costs and relate it to benefits (Matthews, 2000).

One way to justify data mining program is to look at past successes in data mining. Historically, fraud detection has been the highest payoff in data mining, but other areas have also benefited from the approach such as in sales and marketing in the private sector. Statistics (dollars recovered) from efforts such as this can be used to support future data mining projects.

Use Data Mining for Supporting Budgetary Requests

Veteran's Administration Demographics System predicts demographic changes based on patterns among its 3.6 million patients as well as data gathered from insurance companies. Data mining enables the VA to provide Congress with much more accurate budget requests. The VA spends approximately $19 billion a

year to provide medical care to veterans. All government agencies such as the VA are under increasing scrutiny to prove that they are operating effectively and efficiently. This is particularly true as a driving force behind the President's Management Agenda (Executive Office of the President, 2002). For many, data mining is becoming the tool of choice to highlight good performance or dig out waste.

United States Coast Guard developed an executive information system designed for managers to see what resources are available to them and better understand the organization's needs. Also, it is also used to identify relationships between Coast Guard initiatives and seizures of contraband cocaine and establish tradeoffs between costs of alternative strategies. The Coast Guard has numerous databases; content overlap each other; and only one employee understands each database well enough to extract information. In addition, field offices are organized geographically but budgets are drawn up by programs that operate nationwide. Therefore, there is a disconnect between organizational structure and appropriations structure. The Coast Guard successfully used their data mining program to overcome these issues (Ferris, 2000).

DOT Executive Reporting Framework (ERF) aims to provide complete, reliable and timely information in an environment that allows for the cross-cutting identification, analysis, discussion and resolution of issues. The ERF also manages grants and operations data. Grants data shows the taxes and fees that DOT distributes to the states' highway and bridge construction, airport development and transit systems. Operations data covers payroll, administrative expenses, travel, training and other operations cost. The ERF system accesses data from various financial and programmatic systems in use by operating administrators.

Before 1993 there was no financial analysis system to compare the department's budget with congressional appropriations. There was also no system to track performance against the budget or how they were doing with the budget. The ERF system changed this by tracking of the budget and providing the ability to correct any areas that have been over planned. Using ERF, adjustments were made within the quarter so the agency did not go over budget. ERF is being extended to manage budget projections, development and formulation. It can be used as a proactive tool, which allows an agency to be more dynamically to project ahead. The system has improved financial accountability in the agency (Ferris, 1999).

Give Users Continual Computer-Based Training

DoD Medical Logistics Support System (DMLSS) built a data warehouse with a front-end decision support/data mining tools to help manage the growing costs of health care, enhance health care delivery, enhance health delivery in peacetime and promote wartime readiness and sustainability. DMLSS is responsible for the supply of medical equipment and medicine worldwide for DoD medical care facilities. The system received recognition for reducing the inventory in its medical depot system by 80 percent and reducing supply request response time from 71 to 15 days (Government Computer News, 2001). One major challenge faced by the agency was the difficulty in keeping up on the training of users because of the constant turnover of military personnel. It was determined that there is a need to provide quality computer-based training on a continuous basis (Olsen, 1997).

Provide the Right Blend of Technology, Human Capital Expertise and Data Security Measures

General Accountability Office used data mining to identify numerous instances of illegal purchases of goods and services from restaurants, grocery stores, casinos, toy stores, clothing retailers, electronics stores, gentlemen's clubs, brothels, auto dealers and gasoline service stations. This was all part of their effort to audit and investigate federal government purchase and travel card and related programs (General Accounting Office, 2003).

Data mining goes beyond using the most effective technology and tools. There must be well-trained individuals involved who know about the process, procedures and culture of the system being investigated. They need to understand the capabilities and limitation of data mining concepts and tools. In addition, these individual must recognize the data security issues associated with the use of large, complex and detailed databases.

Leverage Data Mining to Detect Identity Theft

Identity theft, the illegal use of another individual's identity, has resulted in significant financial losses for

innocent individuals. *Department of Education's Title IV Identity Theft Initiative* deals with identity theft focusing on education loans. (General Accounting Office, 2004)

FUTURE TRENDS

Despite the privacy concerns, data mining continues to offer much potential in identifying waste and abuse, potential terrorist and criminal activity, and identify clues to improve efficiency and effectiveness within organizations. This approach will become more pervasive because of its integration with online analytical tools, the improved ease of use in utilizing data mining tools and the appearance of novel visualization techniques for reporting results. Also, the emergence of a new branch of data mining called text mining to help improve the efficiency of searching on the Web. This approach transforms textual data into a useable format that facilitates classifying documents, finds explicit relationships or associations among documents, and clusters documents into categories (SAS, 2004).

CONCLUSION

These lessons learned may or may not fit in all environments due to cultural, social and financial considerations. However, the careful review and selection of relevant lessons learned could result in addressing the required goals of the organization by improving the level of corporate knowledge.

A decision maker needs to think "outside the box" and move away from the traditional approaches to successfully implement and manage their programs. Data mining poses a challenging but highly effective approach to improve business intelligence within one's domain.

KEY TERMS

Computer-Based Training: A recent approach involving the use of microcomputer, optical disks such as compact disks, and/or the Internet to address an organization's training needs.

Executive Information sSystem: An application designed for the top executives that often features a dashboard interface, drill-down capabilities and trend analysis.

Federal Government: The national government of the United States, established by the Constitution, which consists of the executive, legislative, and judicial branches. The head of the executive branch is the President of the United States. The legislative branch consists of the United States Congress, and the Supreme Court of the United States is the head of the judicial branch.

Legacy System: Typically, a database management system in which an organization has invested considerable time and money and resides on a mainframe or minicomputer.

Logistics Support System: A computer package that assists in the planning and deploying the movement and maintenance of forces in the military. The package could deals with the design and development, acquisition, storage, movement, distribution, maintenance, evacuation and disposition of material; movement, evacuation, and hospitalization of personnel; acquisition of construction, maintenance, operation and disposition of facilities; and acquisition of furnishing of services.

Purchase Cards: Credit cards used in the federal government used by authorized government official for small purchases, usually under $2,500.

Travel Cards: Credit cards issued to federal employees to pay for costs incurred on official business travel.

A Data Mining Methodology for Product Family Design

Seung Ki Moon

Soundar R. T. Kumara
The Pennsylvania State University, USA

INTRODUCTION

Many companies strive to maximize resource utilization by sharing and reusing distributed design knowledge and information when developing new products. By sharing and reusing assets such as components, modules, processes, information, and knowledge across a family of products and services, companies can efficiently develop a set of differentiated products by improving the flexibility and responsiveness of product development (Simpson, 2004). Product family planning is a way to achieve cost-effective mass customization by allowing highly differentiated products to be developed from a shared platform while targeting products to distinct market segments (Shooter et al., 2005).

In product design, data mining can be used to help identify customer needs, to find relationships between customer needs and functional requirements, and to cluster products based on functional similarity to facilitate modular design (Braha, 2001). The objective in this chapter is to introduce a methodology for identifying a platform along with variant and unique modules in a product family using design knowledge extracted with data mining techniques. During conceptual design, data mining can facilitate decision-making when selecting design concepts by extracting design knowledge and rules, clustering design cases, and exploring conceptual designs in large product design databases interactively (Braha, 2001). Moreover, since design knowledge for a product depends on the experience and knowledge of designers, representation of design knowledge, such as linguistic representation, may fail to describe a crisp representation completely. When clustering design knowledge, the knowledge is needed to assign to clusters with varying degrees of membership. Fuzzy membership can be used to represent and model the fuzziness of design knowledge (Braha, 2001). Design knowledge can be defined as linguistic variables based on the fuzzy set theory to support decision-making in product development (Ma et al., 2007).

BACKGROUND

A product family is a group of related products based on a product platform, facilitating mass customization by providing a variety of products for different market segments cost-effectively (Simpson et al., 2005). A successful product family depends on how well the trade-offs between the economic benefits and performance losses incurred from having a platform are managed. Various data mining approaches have been applied to product family design and product development. Clustering can be used to group customers or functions of similar behavior (Agard & Kusiak, 2004; Jiao & Zhang, 2005). Also, functional requirements in existing products can be clustered based on the similarity between them. This process can be achieved by using clustering methods such as the k-means algorithm, hierarchical algorithms, pattern recognition, Bayesian statistics, neural networks, and support vector machines. Agard and Kusiak (2004) proposed a three-step method for the design of product families based on the analysis of customers' requirements using a data mining approach. In the first step, data mining algorithms are used for customer segmentation. The second step provides a function structure to satisfy the diversified requirements. A product structure and distinguished modules for the product variability are designed in the final step. Moon et al. (2006) introduced a methodology

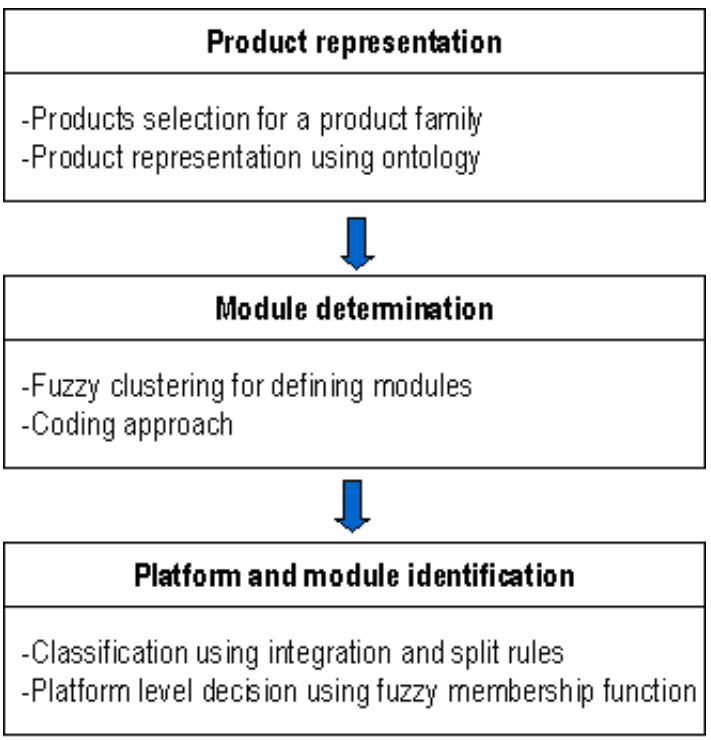
for identifying a platform and modules for product family design using fuzzy clustering, association rule mining, and classification. Ma et al. (2007) presented a decision-making support model for customized product color combination using the fuzzy analytic hierarchy process (FAHP) that utilizes the fuzzy set theory to integrate with AHP.

Sharing and reusing product design information can help eliminate such wastes and facilitate good product family design. To share and reuse the information, it is important to adopt an appropriate representation scheme for components and products. An ontology consists of a set of concepts or terms and their relationships that describe some area of knowledge or build a representation of it (Swartout & Tate, 1999). Ontologies can be defined by identifying these concepts and the relationships between them and have simple rules to combine concepts for a particular domain. Representing products and product families by ontologies can provide solutions to promote component sharing, and assist designers search, explore, and analyze linguistic and parametric product family design information (Nanda et al., 2007).

MAIN FOCUS

This chapter describes a methodology for identifying a platform along with variant and unique modules in a product family using an ontology and data mining techniques. Figure 1 shows the proposed methodology that consists of three phases: (1) product representation, (2) module determination, and (3) platform and module identification. An ontology is used to represent products and components. Fuzzy clustering is employed to determine initial clusters based on the similarity among functional features. The clustering result is identified as the platform while modules are identified through the fuzzy set theory and classification. A description of each phase follows.

Figure 1. Methodology for platform and module identification



Phase 1: Product Representation

The basic idea of modular design is to organize products as a set of distinct components that can be designed independently and develop a variety of products through the combination and standardization of components (Kamrani & Salhieh, 2000). A product can be defined by its modules that consist of specific functions, and functions are achieved by the combination of the module attributes. To effectively define the relationship between functional hierarchies in a product, it is important to adopt an appropriate representation scheme for the products. The Techspecs Concept Ontology (TCO) is used to represent products and components (Moon et al., 2005). TCO provides functional representation-based semantics of products or components to better reflect customers' preferences and market needs.

Suppose that a product family consists of l products, $PF = (P_1, P_2, \ldots, P_l)$ and a product consists of m_i modules, $P_i = (\mathbf{x}_{i,1}, \mathbf{x}_{i,2},\ldots\mathbf{x}_{i,j},\ldots,\mathbf{x}_{i,m_i})$, where $\mathbf{x}_{i,j}$ is a module j in product i and consists of a vector of length n_m, $\mathbf{x}_{i,j} = (x_{i,j,1}, x_{i,j,2},\ldots x_{i,j,k},\ldots,x_{i,j,n_m})$, and the individual scalar components $x_{i,j,k}$ (k=1, 2,…, n_m) of a module $\mathbf{x}_{i,j}$ are called *functional features*. The functional feature consists of several attributes $a_{i,j,k,t}$ (t=1, 2,…, t_n), representing the function, $x_{i,j,k} = (a_{i,j,k,1}, a_{i,j,k,2},..., a_{i,j,k,t},..., a_{i,j,k,t_n})$, where t_n is the number of attributes represented by TCO.

Phase 2: Module Determination

Functional decomposition for a product can be represented in a hierarchical structure. A hierarchical clustering method can classify a set of objects by measuring the similarity between objects (Miyamoto, 1990). Because heuristic methods used to define a module may provide overlapping or non-crisp boundaries among module clusters (Stone et al., 2000), the results of traditional clustering approaches are not appropriate to define clusters as modules in product design. Fuzzy clustering approaches can use fuzziness related to product design features and provide more useful solutions (Liao, 2001). Fuzzy c-means clustering (FCM) (Bezdek, 1981) is employed to determine clusters for identifying modules for the product family. FCM is a clustering technique that is similar to k-means but uses fuzzy partitioning of data that is associated with different membership values between 0 and 1. Since FCM is an iterative algorithm, the aim in FCM is to find cluster centers that minimize a dissimilarity function.

