Robust face recognition is a challenging goal because differences between images of the same face (intraclass variation) due to nuisance variations in lighting conditions, view point, pose, age, health, and facial expression are often much greater than those between different faces (interclass variation) (Adinj, Moses & Ulman, 1997, Zhao, Chellappa, Philips, & Rosenfeld, 2003) An ideal face recognition system should recognize new images of a known face and be insensitive to nuisance variations in image acquisition. Most systems work well only with images taken under constrained or laboratory conditions where lighting, pose, and camera parameters are strictly controlled. This requirement is much too strict to be useful in many data mining situations when only few sample images are available such as in recognizing people from surveillance videos or searching historic film archives. The following is a list of three key problems existing for current face recognition technology:

- Overall accuracy, particularly on large databases
- Sensitivity to changes in lighting, expression, camera angle, pose
- Computational load of searches

Illumination Invariant Face Recognition

Recent research has been focused on diminishing the impact of nuisance factors on face recognition. Two main approaches have been proposed for illumination invariant recognition. The first is to represent images with features that are less sensitive to illumination change (Gao & Leung, 2002) such as using the edge maps of an image. However, the locality problem of edge representation due to small rotation or location errors will degenerate the performance greatly. Yilmaz and Gokmen (2000) overcome the locality problem by using hills to spread the edge profile. These methods assume that features do not change dramatically with variable lighting conditions. Yet this is patently false as edge features generated from shadows may have a significant impact on recognition. Experiments done by Adinj et al. (Adinj, Moses, & Ulman, 1997) show that even when using the best illumination insensitive features for image presentation, the classification error is more than 20%. The second main approach is to construct a low dimensional linear subspace for the images of faces taken under different lighting conditions. This method is based on the assumption that images of a convex Lambertian object under variable illumination form a convex cone in the space of all possible images (Belhumeur & Kriegman, 1998). Ignoring the effect of shadows, this subspace has three dimensions (Zhao & Yang 1999). To account for attached shadows 5 to 9 dimensions are needed (Basri & Jacobs, 2003; Georghiades, Belhumeur, & Kriegman, 2001). All these methods assume that the surface of human face is Lambertian reflective and convex, and thus cannot describe cast shadows. Furthermore, such systems need several images of the same face taken under different lighting source directions to construct a model of a given face — in data mining applications it is often impossible to obtain the required number of images.

Expression Invariant Face Recognition

As for expression invariant face recognition, this is still an open problem for machine recognition and it is also quite a difficult task for humans. The approach adopted in the work of Black, Fleet, and Yacoob (2000) is to morph images to the same expression as the one used for training. A problem is that not all images can be morphed correctly. For example an image with closed eyes cannot be morphed to a standard image because of the lack of texture inside the eyes. Liu, Chen, and Kumar (2003) proposed using optical flow for face recognition with facial expression variations. However, it is hard to learn the motion within the feature space to determine the expression changes, since the way one person expresses a certain emotion is normally

somewhat different from others. Martinez proposed a weighing method to deal with facial expressions (Martinez, 2002). An image is divided into several local areas and those that are less sensitive to expression change are chosen and weighed independently. But features that are insensitive to expression change may be sensitive to illumination variations. These methods also suffer from the need to have large numbers of example images for training.

Mathematical Basis for Face Recognition Technologies

Most face recognition systems are based on one of the following methods:

1. Direct Measurement of Facial Features
2. Principal Components Analysis or "Eigenfaces" (Turk & Pentland, 1991)
3. Fisher Linear Discriminant Function (Liu & Wechsler, 1998)

Early forms of face recognition were based on Method 1 with direct measurement of features such as width of the nose, spacing between the eyes, etc. These measurements were frequently performed by hand using calipers. Many modern systems are based on either of Methods 2 or 3 which are better suited to computer automation. Here we briefly describe the principles behind one of the most popular methods — Principal Components Analysis (PCA), also known as "eigenfaces," as originally popularized by Turk and Pentland (1991).

Principal Components Analysis (PCA)