Let X_k for k = 1, 2, …, n be a functional feature and a d-dimensional vector (d is the number of attributes), and u_{ik} the membership of X_k to the i-th cluster (i=1, 2, …, c). The u_{ik} representing a fuzzy case is between 0 and 1. For example, if $u_{ik} = 0$, u_{ik} has non-membership to cluster i, and if $u_{ik} = 1$, then it has full membership. Values in between 0 and 1 indicate fractional membership. Generally, FCM is defined as the solution of the following minimization problem (Bezdek, 1981):

$$J_{FCM}(U,V) = \{\sum_{i=1}^{c}\sum_{k=1}^{n}(u_{ik})^m \left\|X_k - v_i\right\|^2\} \quad (1)$$

subject to:

$$\sum_{i=1}^{c} u_{ik} = 1, \text{ for all } k \quad (2)$$

$$u_{ik} \in [0,1] \quad (3)$$

where v_i is a cluster center of the i-th cluster that consists of a d-dimensional vector, and m is a parameter ($m \geq 1$) that plays a central role and indicates the fuzziness of clusters. An algorithm for solving this problem is introduced in Refs. (Bezdek, 1981; Torra, 2005). This FCM algorithm does not ensure that it converges to a global optimal solution; however, it always converges to a local optimum that may lead to a different local minima according to different initial cluster centers (Bezdek, 1981; Torra, 2005). The cluster number can be considered as the number of modules. A maximum membership value in clusters is an indicator for assigning to a module that can be considered as a group of similar functional features. Among clusters, clusters including the functional features for all selected products can be common modules for the platform.

In the proposed methodology, a coding approach is used to represent the attributes of components for a given clustering method. Each attribute takes a different code (number) based on functional features that are described as the functional basis proposed by Hirtz et al. (2002). The coding approach is problem-dependent, but an example can be found in the case study as it pertains to a power tool family.

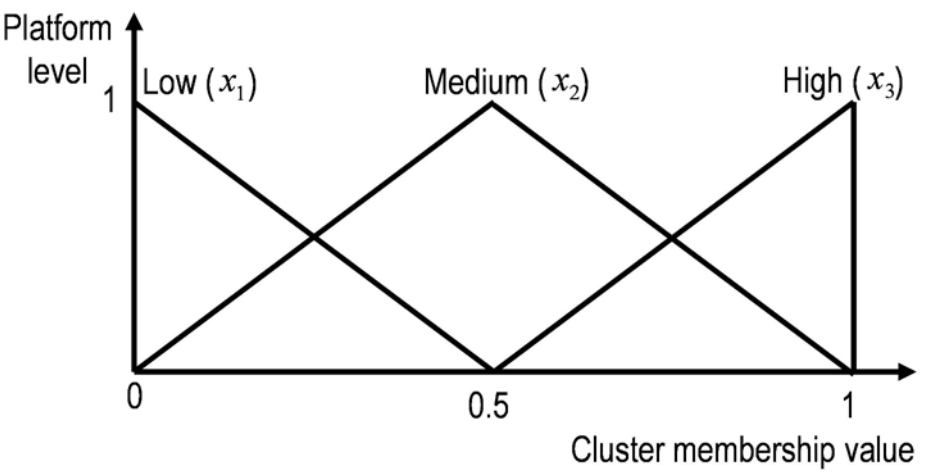
Phase 3: Platform and Module Identification

Classification is a learning technique to separate distinct classes and map data into one of several predefined classes (Johnson & Wichern, 2002). Classification approaches use classification rules that are usually developed from "learning" or "training" samples of pre-classified records (Braha, 2001; Johnson & Wichern, 2002). The process of generating classification rules is achieved using learning algorithms (Braha, 2001). Since the clusters in FCM are determined based on functional features, additional analysis is needed to define the modules. A designer can extract important design features that are represented by integration rules and split rules extracted from TCO. These design features are classified and translated into knowledge and rules for product design. Design rules can be translated into specific integration and split rules that can be used to classify clusters. If two clusters have the same module, then the modules are combined using the integration rule. Otherwise, if a cluster has several modules, then the cluster is divided into the number of products in the cluster using the split rule.

The clustering results provide membership values that represent the corresponding membership level of each cluster, which can be considered as the degree of similarity among functional features. Based on the fuzzy set theory (Zadeh, 1965), the membership values are measured in a rating scale of [0-1], and the ratings can be interpreted as fuzzy numbers based on different platform levels such as Low, Medium, and, High. Let X be a linguistic variable with the label "Platform level" with U = [0, 1]. Terms of this linguistic variable, fuzzy set, could be called "Low (x_1) - Medium (x_2) - High (x_3) platform level". As shown in Figure 2, the membership function of each fuzzy set is assumed to be triangular, and the platform level can take three different linguistic terms. Platform level membership functions are proposed to represent and determine the platform level of a common module. Therefore, the membership values of functions in a common module are transferred into platform level values by the platform level membership functions. The platform level of the common module is determined by the maximum value among average membership level values for the module.

The final results of the proposed methodology determine the platform along with the variant and unique modules for a product family. A platform consists of common modules with a high platform level that are shared. If variant modules are selected as a platform, additional functional features or costs will be required to make them a common module. Since the classification based on design rules considers the hierarchical relationship among functional features, modules can be designed independently. In the conceptual stages of design, these results can help decision-making by defining the set of modules for the product family. The effective set of modules will lead to improved product family design.

Figure 2. Fuzzy membership function representing platform level



CASE STUDY

To demonstrate the proposed methodology, a power tool family is investigated that consists of five distinct cordless power tools (see Table 1). Currently, these products only have common modules related to electrical components at the platform level. The proposed methodology determines if a more suitable platform and set of modules exists for the product family. This case study focuses on a function-based platform for the power tool family during the conceptual design phase. The products representation for the five tools was developed using TCO. Table 1 shows the 75 functional features of the selected five products. The five attributes of these functional features were coded using the values listed in the case study in Moon et al. (2006) as it pertains to a power tool family.

Fuzzy c-means clustering (FCM) was used to determine modules for the five products. Since the number of clusters affects the number of initial modules, it is important to select the number of clusters for FCM effectively. An optimal cluster number c ($6 \le c \le 74$) was estimated using the partition coefficient (PC) (Bezdek, 1981). For this case study, c = 13 was selected as the optimal cluster number to determine a platform and modules for the five products, since 12 to 15 clusters provided higher PC values than the other values. Table 2 shows the results of FCM using 13 clusters.

To determine a platform, 13 clusters were identified modules based on the integration rules and the split rules. For example, since two functional features ($x_{3,2,2}$, $x_{3,3,2}$) of the jig saw in Cluster 2 are related to different modules, a motor module and a conversion module, as shown in Table 2 the features of the jig saw were

Table 1. Product representation for the power tool family

decomposed into two different modules using the split rules. Cluster 4 and Cluster 8 can be combined into one module using the integration rules, since these features in each product have been obtained from the same module and rules related to the functional features and the modules were generated. For instance, in the Cluster 4 and 8, the three functional features ($x_{1,3,1}$, $x_{1,3,2}$, $x_{1,3,3}$) of the circular saw have the integration rules.

Using the platform level membership function described in Phase 3, the platform levels of the clusters were determined. The current common modules in the actual product family shown in Table 3 are a battery module and a batter terminal connector in an input module. Based on the high platform level for the five power tools, a proposed platform consists of functions related to an electronic module, a motor module, a battery module, and an input module. Comparing this to the current platform for the five products, the number of common modules can be increased based on common functional features. This represents a 23% increase in the number of common modules within the family.

FUTURE TRENDS

In knowledge support and management systems, data mining approaches facilitate extraction of information in design repositories to generate new knowledge for product development. Knowledge-intensive and collaborative support has been increasingly important in

Table 3. Comparison to current products and proposed products

Current products		Proposed products	
Common	• Battery module ($x_{1,3,*}, x_{2,3,*}, x_{3,4,*}, x_{4,4,*}, x_{5,4,*}$) • Battery terminal connector ($x_{*,1,1}$)	Common	• Electronic module • Battery module • Motor module • Input module
Variant or Unique	• Electronic module ($x_{*,1,*}$) • Motor module ($x_{*,2,*}$) • Input module (x_{*5*}) • Gear train module ($x_{1,6,*}, x_{2,6,*}$) • Blade module ($x_{1,4,*}$, $x_{3,6,*}$) • Bit module ($x_{2,4,*}$) • Conversion module ($x_{3,3,*}, x_{5,3,*}$) • Nail hitter module ($x_{4,3,*}$) • Magazine module ($x_{4,6,*}$) • Sander M'G module ($x_{5,6,*}$)	Variant	• Gear train module • Conversion module
		Unique	• Blade module • Sander M'G module • Magazine module • Bit module ($x_{2,4,2}$) • Gear train module ($x_{2,6,2}$) • Conversion module ($x_{3,3,1}$) • Sander M'G module ($x_{5,6,2}$)

product development to maintain and create future competitive advantages (Zha & Sriram, 2006). A knowledge support system can provide a solution for iterative design and manufacturing activities that are performed by sharing and reusing knowledge related to product development processes. Representing products by ontologies will be an appropriate approach to support data mining techniques by capturing, configuring, and reasoning both linguistic and parametric design information in a knowledge management system effectively (Nanda et al., 2007).

CONCLUSION

Using an ontology and data mining techniques, a new methodology was described for identifying a module-based platform along with variant and unique modules in a product family. TCO was used to represent the functions of a product as functional hierarchies. Fuzzy c-means clustering was employed to cluster the functional features of products based on the similarity among them. The resulting clusters yield the initial modules, which are then identified through classification. Platform level membership functions were used to identify the platform within the family. The proposed methodology can provide designers with a module-based platform and modules that can be adapted to product design during conceptual design. Therefore, the methodology can help design a variety of products within a product family.

KEY TERMS

Classification: A learning technique to separate distinct classes and map data into one of several predefined classes.

Design Knowledge: The collection of knowledge that can support the design activities and decision-making in product development, and can be represented as constraints, functions, rules, and facts that are associated with product design information.

Fuzzy C-Mean (FCM) Clustering: A clustering technique that is similar to k-means but uses fuzzy partitioning of data that is associated with different membership values between 0 and 1.

Modular Design: A design method to organize products as a set of distinct components that can be designed independently and develop a variety of prod-

ucts through the combination and standardization of components.

Ontology: A set of concepts or terms and their relationships that describe some area of knowledge or build a representation of it.

Product Family: A group of related products based on a product platform, facilitating mass customization by providing a variety of products for different market segments cost-effectively.

Product Platform: A set of features, components or subsystems that remain constraint from product to product, within a given product family.

Data Mining on XML Data

Qin Ding
East Carolina University, USA

INTRODUCTION

With the growing usage of XML data for data storage and exchange, there is an imminent need to develop efficient algorithms to perform data mining on semi-structured XML data. Mining on XML data is much more difficult than mining on relational data because of the complexity of structure in XML data. A naïve approach to mining on XML data is to first convert XML data into relational format. However the structure information may be lost during the conversion. It is desired to develop efficient and effective data mining algorithms that can be directly applied on XML data.

BACKGROUND

In recent years, XML has become very popular for representing semi-structured data and a standard for data exchange over the web. XML stands for Extensible Markup Language. It is a simple and very flexible text format derived from SGML (Standard Generalized Markup Language). Both XML and SGML are meta-languages because they are used for defining markup language. Originally designed to meet the challenges of large-scale electronic publishing, XML is also playing an increasingly important role in the exchange of a wide variety of data on the Web and elsewhere.

Below is a simplified example of an XML document. As can be seen, elements (or called tags) are the primary building blocks of an XML document. Unlike HTML which uses a fixed set of tags, XML allows user to define new collections of tags that can be used to structure any type of data or document. An element can have descriptive attributes that provide additional information about the element. Document Type Definitions (DTDs) can be used to specify which elements and attributes we can use and the constraints on these elements, such as how elements can be nested. XML allows the representation of semi-structured and hierarchal data containing not only the values of individual items but also the relationships between data items.

Data mining is the process to extract useful patterns or knowledge from large amount of data. As the amount of available XML data is growing continuously, it will be interesting to perform data mining

on XML data so that useful patterns can be extracted from XML data. From the example in Figure 1, we might be able to discover such patterns as "researchers who published about XML also published something related to XQuery" where "XML" and "XQuery" are keywords of the publications. This interesting pattern can be represented as an association rule in the format of "XML => XQuery". The task of data mining on XML data can be significant, yet challenging, due to the complexity of the structure in XML data.

Data mining has been successfully applied to many areas, ranging from business, engineering, to bioinformatics (Han & Kamber, 2006). However, most data mining techniques were developed for data in relational format. In order to apply these techniques to XML data, normally we need to first convert XML data into relational data format, and then traditional data mining algorithms can be applied on converted data. One way to map XML data into relational schema is to decompose XML documents entirely, remove the XML tags, and store the element and attribute values in relational tables. In this process, most aspects of the XML document structure are usually lost, such as the relative order of elements in the document, and the nested structure of the elements.

In order to avoid mapping the XML data to relational format, researchers have been trying to utilize XQuery, the W3C (World Wide Web Consortium) standard query language for XML, to support XML mining. On the one hand, XQuery provides a flexible way to extract XML data; on the other hand, by adding another layer using XQuery, the mining efficiency may be greatly affected. In addition, a query language such as XQuery may have limited querying capabilities to support all the data mining functionalities.

MAIN FOCUS

Data mining on XML data can be performed on the content as well as the structure of XML documents. Various data mining techniques can be applied on XML data, such as association rule mining and classification. In this section, we will discuss how to adapt association rule mining and classification techniques to XML data, for example, how to discover frequent patterns from the contents of native XML data and how to mine frequent tree patterns from XML data. We will also discuss other work related to XML data mining, such as mining XML query patterns (Yang et al, 2003) and using XML as a unified framework to store raw data and discovered patterns (Meo & Psaila, 2002).

Association Rule Mining on XML Data

Association rule mining is one of the important problems in data mining (Agrawal et al, 1993; Agrawal & Srikang, 1994; Han et al, 2000). Association rule mining is the process of finding interesting implication or correlation within a data set. The problem of association rule mining typically includes two steps. The first step is to find frequently occurring patterns. This step is also called "Frequent Pattern Mining". The second step is to discover interesting rules based on the frequent patterns found in the previous step. Most association rule algorithms, such as Apriori (Agrawal & Srikant, 1994) and FP-growth (Han et al, 2000), can only deal with flat relational data.

Braga et al addressed the problem of mining association rules from XML data in their recent work (Braga et al, 2002; Braga et al, 2003). They proposed an operator called "XMINE" to extract association rules from native XML documents. The XMINE operator was inspired by the syntax of XQuery and was based on XPath, which is the XML path language, an expression language for navigating XML document. Using the example in Figure 1, the "XMINE" operator can be used, as shown in Figure 2, to discover rules such as "XML => XQuery", where both sides of the rule have the same path, which is specified as "ROOT/Publications//Keyword" using the XPath language. The limitation of this work is that it only focuses on mining specific rules with pre-specified antecedent (the left-hand side) and consequence (the right-hand side), while the general association rule mining should target all the possible rules among any data items (Ding et al, 2003).

Dobbie and Wan proposed an XQuery-based Aprioir-like approach to mining association rules from XML data (Dobbie & Wan, 2003). They show that any XML document can be mined for association rules using only XQuery without any pre-processing and post-processing. However, since XQuery is designed only to be a general-purpose query language, it puts a lot of restriction on using it to do complicated data mining process. In addition, the efficiency is low due to the extra cost of XQuery processing.

Another algorithm called TreeFinder was introduced by Termier et al (Termier et al, 2002). It aims at search-

Figure 2. Operations to mine rules such as "XML => XQuery"

```

   HEAD := ROOT/Publications//Keyword
EXTRACTING RULES WITH SUPPORT = 0.1 AND CONFIDENCE = 0.4
```

ing frequent tress from a collection of tree-structured XML data. It extends the concept of "frequent itemset" to "frequent tree structure". One limitation of this algorithm is that, as mentioned in the paper, TreeFinder is correct but not complete; it only finds a subset of the actually frequent trees.

Ding and Sundarraj proposed an approach to XML association rule mining without using XQuery (Ding & Sundarraj, 2006). Their approach adapted the Apriori and FP-growth algorithms to be able to support association rule mining on XML data. Experimental results show that their approach achieves better performance than XQuery-based approaches.

Data preprocessing on XML documents might be needed before performing the data mining process. XSLT (Extensible Stylesheet Language Transformation) can be used to convert the content of an XML document into another XML document with different format or structure.

The open issue in XML association rule mining is how to deal with the complexity of the structure of XML data. Since the structure of the XML data can be very complex and irregular, identifying the mining context on such XML data may become very difficult (Wan & Dobbie, 2003).

Classification on XML Data

Classification is another important problem in data mining (Breiman et al, 1984; Quinlan, 1993). Similar to association rule mining, many classification algorithms only deal with relational data. The problem of classification on XML data has not been well studied. Current classification methods for XML documents use information retrieval based methods. These methods simply treat an XML document as a regular text document with a bag of words, so XML mining becomes the regular text mining; as a result, a significant amount of structural information hidden in the documents was ignored. In many cases, the classification information is actually hidden in the structural information.

Zaki and Aggarwal proposed an effective rule-based classifier called XRules for XML data (Zaki & Aggarwal, 2003). XRules mines frequent structures from the XML documents in order to create the structural classification rules. Their results show that structural classifier outperforms IR-based classifiers. This work is related to Termier's TreeFinder algorithm (Termier et al, 2002) as they both focus on structure mining on XML data.

Mining Frequent XML Query Patterns

Data mining techniques can also be applied to discover frequent query patterns. Response time to XML query has always been an important issue. Most approaches concentrate on indexing XML documents and processing regular path expression. Yang et al indicated that discovering frequent patterns can improve XML query response time since the answers to these queries can be stored and indexed (Yang et al, 2003). They proposed a schema-guided mining approach to discover frequent rooted subtrees from XML queries. The basic idea is that an XML query can be transformed into a query pattern tree. By computing the frequency counts of rooted subtrees, frequent query patterns can be discovered.

Building XML-Based Knowledge Discovery Systems

XML has also become a format to represent the discovered patterns from data mining. For example, it has become a convention to output the association rules, derived from the input XML data, using XML representation.

Meo & Psaila proposed a data model that uses XML as the unified framework to describe source raw data, heterogeneous mined patterns and data mining state-

ments, so that they can be stored inside a unique XML-based inductive database (Meo & Psaila, 2002).

FUTURE TRENDS

XML data mining research is still in its infant stage. However it will become increasingly important as the volume of XML data grows rapidly and the XML-related technology enhances greatly. So far, only a limited number of areas in XML mining have been explored, such as association rule mining and classification on XML. We believe that there are many other open problems in XML mining that need to be tackled, such as clustering XML documents, discovering sequential patterns in XML data, XML outlier detection, privacy-preserving data mining on XML, to name just a few. How to integrate content mining and structure mining on XML data is also an important issue.

As more researchers become interested and involved in XML data mining research, it is possible and beneficial to develop benchmarks on XML data mining. New XML data mining applications may also emerge, for example, XML mining for Bioinformatics.

CONCLUSION

Since XML is becoming a standard to represent semi-structured data and the amount of XML data is increasing continuously, it is of importance yet challenging to develop data mining methods and algorithms to analyze XML data. Mining of XML data significantly differs from structured data mining and text mining. XML data mining includes both content mining and structure mining. Most existing approaches either utilize XQuery, the XML query language, to support data mining, or convert XML data into relational format and then apply the traditional approaches. It is desired that more efficient and effective approaches be developed to perform various data mining tasks on semi-structured XML data.

KEY TERMS

Association Rule Mining: The process of finding interesting implication or correlation within a data set.

Data Mining: The process of extracting non-trivial, implicit, previously unknown and potentially useful patterns or knowledge from large amount of data.

Document Type Definition (DTD): A DTD is the formal definition of the elements, structures, and rules for marking up a given type of SGML or XML document.

Semi-Structured Data: The type of data with implicit and irregular structure but no fixed schema.

SGML (Standard Generalized Markup Language): SGML is a meta-language for how to specify a document markup language or tag sets.

XML (Extensible Markup Language): XML is a W3C-recommended general-purpose markup language for creating special-purpose markup languages. It is a simplified subset of SGML, capable of describing many different kinds of data.

XPath (XML Path Language): XPath is a language for navigating in XML documents. It can be used to address portions of an XML document.

XQuery: XQuery is the W3C standard query language for XML data.

XSLT (Extensible Stylesheet Language Transformation): XSLT is a language for transforming XML documents into other XML documents with different format or structure.

W3C (World Wide Web Consortium): An international consortium that develops interoperable technologies (specifications, guidelines, software, and tools) related to the internet and the web.

Data Mining Tool Selection

Christophe Giraud-Carrier
Brigham Young University, USA

INTRODUCTION

It is sometimes argued that all one needs to engage in Data Mining (DM) is data and a willingness to "give it a try." Although this view is attractive from the perspective of enthusiastic DM consultants who wish to expand the use of the technology, it can only serve the purposes of one-shot proofs of concept or preliminary studies. It is not representative of the complex reality of deploying DM within existing business processes. In such contexts, one needs two additional ingredients: a process model or methodology, and supporting tools.

Several Data Mining process models have been developed (Fayyad et al, 1996; Brachman & Anand, 1996; Mannila, 1997; Chapman et al, 2000), and although each sheds a slightly different light on the process, their basic tenets and overall structure are essentially the same (Gaul & Saeuberlich, 1999). A recent survey suggests that virtually all practitioners follow some kind of process model when applying DM and that the most widely used methodology is CRISP-DM (KDnuggets Poll, 2002). Here, we focus on the second ingredient, namely, supporting tools.

The past few years have seen a proliferation of DM software packages. Whilst this makes DM technology more readily available to non-expert end-users, it also creates a critical decision point in the overall business decision-making process. When considering the application of Data Mining, business users now face the challenge of selecting, from the available plethora of DM software packages, a tool adequate to their needs and expectations. In order to be informed, such a selection requires a standard basis from which to compare and contrast alternatives along relevant, business-focused dimensions, as well as the location of candidate tools within the space outlined by these dimensions. To meet this business requirement, a standard schema for the characterization of Data Mining software tools needs to be designed.

BACKGROUND

The following is a brief overview, in chronological order, of some of the most relevant work on DM tool characterization and evaluation.

Information Discovery, Inc. published, in 1997, a taxonomy of data mining techniques with a short list of products for each category (Parsaye, 1997). The focus was restricted to implemented DM algorithms.

Elder Research, Inc. produced, in 1998, two lists of commercial desktop DM products (one containing 17 products and the other only 14), defined along a few, yet very detailed, dimensions (Elder & Abbott, 1998; King & Elder, 1998). Another 1998 study contains an overview of 16 products, evaluated against pre-processing, data mining and post-processing features, as well as additional features such as price, platform, release date, etc. (Gaul & Saeuberlich, 1999). The originality of this study is its very interesting application of multi-dimensional scaling and cluster analysis to position 12 of the 16 evaluated tools in a four-segment space.

In 1999, the Data & Analysis Center for Software (DACS) released one of its state-of-the-art reports, consisting of a thorough survey of data mining techniques, with emphasis on applications to software engineering, which includes a list of 55 products with both summary information along a number of technical as well as process-dependent features and detailed descriptions of each product (Mendonca & Sunderhaft, 1999). Exclusive Ore, Inc. released another study in 2000, including a list of 21 products, defined mostly by the algorithms they implement together with a few additional technical dimensions (Exclusive Ore, 2000).

In 2004, an insightful article discussing high-level considerations in the choice of a DM suite—highlighting the fact that no single suite is best overall—together with a comparison of five of the then most widely used commercial DM software packages, was published in a well-read trade magazine (Nisbett, 2004). About the same time, an extensive and somewhat formal DM tool

characterization was proposed, along with a dynamic database of the most popular commercial and freeware DM tools on the market (Giraud-Carrier & Povel, 2003).[1] In a most recent survey of the field, the primary factors considered in selecting a tool were highlighted, along with a report on tool usage and challenges faced (Rexer et al, 2007).

Finally, it is worth mentioning a number of lists of DM tools that, although not including any characterization or evaluation, provide an useful starting point for tool evaluation and selection exercises by centralizing (and generally maintaining in time) basic information for each tool and links to the vendor's homepage for further details (KDNet, 2007; KDnuggets, 2007; Togaware, 2007).

MAIN FOCUS

The target audience of this chapter is business decision-makers. The proposed characterization, and accompanying database, emphasize the complete Data Mining process and are intended to provide the basis for informed, business-driven tools comparison and selection. Much of the content of this chapter is an extension of the work in (Giraud-Carrier & Povel, 2003), with additional insight from (Worthen, 2005; Smalltree, 2007; SPSS, 2007).

The set of characteristics for the description of DM tools can be organized naturally in a hierarchical fashion, with the top level as depicted in Figure 1. Each branch is expanded and discussed in the following sections.

Business Context and Goals

Data mining is primarily a *business-driven process* aimed at the discovery and consistent use of profitable knowledge from corporate data. Naturally, the first questions to ask, when considering the acquisition of supporting DM tools, have to do with the business context and goals, as illustrated in Figure 2.

Since different business contexts and objectives call for potentially different DM approaches, it is critical to understand what types of questions or business problems one intends to solve with data mining, who will be responsible for executing the process and presenting the results, where the data resides, and how the results of the analysis will be disseminated and deployed to the business. Answers to these high-level questions provide necessary constraints for a more thorough analysis of DM tools.

Model Types

The generative aspect of data mining consists of the building of a model from data. There are many available (machine learning) algorithms, each inducing one of a variety of types of models, including predictive models (e.g., classification, regression), descriptive models (e.g., clustering, segmentation), dependency

Figure 1. Top level of the DM tool description hierarchy

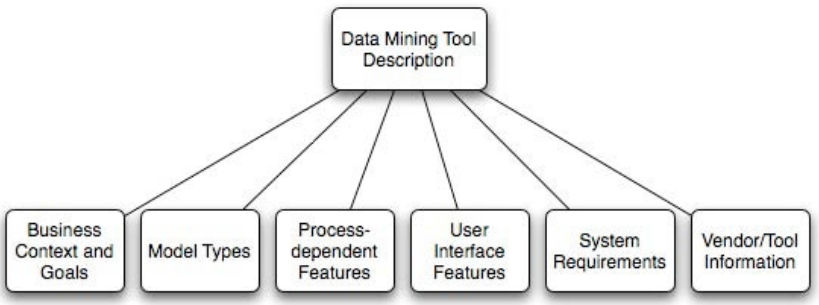

Figure 2. Business context and goals description

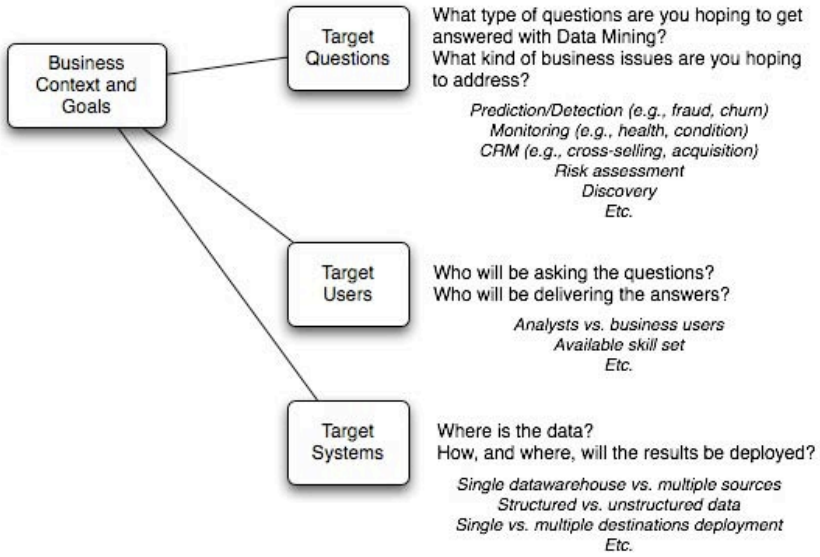


models (e.g., association), anomaly or novelty detection models, and time-series analysis models.

Given the dependency between business objectives and classes of models, one must ensure that the candidate DM tools support the kinds of modeling algorithms necessary to address the business questions likely to arise.

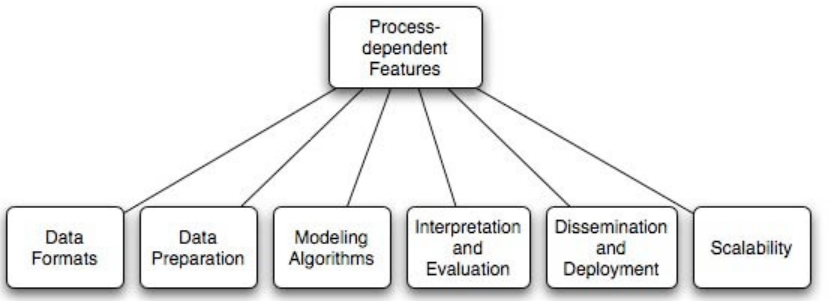
Process-Dependent Features

The data mining process is iterative by nature, and involves a number of complementary activities (e.g., CRISP-DM has 6 phases). Just as business environments differ, DM tools differ in their functionality and level of support of the DM process. Some are more complete and versatile than others. Users must therefore ensure that the selected tool supports their needs, standards and practices.

The main issues associated with process-dependent features and relevant to DM tool selection are summarized in Figure 3. A short description and discussion of each feature follows.

1. Data Formats: Data generally originates in a number of heterogeneous databases in different formats. To avoid unnecessary "interfacing" work, users should strive to select a tool able to read their various data formats. Most commonly DM tool supported formats/connectivity include flat file (e.g., comma-separated), ODBC/JDBC, SAS, and XML.
2. Data Preparation: Raw data is seldom readily usable for DM. Instead, before it can be further analyzed, it may be usefully enriched and transformed, e.g., to add new features or to remove noise. Users must not underestimate the need for pre-processing and data preparation. Experience suggests that such activities represent the bulk of the DM process, reaching as much as 80% of the overall process' time. It is thus critical to ensure that the tool selected is able to assist effectively, both from an usability point of view and from a functionality perspective. Data preparation, or pre-processing techniques, can be broadly categorized as follows.

Figure 3. Process-dependent features description



- Data Characterization: statistical and information theoretic measurements such as mean value, mutual entropy, kurtosis, etc.
- Data Visualization: graphical representations to quickly "eye-ball" underlying distributions, data spread, etc.
- Data Cleaning: automatic detection of undesirable conditions, such as outliers, single-valued attributes, identifier attributes (i.e., key attributes with as many values as there are records), records or attributes with too many missing values, etc.
- Record Selection: mechanisms to select specific records (or rows) based on ad-hoc queries.
- Attribute Selection: mechanisms to select specific attributes (or columns) based on ad-hoc queries.
- Data Transformation: mechanisms to transform data such as discretization, definition of new attributes, thresholding, etc.

3. Modeling Algorithms: There are a number of algorithmic techniques available for each DM approach, with features that must be weighed against data characteristics and additional business requirements (e.g., understandability). Users must ensure that their chosen tool implements algorithms that meet their needs. The following are the standard classes of DM modeling algorithms.
   - Decision Trees
   - Rule Learning
   - Neural Networks
   - Linear/Logistic Regression
   - Kernel-based Learning (e.g., SVM)
   - Association Learning
   - Instance-based/Nearest-neighbor Learning
   - Unsupervised Learning
   - Probabilistic Learning
   - Reinforcement Learning
   - Sequence Learning
   - Text Mining

   Note that there is a natural dependency between modeling algorithm classes and model types, as each modeling algorithm class is targeted at a specific type of model (Giraud-Carrier & Povel, 2003). If the potential uses of DM are varied, one may choose a tool that implements a great variety of techniques. On the other hand, if the application is fairly narrow and well-defined, one may opt for a specialized tool implementing a technique proven to be most suitable to the target application.
4. Evaluation and Interpretation: DM will produce results. These, however, are not always actionable or profitable. Ultimately, the "buck stops with the business users." Hence, users must be able to "see" enough of what they need in order to assess the results' potential value to the business. The

following are the standard methods of DM results evaluation. These are not mutually exclusive, but rather complementary in many cases.
   - Hold-out/Independent Test Set
   - Cross-validation
   - Lift/Gain Charts
   - ROC Analysis
   - Summary Reports (e.g., confusion matrix, F-measure)
   - Model Visualization
5. Dissemination and Deployment: In order to "close the loop," knowledge acquired through Data Mining must become part of business-as-usual. Hence, users must decide on what and how they wish to disseminate/deploy results, and how they integrate DM into their overall business strategy. The selected tool, or custom implementation, must support this view. Available methods are as follows.
   - Comment Fields
   - Save/Reload Models
   - Produce Executable
   - PMML/XML Export
6. Scalability: It is not unusual to be dealing with huge amounts of data (e.g., bank transactions) and/or to require near real-time responses (e.g., equipment monitoring). In such cases, users must consider how well the selected tool scales with the size of their data sets and their time constraints. Three features capture this issue, namely, dataset size limit, support for parallelization, and incrementality (of the modeling algorithms).

In addition to the "core" elements described above, several tools offer a number of special features that facilitate or enhance the work of users. The following are particularly relevant:

1. Expert Options: Most algorithms require the setting of numerous parameters, which may have significant impact on their performance. Typical DM tools implement the vanilla version of these algorithms, with default parameter settings. Although useful to novice users, this is limiting for advanced users who may be able to leverage the algorithms' parametrizability.
2. Batch Processing: For applications requiring the generation of many models or the re-creation of new models (e.g., customer targeting in successive marketing campaigns), the ability to run algorithms in batch mode greatly increases users effectiveness.

User Interface Features

Most of the algorithms (both for pre-processing and modeling) used in Data Mining originate from research labs. Only in the past few years have they been incorporated into commercial packages. Users differ in skills (an issue raised above under Business Context and Goals), and DM tools vary greatly in their type and style of user interaction. One must think of the DM tool target audience and be sure to select a tool that is adapted to the skill level of such users. In this dimension, one may focus on three characteristics:

- Graphical Layout: Does the selected tool offer a modern GUI or is it command-line driven? Are the DM process steps presented in an easy-to-follow manner?
- Drag&Drop or Visual Programming: Does the selected tool support simple visual programming based on selecting icons from palettes and sequencing them on the screen?
- On-line Help: Does the tool include any on-line help? How much of it and of what quality for the inexperienced user?

System Requirements

Software tools execute in specific computer environments. It is therefore important for users to be aware of the specific requirements of their selected tool, such as hardware platform (e.g., PC, Unix/Solaris workstation, Mac, etc.), additional software requirements (DB2, SAS Base, Oracle, Java/JRE, etc.), and software architecture (e.g., standalone vs. client/server).

One should carefully consider what the impact of deploying the tool would have on the existing IT infrastructure of the business. Will it require additional investments? How much work will be needed to interface the new software with existing one?

Vendor/Tool Information

In addition to, or sometimes in spite of, the technical aspects described above, there are also important com-

mercial issues, which must be addressed when selecting a software package. These may for example include:

- Availability of several contact points: 24-hr toll-free phone number, Web site's FAQ, email address for general inquiries, etc.
- Level of technical support: How well is the vendor/distributor able to carry out such activities as maintenance, upgrades, technical support, help desk, etc.?
- Price: How much does the tool cost (for 1 license on 1 machine)? What licensing options exist?
- Availability of a free demo or evaluation version: Is it possible to download (or otherwise obtain) a free evaluation copy of the software?
- Training needed: Does our current skill set support the use of the tool? If not, how much training (time and effort) will my users need before they can successfully leverage the DM tool's strength?
- Company's market penetration: How much of the DM tool market does the vendor hold (i.e., number of customers/sites)? What types of customers (e.g., activity sector, size, etc.)?
- Successful case studies: What is the tool's track record? Are there documented cases of successful applications of the tool to a variety of business problems, including the ones we are interested in?
- Company's longevity: How long has the vendor been in business? How likely is it to continue?

FUTURE TRENDS

The DM tool characterization presented here offers business users a standard way to compare and contrast candidate DM tools against each other, as well as against their own business requirements. However, the multi-dimensional nature of the characterizations, together with the many possible business constraints and preferences, mean that a direct comparison may be unwieldy. However, the characterizations may be used as inputs into semi-automatic methodologies that assist users in evaluating and selecting an appropriate tool, based on a weighted score of a large number of relevant criteria (Collier et al, 1999; Britos et al, 2006).

CONCLUSION

A general schema for the characterization of Data Mining tools, organized around the several phases of the DM process, has been outlined. The dimensions proposed are meant to be accessible to business users and serve to assist them as a first, essential step in the DM tool selection process.

KEY TERMS

Cross-Validation: Method of predictive model evaluation. It consists of splitting the available data into *N* subsets, or folds, of roughly equal size (and target feature distribution), successively building a predictive model from *N*-1 folds and testing on the remaining fold, making sure that each fold is used exactly once for testing. The model's overall performance is the average performance over all folds.

Data Mining: Application of visualization, statistics and machine learning to the discovery of knowledge in databases. There is general consensus that knowledge found by data mining should in some way be novel and actionable.

Dependency Model: Data Mining model that finds patterns of association among the components of aggregate data elements (e.g., market basket analysis). It is the result of unsupervised learning and its output generally takes the form of association rules.

Descriptive Model: Data Mining model that shows patterns of similarity among data elements (e.g., customer segmentation). It is the result of unsupervised learning and its output generally takes the form of clusters.

Predictive Model: Data Mining model that captures patterns of regularity between the characteristics of data elements and some specified target feature (e.g., credit risk assessment). It is the result of supervised learning and its output takes the form of a decision tree, decision list, probability model, neural network, etc.

ROC Analysis: Method of predictive model evaluation. It is based on the notion of Receiver Operating Characteristics (ROC) curve, where the evaluation consists not of a single accuracy value, but rather of a number of trade-off points (or curve) between false positive rate and true positive rate.

ENDNOTE

[1] The current database contains over 60 tools. It is updated on a regular basis so as to remain current, and is available freely from the author. Although it did not arise that way, this database can be viewed as a natural extension and update of the earlier list of Goebel & Gruenwald (1999).

Data Mining with Cubegrades

Amin A. Abdulghani
Data Mining Engineer, USA

INTRODUCTION

A lot of interest has been expressed in database mining using association rules (Agrawal, Imielinski, & Swami, 1993). In this chapter, we provide a different view of the association rules, referred to as *cubegrades* (Imielinski, Khachiyan, & Abdulghani, 2002) .

An example of a typical *association rule* states that, say, 23% of supermarket transactions (so called market basket data) which buy bread and butter buy also cereal (that percentage is called *confidence*) and that 10% of all transactions buy bread and butter (this is called *support*). Bread and butter represent the body of the rule and cereal constitutes the consequent of the rule. This statement is typically represented as a probabilistic rule. But *association rules* can also be viewed as statements about how the cell representing the body of the rule is affected by specializing it by adding an extra constraint expressed by the rule's consequent. Indeed, the confidence of an association rule can be viewed as the ratio of the support drop, when the cell corresponding to the body of a rule (in our case the cell of transactions buying bread and butter) is augmented with its consequent (in this case cereal). This interpretation gives association rules a "dynamic flavor" reflected in a hypothetical change of support affected by specializing the body cell to a cell whose description is a union of body and consequent descriptors. For example, our earlier association rule can be interpreted as saying that the count of transactions buying bread and butter drops to 23% of the original when restricted (rolled down) to the transactions buying bread, butter and cereal. In other words, this rule states how the count of transactions supporting buyers of bread and butter is affected by buying cereal as well.

With such interpretation in mind, a much more general view of association rules can be taken, when support (count) can be replaced by an arbitrary measure or aggregate and the specialization operation can be substituted with a different "delta" operation. Cubegrades capture this generalization. Conceptually, this is very similar to the notion of gradients used in calculus. By definition the gradient of a function between the domain points x_1 and x_2 measures the ratio of the *delta change* in the function value over the *delta change* between the points. For a given point x and function f(), it can be interpreted as a statement of how a change in the value of x (Δx), affects a change of value in the function ($\Delta f(x)$).

From another viewpoint, *cubegrades* can also be considered as defining a primitive for *data cubes*. Consider a 3-D cube model shown in Figure 1 representing sales data. It has three dimensions year, product and location. The measurement of interest is total sales. In olap terminology, since this cube models the base data, it forms a 3-D *base cuboid*. A *cuboid* in general is a group-by of a subset of dimensions of the base data, obtained by aggregating all tuples on these dimensions. So, for example for our sales data we have three 2-d cuboids namely (year, product), (product, location) and (year, location), three 1-d cuboids (year), (location) and (product) and one 0-d cuboid in which aggregation is performed on the whole data. For base data, with n diemensions, the union of all *k*-dimensional (k<=n) cuboids forms *an n-dimensional data cube*. A *cell* represents an association of a measure *m* (e.g., total sales) with a member of every dimension in a cuboid e.g. C1(product="toys", location="NJ", year="2004"). The dimensions not present in the cell are aggregated over all possible members. For example, you can have a two-dimensional (2-D) cell, C2(product="toys", year="2004"). Here, the implicit value for the dimension location is '*', and the measure *m* (e.g., total sales) is aggregated over all locations. Any of the standard aggregate functions such as count, total, average, minimum, or maximum can be used for aggregating. Suppose the sales for toys in 2004 for NJ, NY, PA were $2.5M, $3.5M, $1.5M respectively and that the aggregating function is total. Then, the measure value for cell C2 is $7.5M.

The scope of interest in OLAP is to evaluate one or more measure values of the cells in the cube. Cubegrades allow a broader, more dynamic view. In addition to evaluating the measure values in a cell,

Figure 1. A 3-D base cuboid with an example 3-D cell.

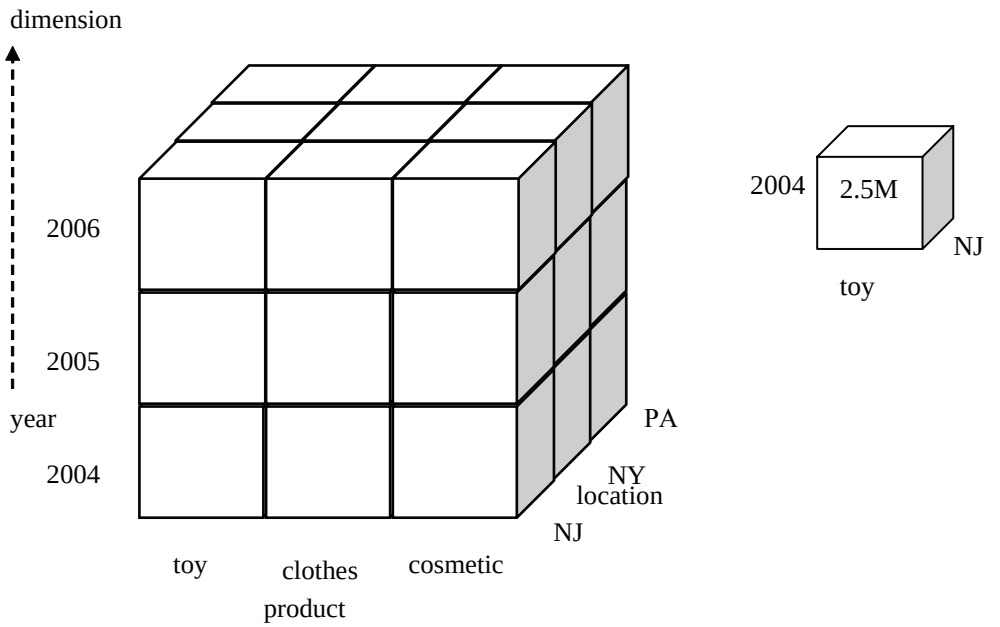

Figure 2. An example 2-D cuboid on (product, year) for the 3-D cube in Figure 1 (location=''); total sales needs to be aggregated (e.g., SUM)*

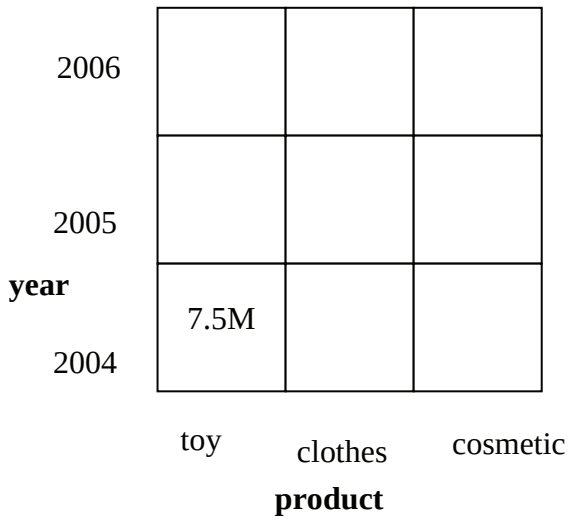


they evaluate how the measure values change or are affected in response to a change in the dimensions of a cell. Traditionally, OLAP have had operators such as drill downs, rollups defined, but the cubegrade operator differs from them as it returns a value measuring the effect of the operation. There have been additional operators proposed to evaluate/measure cell *interestingness* (Sarawagi, 2000; Sarawagi, Agrawal, & Megiddo, 1998). For example, Sarawagi et al., (1998) computes anticipated value for a cell using the neighborhood values, and a cell is considered an exception if its value is significantly different from its anticipated value. The difference is that cubegrades perform a direct cell to cell comparison.

BACKGROUND

An *association* or propositional rule can be defined in terms of cube cells. It can be defined as a quadruple *(body, consequent, support, confidence*) where *body* and *consequent* are cells over disjoint sets of attributes, *support* is the number of records satisfying the *body* and *confidence* is the ratio of the number of records which satisfy the *body* and the *consequent* to the number of records which satisfy just the body. We can also consider an association rule as a statement about a *"relative change"* of measure, COUNT, when "specializing" or "drilling down" the cell denoted by the *body* to the cell denoted by the *body* + *consequent*. The *confidence* of the rule measures how the *consequent* affects the support when drilling down the *body*. There are two ways these association rules can be generalized:

- By allowing relative changes in other measures, instead of just confidence, to be returned as part of the rule.
- By allowing cell modifications to be able to occur in different ``directions'' instead of just specializations (or drill-downs).

These generalized cell modifications are denoted as *cubegrades*. A cubegrade expresses how a change in the structure of a given cell affects a set of predefined measures. The original cell which is being modified is referred to as the *source* and the modified cell as *target*.

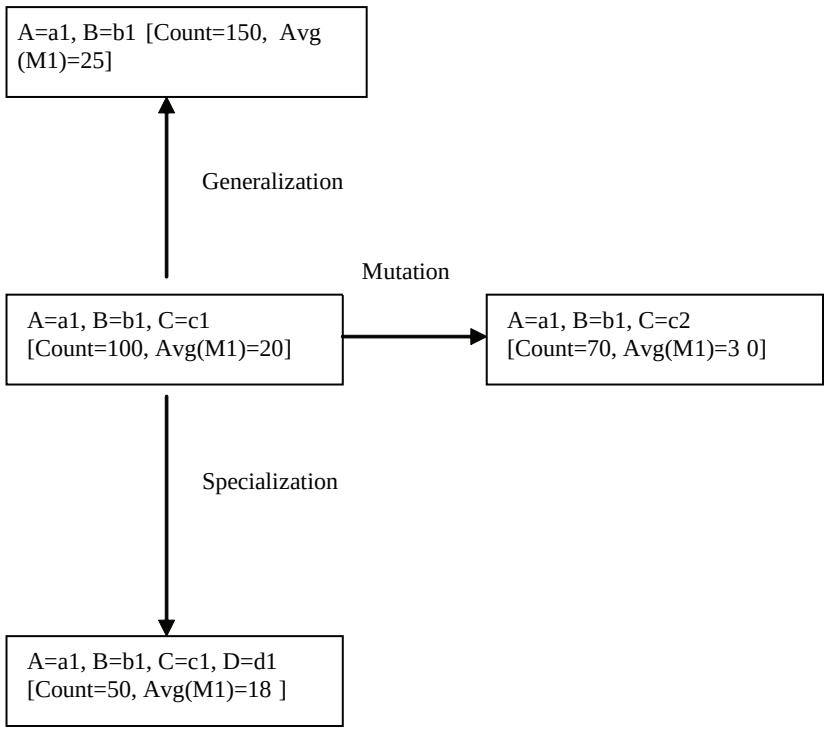
More formally, a cubegrade is a 5-tuple *(source, target, measures, value, delta-value)* where:.

- *source* and *target* are cube cells,
- *measures* is the set of measures which are evaluated both in the *source* as well as in the *target*,
- *value* is a function, value: *measures* → *R*, which evaluates measure *m* ∈ *measures* in the *source*,
- *delta-value* is also a function, *delta-value: measures* → *R,* which computes the ratio of the value of *m* ∈ *measures* in the *target* versus the *source.*

A cubegrade can visually be represented as a rule form:

Source → target, [measures, value, delta-value]

Figure 3. Cubegrade: Specialization, generalization and mutation



Define a *descriptor* to be an attribute value pair of the form *dimension=value* if the dimension is a discrete attribute *or dimension = [lo, hi]* if the attribute is a dimension attribute. We distinguish three types of the cubegrades:

- *Specializations:* A cubegrade is a *specialization* if the set of descriptors of the target are a superset of those in the source. Within the context of OLAP, the target cell is termed as a *drill-down* of *source.*
- *Generalizations:* A cubegrade is a *generalization* if the set of descriptors of the target cell are a subset of those in the source. Here, in OLAP, the target cell is termed as a *roll-up* of *source.*
- *Mutations:* A cubegrade is a *mutation* if the target and source cells have the same set of attributes but differ on the descriptor values (they are "union compatible" so to speak, as the term has been used in relational algebra).

Figure 2 illustrates the operations of these cubegrades. Following, we illustrate some specific examples to explain the use of these cubegrades

- (Specialization Cubegrade). The average sales of toys drops by 10% among buyers who live in PA.

  (product= "toy") → (product= "toy", location= "NJ")
  [AVG(sales),AVG(sales) = $85, DeltaAVG(sales) = 90%]

- (Mutation Cubegrade). The average sales drops by 30% when moving from NY buyers to PA buyers.

  (location= "NY") → (location= "PA")
  [AVG(sales), AVG(sales) = $110, DeltaAVG(sales)= 70%]

MAIN THRUST

Similar to association rules(Agrawal, & Srikant, 1994), the generation of *cubegrades* can be divided into two phases: (i) generation of significant cells (rather than frequent sets) satisfying the source cell conditions (ii) computation of cubegrades from the source (rather than computing association rules from frequent sets) satisfying the join conditions between source and target and target conditions.

The first task is similar to the computation of iceberg cube queries (Beyer & Ramakrishnan, 1999; Han, Pei, Dong, & Wang, 2001; Xin, Han, Li, & Wah, 2003). The fundamental property which allows for pruning in these computations is called *monotonicity* of the query: Let D be a database and $X \subseteq D$ be a cell. A query $Q(\cdot)$ is *monotonic* at X, if the condition Q(X) is FALSE implies Q(X') is FALSE for any $X` \subseteq X$.

However, as described by Imielinski et al (2002), determining whether a query Q is monotonic in terms of this definition is an NP-hard problem for many simple class of queries. To workaround this problem, the authors introduced another notion of monotonicity referred to *as view monotonicity* of a query. An important property of view monotonicity is that the time and space required for checking it for a query depends on the number of terms in the query and not the size of the database or the number of its attributes. Since most of the queries typically have few terms, it would be useful in many practical situations. The method presented can be used for checking for view monotonicity for queries that include constraints of type (Agg {<, >, =, !=} c) where c is a constant, and Agg can be MIN, SUM, MAX, AVERAGE and COUNT or an aggregate that is an higher order moment about the origin or an aggregate that is an integral of a function on a single attribute.

Consider a hypothetical query, asking for cells with 1000 or more buyers and with total milk sales less than $50,000. In addition, the average milk sales per customers should be between 20 to 50 dollars and with maximum sales greater than $75. This query can be expressed as follows:

COUNT(*)>=1000 and AVG(salesMilk)>=20 and AVG(salesMilk)<50 and MAX(salesMilk)>=75 and SUM(saleMilk)<50K

Suppose, while performing bottom up cube computation we have a cell C with the following view V (Count =1200; AVG(salesMilk) = 50; MAX(salesMilk) = 80; MIN(salesMilk) = 30; SUM(salesMilk) =60000). Then using the method for checking view monotonicity, it can be shown that there can exist some cell C' of C (though it's not guaranteed that this sub cell exists

in this database) with 1000<= count <1075 for which this query can be satisfied. Thus, this query can not be pruned on the cell.

However, if the view for C was (Count = 1200; AVG(salesMilk) = 57; MAX(salesMilk) =80; MIN(salesMilk) = 30; SUM(salesMilk) = 68400), then it can be shown that there doesn't exist any sub cell C' of C in any database for which the original query can be satisfied. Thus, the query can be pruned on cell C.

Once, the *source* cells have been computed, the next task is to compute the set of *target* cells. This is done by performing a set of query conversions which will make it possible to reduce cubegrade query evaluation to iceberg queries. Given a specific candidate source cell C, define Q[C] as the query which results from Q by *source substitution*. Here, Q is transformed by substituting into its "where" clause all *the values* of the *measures*, and the descriptors of the source cell C. This also includes performing the *delta elimination* step which replaces all the relative *delta values* (expressed as fractions) by the regular less than, greater than conditions. This is possible since the values for the *measure*s of C are known. With this, the *delta-values* can now be expressed as conditions on *values* of the *target*. For example, if AVG(Salary)=40K in cell C and DeltaAVG(Salary) is of the form DeltaAVG(Salary) >1.10, the transformed query would have the condition AVG(Salary) >44K where AVG(Salary) references the target cell. The final step in *source substitution* is *join transformation* where the join conditions (specializations, generalizations, mutations) in Q are transformed into the target conditions since the source cell is known. Notice, thus, that Q[C] is the cube query specifying for the target cell.

Dong, Han, Lam, Pei and Wang (2001) presents an optimized version of target generation which is particularly useful for the case where the number of source cells are few in numbers. The ideas in the algorithm include:

- Perform for the set of identified source cells the *lowest common delta elimination* such that the resulting *target condition* do not exclude any possible target cells.
- Perform a bottom-up iceberg query for the target cells based on the *target condition*. Define *LiveSet(T)* of a target cell T as the candidate set of source cells that can possibly match or join with target. A target cell, T, may identify a source, S, in its *LiveSet* to be prunable based on its monotonicity and thus removable from its *LiveSet.* In such a case, all descendants of T would also not include S in their *LiveSets*.
- Perform a join of the target and each of its *LiveSet's* source cells and for the resulting cubegrade, check if it satisfies the join criteria and the *Delta-Value* condition for the query.

In a typical scenario, it is not expected that users would be asking for cubegrades per se. Rather, it may be more likely that they pose a query on how a given delta change affects a set of cells, which cells are affected by a given delta change, or what delta changes affect a set of cells in a prespecified manner.

Further, more complicated set of applications can be implemented using cubegrades. For example, one may be interested in finding cells which remain stable and are not significantly affected by generalization, specialization or mutation. An illustration for that would be to find cells that remain stable on the blood pressure measure and are not affected by different specialization on age or area demographics.

FUTURE TRENDS

A major challenge for cubegrade processing is its computational complexity. Potentially, an exponential number of source/target cells can be generated. A positive development in this direction is the work done on Quotient Cubes (Lakshmanan, Pei, & Han, 2002). This work provides a method for partitioning and compressing the cells of a data cube into equivalent classes such that the resulting classes have cells that cover the same set of tuples and preserve the cube's semantic rollup/drilldown. In this context, we can reduce the number of cells generated for the source and target. Further, the pairings for the cubegrade can be reduced by restricting the source and target to belong to different classes. Another approach, recently proposed, for reducing the set of cubegrades to evaluate is to mine for the top-k cubegrades based on delta-values (Alves, R., Belo, O. & Ribeiro, J., 2007). The key additional pruning utilized there is to mine for regions in the cube that have high variance based on a given measure and thus provide a good candidate set for the set of target cells to consider for computing the cubegrades.

Another related challenge for cubegrades is to identify the set of interesting cubegrades (cubegrades that are somewhat surprising). Insights to this problem can be obtained from similar work done in the context of association rules (Bayardo & Agrawal, 1999; Liu, Ma, &Yu, 2001). Some progress has been made in direction with the extensions of the Lift criterion and Loevinger criterion to sum-based aggregate measures (Messaoud, Rabaseda, Boussaid, & Missaou, 2006).

CONCLUSION

In this chapter, we looked at a generalization of association rules referred to as cubegrades .These generalizations include allowing to evaluate relative changes in other measures, instead of just confidence, to be returned as well as allowing cell modifications to be able to occur in different "directions". The additional directions, we consider here, include generalizations which modifies cells towards the more general cell with fewer descriptors, and mutations, which modifies the descriptors of a subset of the attributes in the original cell definition with the others remaining the same. The paradigm allows us to ask queries that were not possible through association rules. The downside is that it comes with the price of relatively increased computation/storage costs that need to be tackled with innovative methods.

KEYTERMS

Cubegrade: A *cubegrade* is a 5-tuple (source, target, measures, value, delta-value) where:.

- source and target are cells,
- measures is the set of measures which are evaluated both in the source as well as in the target,
- value is a function, value: measures → R, which evaluates measure m ∈ measures in the source,
- delta-value is also a function, delta-value: measures → R, which computes the ratio of the value of m ∈ measures in the target versus the source

Drill-Down: A cube operation that allows users to navigate from summarized cells to more detailed cells.

Generalizations: A cubegrade is a *generalization* if the set of descriptors of the target cell are a subset of the set of attribute-value pairs of the source cell.

Gradient Cell: Synonym for a target cell of a cubegrade

Iceberg Cubes: Set of cells in a cube that satisfies an *iceberg query*.

Iceberg Query: A query on top of a cube that is asks for aggregates above a certain threshold.

Mutations: A cubegrade is a *mutation* if the target and source cells have the same set of attributes but differ on the values.

Query Monotonicity: A query $Q(\cdot)$ is *monotonic* at a cell X if the condition Q(X) is FALSE implies Q(X') is FALSE for any cell $X` \subseteq X$.

Roll-Up: A cube operation that allows users to aggregate from detailed cells to summarized cells.

Specialization: A cubegrade is a *specialization* if the set of attribute-value pairs of the target cell are a superset of the set of attribute-value pairs of the source cell.

View: A *view* V on S is an assignment of values to the elements of the set. If the assignment holds for the dimensions and measures in a given cell X, then V is a view for X on the set S.

View Monotonicity: A query Q is *view monotonic* on view V if for any cell X in any database D such that V is the view for X for query Q , the condition Q is FALSE for X implies Q is FALSE for all $X' \subseteq X$.

Data Mining with Incomplete Data

Hai Wang
Saint Mary's University, Canada

Shouhong Wang
University of Massachusetts Dartmouth, USA

INTRODUCTION

Survey is one of the common data acquisition methods for data mining (Brin, Rastogi & Shim, 2003). In data mining one can rarely find a survey data set that contains complete entries of each observation for all of the variables. Commonly, surveys and questionnaires are often only partially completed by respondents. The possible reasons for incomplete data could be numerous, including negligence, deliberate avoidance for privacy, ambiguity of the survey question, and aversion. The extent of damage of missing data is unknown when it is virtually impossible to return the survey or questionnaires to the data source for completion, but is one of the most important parts of knowledge for data mining to discover. In fact, missing data is an important debatable issue in the knowledge engineering field (Tseng, Wang, & Lee, 2003).

In mining a survey database with incomplete data, patterns of the missing data as well as the potential impacts of these missing data on the mining results constitute valuable knowledge. For instance, a data miner often wishes to know how reliable a data mining result is, if only the complete data entries are used; when and why certain types of values are often missing; what variables are correlated in terms of having missing values at the same time; what reason for incomplete data is likely, etc. These valuable pieces of knowledge can be discovered only after the missing part of the data set is fully explored.

BACKGROUND

There have been three traditional approaches to handling missing data in statistical analysis and data mining. One of the convenient solutions to incomplete data is to eliminate from the data set those records that have missing values (Little & Rubin, 2002). This, however, ignores potentially useful information in those records. In cases where the proportion of missing data is large, the data mining conclusions drawn from the screened data set are more likely misleading.

Another simple approach of dealing with missing data is to use generic "unknown" for all missing data items. However, this approach does not provide much information that might be useful for interpretation of missing data.

The third solution to dealing with missing data is to estimate the missing value in the data item. In the case of time series data, interpolation based on two adjacent data points that are observed is possible. In general cases, one may use some expected value in the data item based on statistical measures (Dempster, Laird, & Rubin, 1997). However, data in data mining are commonly of the types of ranking, category, multiple choices, and binary. Interpolation and use of an expected value for a particular missing data variable in these cases are generally inadequate. More importantly, a meaningful treatment of missing data shall always be independent of the problem being investigated (Batista & Monard, 2003).

More recently, there have been mathematical methods for finding the salient correlation structure, or aggregate conceptual directions, of a data set with missing data (Aggarwal & Parthasarathy, 2001; Parthasarathy & Aggarwal, 2003). These methods make themselves distinct from the traditional approaches of treating missing data by focusing on the collective effects of the missing data instead of individual missing values. However, these statistical models are data-driven, instead of problem-domain-driven. In fact, a particular data mining task is often related to its specific problem domain, and a single generic conceptual construction algorithm is insufficient to handle a variety of data mining tasks.

MAIN THRUST

There have been two primary approaches of data mining with incomplete data: conceptual construction and enhanced data mining.

Conceptual Construction with Incomplete Data

Conceptual construction with incomplete data reveals the patterns of the missing data as well as the potential impacts of these missing data on the mining results based only on the complete data. Conceptual construction on incomplete data is a knowledge development process. To construct new concepts on incomplete data, the data miner needs to identify a particular problem as a base for the construction. According to (Wang, S. & Wang, H., 2004), conceptual construction is carried out through two phases. First, data mining techniques (e.g., cluster analysis) are applied to the data set with complete data to reveal the unsuspected patterns of the data, and the problem is then articulated by the data miner. Second, the incomplete data with missing values related to the problem are used to construct new concepts. In this phase, the data miner evaluates the impacts of missing data on the identification of the problem and develops knowledge related to the problem. For example, suppose a data miner is investigating the profile of the consumers who are interested in a particular product. Using the complete data, the data miner has found that variable *i* (e.g., income) is an important factor of the consumers' purchasing behavior. To further verify and improve the data mining result, the data miner must develop new knowledge through mining the incomplete data. Four typical concepts as results of knowledge discovery in data mining with incomplete data are described as follows:

(1) **Reliability:** The reliability concept reveals the scope of the missing data in terms of the problem identified based only on complete data. For instance, in the above example, to develop the reliability concept, the data miner can define index $V_M(i)/V_C(i)$ where $V_M(i)$ is the number of missing values in variable *i*, and V_C(i) is the number of samples used for the problem identification in variable *i*. Accordingly, the higher $V_M(i)/V_C(i)$ is, the lower the reliability of the factor would be.

(2) **Hiding:** The concept of hiding reveals how likely an observation with a certain range of values in one variable is to have a missing value in another variable. For instance, in the above example, the data miner can define index $V_M(i)|x(j) \in (a,b)$ where $V_M(i)$ is the number of missing values in variable *i*, x(*j*) is the occurrence of variable *j* (e.g., education years), and (a,b) is the range of x(*j*); and use this index to disclose the hiding relationships between variables *i* and *j*, say, more than two thousand records have missing values in variable income given the value of education years ranging from 13 to 19.

(3) **Complementing:** The concept of complementing reveals what variables are more likely to have missing values at the same time; that is, the correlation of missing values related to the problem being investigated. For instance, in the above example, the data miner can define index $V_M(i,j)/V_M(i)$ where $V_M(i,j)$ is the number of missing values in both variables *i* and *j*, and $V_M(i)$ is the number of missing values in variable *i*. This concept discloses the correlation of two variables in terms of missing values. The higher the value $V_M(i,j)/V_M(i)$ is, the stronger the correlation of missing values would be.

(4) **Conditional Effects:** The concept of conditional effects reveals the potential changes to the understanding of the problem caused by the missing values. To develop the concept of conditional effects, the data miner assumes different possible values for the missing values, and then observe the possible changes of the nature of the problem. For instance, in the above example, the data miner can define index $\Delta P|\forall z(i)=k$ where ΔP is the change of the size of the target consumer group perceived by the data miner, $\forall z(i)$ represents all missing values of variable *i*, and k is the possible value variable *i* might have for the survey. Typically, k={*max*, *min*, *p*} where *max* is the maximal value of the scale, *min* is the minimal value of the scale, and *p* is the random variable with the same distribution function of the values in the complete data. By setting different possible values of k for the missing values, the data miner is able to observe the change of the size of the consumer group and redefine the problem.

Enhanced Data Mining with Incomplete Data

The second primary approach to data mining with incomplete data is enhanced data mining, in which incomplete data are fully utilized. Enhanced data mining is carried out through two phases. In the first phase, observations with missing data are transformed into fuzzy observations. Since missing values make the observation fuzzy, according to fuzzy set theory (Zadeh, 1978), an observation with missing values can be transformed into fuzzy patterns that are equivalent to the observation. For instance, suppose there is an observation $\boldsymbol{A}=\mathbf{X}(x_1, x_2, \ldots x_c \ldots x_m)$ where x_c is the variable with missing value, and $x_c \in \{ r_1, r_2 \ldots r_p \}$ where r_j (j=1, 2, ... p) is the possible occurrence of x_c. Let $\mu_j = P_j(x_c = r_j)$, the fuzzy membership (or possibility) that x_c belongs to r_j (j=1, 2, ...p), and $\sum_j \mu_j = 1$. Then, $\mu_j [\mathbf{X} | (x_c = r_j)]$ (j=1, 2, ... p) are fuzzy patterns that are the equivalence to the observation $\boldsymbol{A}$.

In the second phase of enhanced data mining, all fuzzy patterns, along with the complete data, are used for data mining using tools such as self-organizing maps (SOM) (Deboeck & Kohonen, 1998; Kohonen, 1989; Vesanto & Alhoniemi, 2000) and other types of neural networks (Wang, 2000, 2002). These tools used for enhanced data mining are different from the original ones in that they are capable of retaining information of fuzzy membership for each fuzzy pattern. Wang (2003) has developed a SOM-based enhanced data mining model to utilize all fuzzy patterns and the complete data for knowledge discovery. Using this model, the data miner is allowed to compare SOM based on complete data and fuzzy SOM based on all incomplete data to perceive covert patterns of the data set. It also allows the data miner to conduct what-if trials by including different portions of the incomplete data to disclose more accurate facts. Wang (2005) has developed a Hopfield neural network based model (Hopfield & Tank, 1986) for data mining with incomplete survey data. The enhanced data mining method utilizes more information provided by fuzzy patterns, and thus makes the data mining results more accurate. More importantly, it produces rich information about the uncertainty (or risk) of the data mining results.

FUTURE TRENDS

Research into data mining with incomplete data is still in its infancy. The literature on this issue is still scarce. Nevertheless, the data miners' endeavor for "knowing what we do not know" will accelerate research in this area. More theories and techniques of data mining with incomplete data will be developed in the near future, followed by comprehensive comparisons of these theories and techniques. These theories and techniques will be built on the combination of statistical models, neural networks, and computational algorithms. Data management systems on large-scale database systems for data mining with incomplete data will be available for data mining practitioners. In the long term, techniques of dealing with missing data will become a prerequisite of any data mining instrument.

CONCLUSION

Generally, knowledge discovery starts with the original problem identification. Yet the validation of the problem identified is typically beyond the database and generic algorithms themselves. During the knowledge discovery process, new concepts must be constructed through demystifying the data. Traditionally, incomplete data in data mining are often mistreated. As explained in this chapter, data with missing values must be taken into account in the knowledge discovery process.

There have been two major non-traditional approaches that can be effectively used for data mining with incomplete data. One approach is conceptual construction on incomplete data. It provides effective techniques for knowledge development so that the data miner is allowed to interpret the data mining results based on the particular problem domain and his/her perception of the missing data. The other approach is fuzzy transformation. According to this approach, observations with missing values are transformed into fuzzy patterns based on fuzzy set theory. These fuzzy patterns along with observations with complete data are then used for data mining through, for examples, data visualization and classification.

The inclusion of incomplete data for data mining would provide more information for the decision maker in identifying problems, verifying and improving the

data mining results derived from observations with complete data only.

KEY TERMS

Aggregate Conceptual Direction: Aggregate conceptual direction describes the trend in the data along which most of the variance occurs, taking the missing data into account.

Conceptual Construction with Incomplete Data: Conceptual construction with incomplete data is a knowledge development process that reveals the patterns of the missing data as well as the potential impacts of these missing data on the mining results based only on the complete data.

Enhanced Data Mining with Incomplete Data: Data mining that utilizes incomplete data through fuzzy transformation.

Fuzzy Transformation: The process of transforming an observation with missing values into fuzzy patterns that are equivalent to the observation based on fuzzy set theory.

Hopfield Neural Network: A neural network with a single layer of nodes that have binary inputs and outputs. The output of each node is fed back to all other nodes simultaneously, and each of the node forms a weighted sum of inputs and passes the output result through a

nonlinearity function. It applies a supervised learning algorithm, and the learning process continues until a stable state is reached.

Incomplete Data: The data set for data mining contains some data entries with missing values. For instance, when surveys and questionnaires are partially completed by respondents, the entire response data becomes incomplete data.

Neural Network: A set of computer hardware and/or software that attempt to emulate the information processing patterns of the biological brain. A neural network consists of four main components:

(1) Processing units (or neurons); and each of them has a certain output level at any point in time.
(2) Weighted interconnections between the various processing units which determine how the output of one unit leads to input for another unit.
(3) An activation rule which acts on the set of input at a processing unit to produce a new output.
(4) A learning rule that specifies how to adjust the weights for a given input/output pair.

Self-Organizing Map (SOM): Two layer neural network that maps the high-dimensional data onto low-dimensional grid of neurons through unsupervised learning or competitive learning process. It allows the data miner to view the clusters on the output maps.

INTRODUCTION

Data mining can be described as data processing using sophisticated data search capabilities and statistical algorithms to discover patterns and correlations in large pre-existing databases (Agrawal & Srikant 1995; Zhao & Sourav 2003). From these patterns, new and important information can be obtained that will lead to the discovery of new meanings which can then be translated into enhancements in many current fields.

In this paper, we focus on the usability of sequential data mining algorithms. Based on a conducted user study, many of these algorithms are difficult to comprehend. Our goal is to make an interface that acts as a "tutor" to help the users understand better how data mining works. We consider two of the algorithms more commonly used by our students for discovering sequential patterns, namely the AprioriAll and the PrefixSpan algorithms. We hope to generate some educational value, such that the tool could be used as a teaching aid for comprehending data mining algorithms. We concentrated our effort to develop the user interface to be easy to use by naïve end users with minimum computer literacy; the interface is intended to be used by beginners. This will help in having a wider audience and users for the developed tool.

BACKGROUND

Kopanakis and Theodoulidis (2003) highlight the importance of visual data mining and how pictorial representation of data mining outcomes are more meaningful than plain statistics, especially for non-technical users. They suggest many modeling techniques pertaining to association rules, relevance analysis, and classification. With regards to association rules they suggest using grid and bar representations for visualizing not only the raw data but also support, confidence, association rules, and evolution of time.

Eureka! is a visual knowledge discovery tool that specializes in two dimensional (2D) modeling of clustered data for extracting interesting patterns from them (Manco, Pizzuti & Talia 2004). VidaMine is a general purpose tool that provides three visual data mining modeling environments to its user: (a) the meta-query environment allows users through the use of "hooks" and "chains" to specify relationships between the datasets provided as input; (b) the association rule environment allows users to create association rules by dragging and dropping items into both the IF and THEN baskets; and (c) the clustering environment for selecting data clusters and their attributes (Kimani, *et al.*, 2004). After the model derivation phase, the user can perform analysis and visualize the results.

MAIN THRUST

AprioriAll is a equential data pattern discovery algorithm. It involves a sequence of five phases that work together to uncover sequential data patterns in large datasets. The first three phases, Sorting, L-itemset, and Transformation, take the original database and prepare the information for AprioriAll. The Sorting phase begins by grouping the information, for example a list of customer transactions, into groups of sequences with customer ID as a primary key. The L-itemset phase then scans the sorted database to obtain length one itemsets according to a predetermined minimum support value. These length one itemsets are then mapped to integer value, which will make generating larger candidate patterns much easier. In the Transformation phase, the sorted database is then updated to use the mapped values from the previous phase. If an item in the original sequence does not meet minimum support, it is removed in this phase, as only the parts of the customer sequences that include items found in the length one itemsets can be represented.

After preprocessing the data, AprioriAll efficiently determines sequential patterns in the Sequence phase. Length K sequences are used to generate length K+1 candidate sequences until K+1 sequences can no longer be generated (i.e., K+1, is greater than the largest sequence in the transformed database. Finally, the Maximal Phase prunes down this list of candidates by removing any sequential patterns that are contained within a larger sequential pattern.

Although this algorithm produces the desired results, it has several disadvantages. The potential for huge sets of candidate sequences is a major concern (Pei, *et al*., 2001). This results in an immensely large amount of memory space being used, especially when databases contain several large sequences. Another disadvantage is the time required to process large datasets since the algorithm requires multiple passes over the database. Additionally, AprioriAll has some difficulty mining long sequential patterns.

PrefixSpan requires preprocessing the database into a database consisting of sequences. The initial step scans the database and finds all length-1 prefixes that meet the minimum support. Next, the search space is partitioned into chunks corresponding to each length-1 prefix found in the previous step. Finally, the subsets of each of the prefixes can be mined by constructing corresponding projected databases; then each will be mined recursively. The final result is a compiled table consisting of the prefixes, postfixes, and all sequential patterns generated by the algorithm.

The major cost of PrefixSpan is the cost of construction of all the projected databases. In its worst case, it will construct a projected database for every sequential pattern (Pei, *et al*., 2001). "If the number and/or the size of projected databases can be reduced, the performance of sequential data mining can be improved substantially." (Pei, *et al*., 2001). One solution is the Bi-Level Projection. The Bi-Level Projection is represented in a lower triangular matrix, which can be used to generate the candidate sequential patterns.

The data mining technology is becoming increasingly popular and attractive as prediction technique, especially for advanced and emerging challenging applications. To compensate for this trend, it is crucial that more time be spent in the teaching process of many data mining algorithms. However, current resources that could serve as a learning aid lack the necessary tools to successfully present the material in an easy to understand manner. Taking a closer look at both AprioriAll and PrefixSpan, we found that they are not as straight forward as one might have liked. Needless to say, our experience with beginners tells that someone who decides to learn these algorithms may be left frustrated and confused. On a positive note, a visual interface which could be used as a tutor is an ideal solution to overcome the frustration and confusion. Compiling as many of the current resources and ideas regarding these algorithms into one user friendly visual interface seems like a good start. We decided to start from the bottom up. This means a systematical completion of the entire design process. With some basic background in Human Computer Interaction principles, we implemented a design that is best suited to be a potential ideal learning tool for both algorithms.

While designing our interface we implemented several features that allow for easier learning. The first implemented feature is to provide to the user all the steps of the algorithm while giving the user the option to selectively choose what step they want to display. Another feature of our interface is the clear textural description that couples with the selected step. Our system allows for some aspects of the interface to be interactive and better demonstrate how an algorithm works. Our interface also allows for a slideshow type feature to consecutively traverse all steps in an algorithm. A feature that we felt quite useful is to include

help features to aid a user who needs more than a general description of each algorithm. The introduction of color in the tables gives a better understanding of what is happening in each step. Allowing the user to output results based on the run-though of our interface is a necessary feature to allow the user to review at their own leisure. All of these features add to the ease of learning of the complex data mining algorithms.

Introducing the algorithms in an easy to understand manner is a vital aspect of our design. To accomplish this goal, we want to allow each part of the algorithm to be displayed when the interface is initially loaded. Since each algorithm has several steps or phases, an efficient way to present the numerous steps is very important. We decided to implement an "Aqua-Doc" style tool bar; this concept is borrowed from the Mac OS (see Figure 1). Each step of the algorithm is represented in small icon image and when the cursor passes over one of these icons, it magnifies that icon and half magnifies the icons direct neighbors. This allows a user to move the cursor slowly over each icon to navigate through the steps or phases. The interface initially boots up into a starting state. This starting state begins by putting all of the icons in a neutral state, with the main view of the current step and description set to the first step. By doing this, we are giving the user a place to begin, and giving them the overall feel of a tutorial beginning. When a user clicks or selects a certain step, that step is then projected into the main focus area with a clear textual description of the step directly beside it (see Figure 2). In introducing the steps in this fashion, a user will have a greater understanding of the complex algorithm, and can easily navigate through the said algorithm easily and efficiently.

When it comes to writing the textual descriptions that are used in correlation with each step, we tried to come up with a simple explanation of what is occurring in the step. This description is a key in the understanding of an algorithm. So by looking at a collection of previously written descriptions of a step and either

Figure 1. A view of the interactive tool bar that uses the Mac OS inspired "Aqua-Doc"

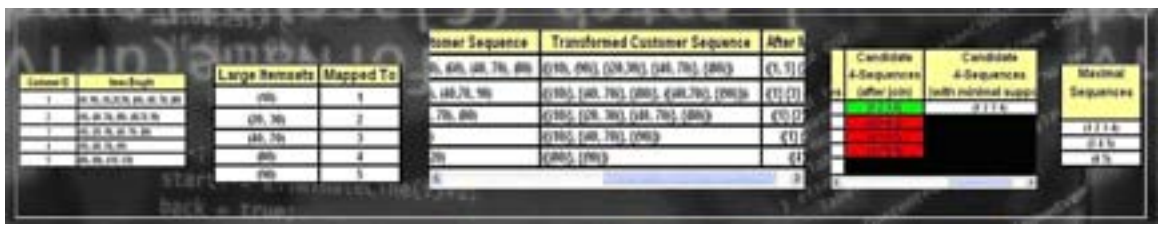

Figure 2. Textual description is generated by clicking on the interactive tool bar, and corresponds to the current step in the main focus area

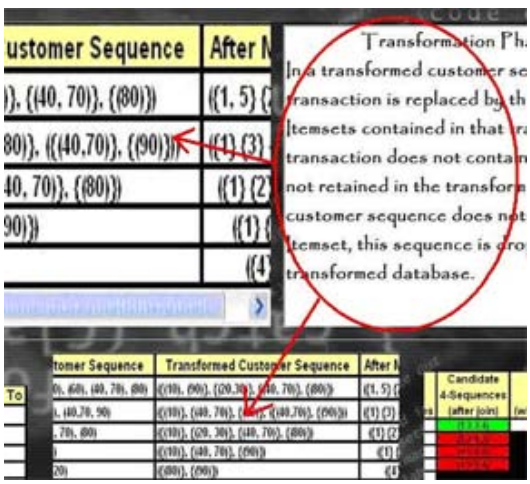

taking the most understandable description or rewriting the description, we are successfully able to present the description efficiently.

With a learning tool, it is essential that you allow the user to interact with the data in a way that enhances their understanding of the material. We had two main areas within our interface that would allow the performance of the algorithms to be manipulated to the benefit of the user (see Figure 3). The first is the ability to change the minimum support. This can prove to be very advantageous for adjusting the amount and the overall size of sequential patterns used. Typically it starts as a small value, which will produce smaller and less complex sequential patterns. The second area that can be modified is the percent rules to show. When dealing with large datasets, the final resulting number of rules can be increasingly large. With so many rules visible to the user, the final result could prove to be somewhat overwhelming. If a user is just starting to understand an algorithm, just a few simple results are more than enough to develop a basic understanding.

Another helpful feature of our interface is the use of a slideshow feature. The actual toolbar has been developed using the Windows Media Player toolbar as a foundation, and has been altered to meet the needs of our slideshow toolbar. If the user selects play, the steps of the algorithm will be traversed using a predetermined amount of time per step. Users still have the opportunity to use the interactive toolbar on the bottom of the interface to override the slideshow. As the slideshow moves between each step, the interactive tool bar will also procedurally traverse the steps in direct correlation to the current step displayed by the slideshow. This is demonstrated to the users, where they are in the overall algorithm. The ability to move back and forth between algorithms using the tab structure can also pause the current slideshow, allowing for a "current state" of the interface to be temporarily saved (see Figure 4).

By showing exactly how the results for L-itemset phase in AprioriAll are determined, a user would have a much better understanding of the underlying processes. We display all potential length one itemsets in a color coordinated table (see Figure 5). All itemsets that meet the minimum support will be colored green, and the other rejected itemsets are colored red. The color scheme mentioned above has been also implemented in other areas of the interface corresponding to steps that preform any kind of removal from the final result. In the PrefixSpan algorithm, the final result is displayed

Figure 3. Drop down boxes for changing minimum support and percent of rules to show

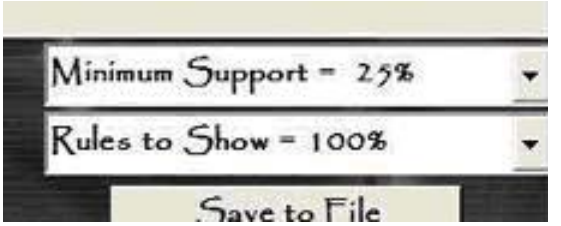

Figure 4. The tab for users to Pause, Play, Stop, and skip ahead or back a step through the slide show

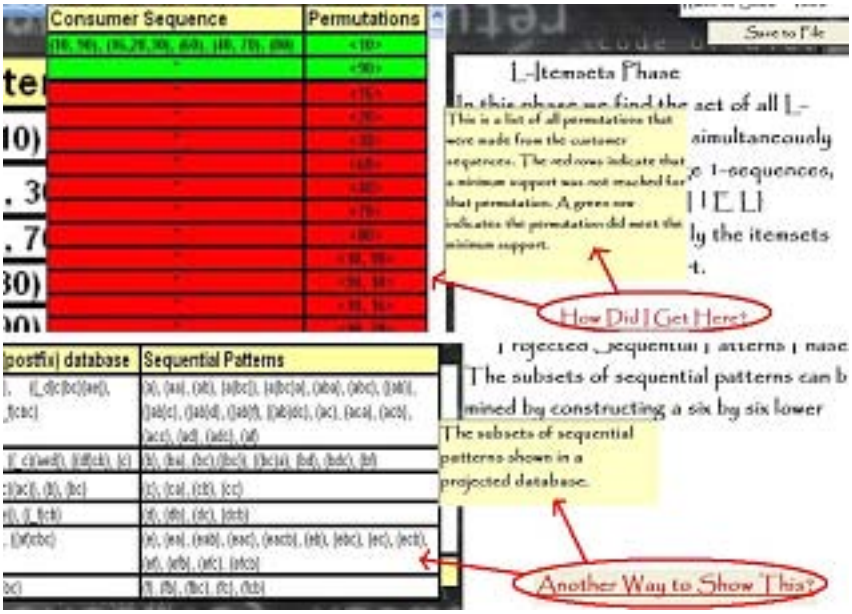
Figure 5. Two instances of the help step being used. The top implements the "How Did I Get Here" feature while the bottom uses the "Another Way to Show This?" feature



in the matrix view. Just looking at this view initially can be slightly confusing. Here the option to show the results in a different format adds to the overall appeal of our design (see Figure 5).

Finally, we have added the functionality to be able to output the resulting sequential patterns to a file. This gives an additional benefit to users because they are then able to go back and look at this file to review what they have learned. The minimum support and percentage of rules to show are linked directly to this as the output file will be a direct representation of what the interactive attributes in the interface have been set to. The output file is also formatted to easily get useful information from.

Some of the highlighting points of our system that are clear benefits to students are the advantage of using continuing examples and the ability to interact with examples to make them easier to follow. In many of the resources we investigated, it is very uncommon for an example to use the same data from start to end. Our interface makes better understandable how an algorithm works much more practical as the example the user started with is the one that he/she has results for throughout the process. As well, being able to manipulate the current example, allows users to begin with a small set of data and slowly work their way up to a complete example. When a user wants to go back and review the material, the option to have previously saved output file is a major advantage. This cuts down on the time it would take to redo the algorithm example, especially because the output file that was previously saved based on the customized dataset (using results to show and minimum support).

We have already tested the usage and friendliness of the tool described in this paper on two different groups of students. The two groups were first given a tutorial about the general usage of the tool presented in this paper without any description of the algorithms; only they were introduced to the general usage of the interface. Then, one of the groups was first asked to learn the two algorithms using the visual tool presented in this paper and then the students were introduced to the algorithms in a classroom setting. On the other hand, the opposite was done with the other group, i.e., the students were first introduced to the algorithms in the classroom and then the students were asked to practice using the visual tool presented in this paper. It was surprisingly found out that most of the students (close to 95%) who were asked to use the tool first learned the algorithms faster and found it easier to follow the

material in the classroom. From the other group, only few students (close to 15%) enjoyed the way they followed in learning the algorithms first in class then practicing using the described tool.

FUTURE TRENDS

As discussed above, our interface only encompasses two of the many sequential data pattern algorithms. While this is an excellent start, it is a small portion of all the data mining algorithms out there. If we could expand our system to handle more of the algorithms, this would only increase the educational value of our tool and would make it a viable asset to any data mining classroom environment.

We would also like to introduce the capability of using datasets of arbitrary size for the examples, i.e., increase the level of difficulty where the user is expected to follow the mining process. Currently, small datasets are expected to be used to run though each of the algorithms. While this is presently a necessity to demonstrate each of the algorithms in our interface, the ability to explore any dataset would be much more beneficial to a user after building some background with the two algorithms. Users would then be able to create and run through any dataset that they would find useful to them. This would add immensely to the learning process as a user would not be restricted to use small datasets. However, expanding to larger datasets requires using a sampling technique to decide on parts of the output of each step to be displayed on the screen, and also requires the capability to save the whole intermediate results for later manual check of them. On the other hand, by creating a unique dataset, the perception of how datasets are generated is also added to the understanding of the data mining process.

As an added feature, the ability to have online support would be helpful to students who still have some hard questions that our interface does not answer. Using either an online tutor service via an email correspondence or an online discussion board, we feel that the needs of students using the system could definitely be satisfied.

CONCLUSION

In retrospect, the importance of data mining in the current industry is becoming more apparent. With this ever increasing demand for algorithms and systems to effectively deliver usable results, the fundamentals must first be reviewed. Learning how exactly data mining algorithms work will be crucial to understanding how they can be applied to the industry.

Given that AprioriAll and PrefixSpan are well known algorithms, they have been excellent methods for us to start with. Both demonstrate the basics of how data mining algorithms discover sequential data patterns, which make the overall appeal of our system a good one. However, with more time, our system can easily be expanded to handle even more algorithms. This in turn will add to the overall educational value that our system provides. The current system successfully meets the initial goals of our project. With a better understanding of how data mining works, the potential for young minds to create better more efficient algorithms and data mining tools is amplified to the level required by the current industry. As a result, the technological world as a whole will serve to benefit.

KEY TERMS

Association Rule: Generally represented as a correlation X→Y, where X and Y are two no-empty and disjoint sets of items; X is called antecedent, Y is called consequence.

Confidence: Measures the rule's strength; the rule X→Y has confidence *c* if *c*% of transactions in the database that contain X also contain Y.

Data Mining: Extraction of non-trivial, implicit, previously unknown and potentially useful information or patterns from data in large databases.

Frequent Itemset: An itemset is said to be frequent if its support is greater than a predefined threshold (minimum support value).

Itemset: A collection of one or more items; a subset of the items that appear in a given dataset.

Support: Indicates the frequencies of the occurring patterns; rule X→Y has support *s* if *s*% of transactions in the database contain X∪Y.

User Interface: A mode of interaction provided for the user to easily communicate with a given program or system.

Data Preparation for Data Mining

Magdi Kamel
Naval Postgraduate School, USA

INTRODUCTION

Practical experience of data mining has revealed that preparing data is the most time-consuming phase of any data mining project. Estimates of the amount of time and resources spent on data preparation vary from at least 60% to upward of 80% (SPSS, 2002a). In spite of this fact, not enough attention is given to this important task, thus perpetuating the idea that the core of the data mining effort is the modeling process rather than all phases of the data mining life cycle. This article presents an overview of the most important issues and considerations for preparing data for data mining.

BACKGROUND

The explosive growth of government, business, and scientific databases has overwhelmed the traditional, manual approaches to data analysis and created a need for a new generation of techniques and tools for intelligent and automated knowledge discovery in data. The field of knowledge discovery, better known as data mining, is an emerging and rapidly evolving field that draws from other established disciplines such as databases, applied statistics, visualization, artificial intelligence and pattern recognition that specifically focus on fulfilling this need. The goal of data mining is to develop techniques for identifying novel and potentially useful patterns in large data sets (Tan, Steinbach, & Kumar, 2006).

Rather than being a single activity, data mining is as an interactive and iterative process that consists of a number of activities for discovering useful knowledge (Han & Kamber, 2006). These include data selection, data reorganization, data exploration, data cleaning, and data transformation. Additional activities are required to ensure that useful knowledge is derived from the data after data-mining algorithms are applied such as the proper interpretation of the results of data mining.

MAIN FOCUS

In this article, we address the issue of data preparation—how to make the data more suitable for data mining. Data preparation is a broad area and consists of a number of different approaches and techniques that are interrelated in complex ways. For the purpose of this article we consider data preparation to include the tasks of data selection, data reorganization, data exploration, data cleaning, and data transformation. These tasks are discussed in detail in subsequent sections.

It is important to note that the existence of a well designed and constructed data warehouse, a special database that contains data from multiple sources that are cleaned, merged, and reorganized for reporting and data analysis, may make the step of data preparation faster and less problematic. However, the existence of a data warehouse is not necessary for successful data mining. If the data required for data mining already exist, or can be easily created, then the existence of a data warehouse is immaterial.

Data Selection

Data selection refers to the task of extracting smaller data sets from larger databases or data files through a process known as sampling. Sampling is mainly used to reduce overall file sizes for training and validating data mining models (Gaohua & Liu, 2000). Sampling should be done so that the resulting smaller dataset is representative of the original, large file. An exception of this rule is when modeling infrequent events such as fraud or rare medical conditions. In this case oversampling is used to boost the cases from the rare categories for the training set (Weiss, 2004). However, the validation set must approximate the population distribution of the target variable.

There are many methods for sampling data. Regardless to the type of sampling it is important to construct

a *probability sample*, one in which each record of the data has a known probability of being included in the sample. The importance of using probability samples is that it allows us to calculate a level of error on the statistics calculated from the sample data when using statistical inferential techniques.

The two main types of sampling include simple random sampling and stratified random sampling. In *simple random sampling*, each record in the original data file has an equal probability of being selected. In *stratified random sampling*, records are selected such that they are proportional to the segments of population they represent. A similar type of sampling is sampling over time. In this type, samples are selected so as to adequately represent all time periods of interest.

Another aspect of data selection is the selection of a subset of variables, an approach knows as dimensionality reduction (Liu & Motoda, 1998). With a smaller number of variables many data mining algorithms work better, and the resulting models are more understandable.

As data is being prepared, it is usually difficult to determine which variables are likely to be important for data mining. A good understanding of the business and the goals of data mining should provide at this stage a general idea on what variables might be important and therefore should be included in the analysis.

Data Reorganization

Data reorganization is used to change the case basis of a data set. Data can be reorganized through summarization or other complex file manipulation. Summarization replaces the current dataset with one containing summary information based on one or more subgroups. For example, a bank transactions dataset can be summarized by customer, account type, or branch.

Complex file manipulation tasks can include one or many types of operations, such as matching, appending, aggregating, and distributing data from one variable into several other new variables (Bock & Diday, 2000).

It is important to note that data needs to be explored, cleaned and checked before it is summarized. The reason for doing so is that failure to eliminate errors at a lower level of summarization will make it impossible to find at a higher level of summarization.

Data Exploration

Data exploration is the preliminary investigation of the data in order to better understand its characteristics. There is nothing particularly distinctive about data exploration for data mining than that used for Exploratory Data Analysis (EDA), which was created by John Tukey in the 1970's (1977). It usually involves the following tasks:

1. Examining the distribution of each variable, summary statistics, and the amount and type of missing data. This can be accomplished by creating frequencies table and/or appropriate graphs such as bar charts and histograms.
2. Studying the relationship between two variables of interest using techniques such as crosstabulations, correlations, and On-Line Analytical Processing (OLAP), as well as graphs such as clustered bar charts, scatterplots, and web graphs.
3. Determining the extent and patterns of missing data.

We briefly examine three major areas of data exploration: summary statistics, data visualization, and OLAP.

Summary Statistics

Summary statistics capture many characteristics of large set of values with a single number or a small set of numbers (Devore, 2003). For categorical data, summary statistics include the *frequency* which is the number of times each value occurs in a particular set of data, and the *mode* which is the value that has the highest frequency. For continuous data, the most widely used summary statistics are the mean and median, which are measures of central tendency. The *mean* is the average value of a set of values, while the *median* is the middle value if there are an odd number of values and the average of the two middle values if the number of values is even.

Another set of commonly used summary statistics for continuous data measures the variability or spread of a set of values. These measures include the range, the standard deviation, and the variance. The *range* is the difference between the highest and lowest values in a

set of numbers. The *standard deviation* is a measure of the average deviation from the mean, and the *variance* is the square of the standard deviation.

For multivariate data with continuous data, summary statistics include the covariance and correlation matrices. The *covariance* of two attributes is a measure of the degree to which two attributes vary together and depends on the magnitude of the variables. The *correlation* of two attributes is a measure of how strongly two attributes are linearly related. It is usually preferred to covariance for data exploration.

Other types of summary statistics include the *skewness* which measures the degree to which a set of values is symmetrically distributed around the mean, and the *modality* which indicates whether the data has multiple "bumps" where a majority of the data is concentrated.

Data Visualization

Data Visualization is the display of data in tabular or graphic format. A main motivation for using visualization is that data presented in visual form is the best way of finding patterns of interest (SPSS, 2002b). By using domain knowledge, a person can often quickly eliminate uninteresting patterns and focus on patterns that are important.

There are numerous ways to classify data visualization techniques (Fayyad, Grinstein, & Wierse, 2001). One such classification is based on the number of variables involved (one, two, or many). Another classification is based on the characteristics of the data, such as graphical or graph structure. Other classifications are based on the type of variables involved, and the type of application: scientific, business, statistical, etc. In the following section, we discuss the visualization of data with a single variable and with two variables in line with our approach described in at the beginning of the Data Exploration Section.

Visualization of Single Variables

There are numerous plots to visualize single variables. They include bar charts, histograms, boxplots, and pie charts. A *bar chart* is a graph that shows the occurrence of categorical values, while a *histogram* is a plot that shows the occurrence of numeric values by dividing the possible values into bins and showing the number of cases that fall into each bin. Bar charts and histograms are frequently used to reveal imbalances in the data.

Boxplots indicate the 10^{th}, 25^{th}, 50^{th}, 75^{th}, and 90^{th} percentiles of single numerical variables. They also show outliers which are shown by "+" marks. *Pie charts* are used with categorical variables that have a relatively small number of values. Unlike a histogram, a pie chart uses the relative area of a circle to indicate relative frequency.

Visualization of Two Variables

Graphs for visualizing the relationship between two variables include clustered bar charts and histograms, scatter plots, and Web charts. C*lustered bar charts* and *histograms* are used to compare the relative contribution of a second variable on the occurrence of a first variable.

A *scatter plot* shows the relationship between two numeric fields. Each case is plotted as a point in the plane using the values of the two variables as *x* and *y* coordinates. A *Web chart* illustrates the strength of the relationship between values of two (or more) categorical fields. The graph uses lines of various widths to indicate connection strength.

OLAP

On-Line Analytical Processing (OLAP) is an approach that represents data sets as multidimensional arrays (Ramakrishnan & Gehrke, 2002). Two main steps are necessary for this representation: 1) the identification of the dimensions of the array, and 2) the identification of a variable that is the focus of the analysis. The dimensions are categorical variables or continuous variables that have been converted to categorical variables. The values of the variable serve as indices into the array for the dimension corresponding to the variable. Each combination of variable values defines a cell of the multidimensional array. The content of each cell represents the value of a target variable that we are interested in analyzing. The target variable is a numerical field that can be aggregated and averaged.

Once a multidimensional array, or OLAP cube, is created, various operations could be applied to manipulate it. These operations include slicing, dicing, dimensionality reduction, roll up, and drill down. *Slicing* is selecting a group of cells from the entire multidimen-

sional array by specifying a specific value for one or more dimension variables. *Dicing* involves selecting a subset of cells by specifying a range of attribute values. *Dimensionality reduction* eliminates a dimension by summing over it, and is similar to the concept of aggregation discussed earlier. A *roll-up* operation performs aggregation on the target variable of the array either by navigating up the data hierarchy for a dimension or by dimensionality reduction. A *drill-down* operation is the reverse of roll-up. It navigates the data hierarchy from less detailed data to more detailed data.

Data Cleaning

Real-world data sources tend to suffer from inconsistency, noise, missing values, and a host of other problems (Berry & Linoff, 2004; Olson, 2003). Data cleaning (or data cleansing) techniques attempt to address and resolve these problems. Some common problems include:

a. *Inconsistent values of same variables in different datasets* - Marital status could be represented as "S", "M", and "W" in one data source and "1", "2", "3" in another. Misspelling of text data in some data sources is another example of this type of error
b. *Errors or noise in data* - This problem refers to fields that contain values that are incorrect. Some errors are obvious, such as a negative age value. Others are not as obvious, such as an incorrect date of birth.
c. *Outliers and skewed distributions* - Although not errors in the data, outliers are values of a variable that are unusual with respect to the typical values for that variable and can bias the analysis of data mining. Similarly skewed distributions may lead to lower model accuracy of the data mining algorithm.
d. *Missing values* - These refer to data that should be present but is not. In some cases, the data was not collected. In other cases, the data is not applicable to a specific case. Missing values are usually represented as NULL values in the data source. Data mining tools vary in their handling of missing value, but usually do not consider the records with missing data. NULL values may however represent acceptable values and therefore need to be included in the analysis.
e. *Missing cases* - This problem occurs when records of a segment of interest are completely missing from the data source. In this case the models developed will not apply to the missing segment.

In the next section we discuss ways of handling missing values, and in the following section, we discuss a general process for data cleaning.

Missing Values

Missing values are a most subtle type of data problem in data mining because the effect is not easily recognized. There are at least two potential problems associated with missing values. The first relates to sample size and statistical power, the second to bias.

If the amount of missing values is large, the number of valid records in the sample will be reduced significantly, which leads to loss of statistical power. On the other hand, if missing values are associated with specific segments of the population, the resulting analysis may be biased.

There are several choices to handle missing values (Tan, Steinbach, & Kumar, 2006):
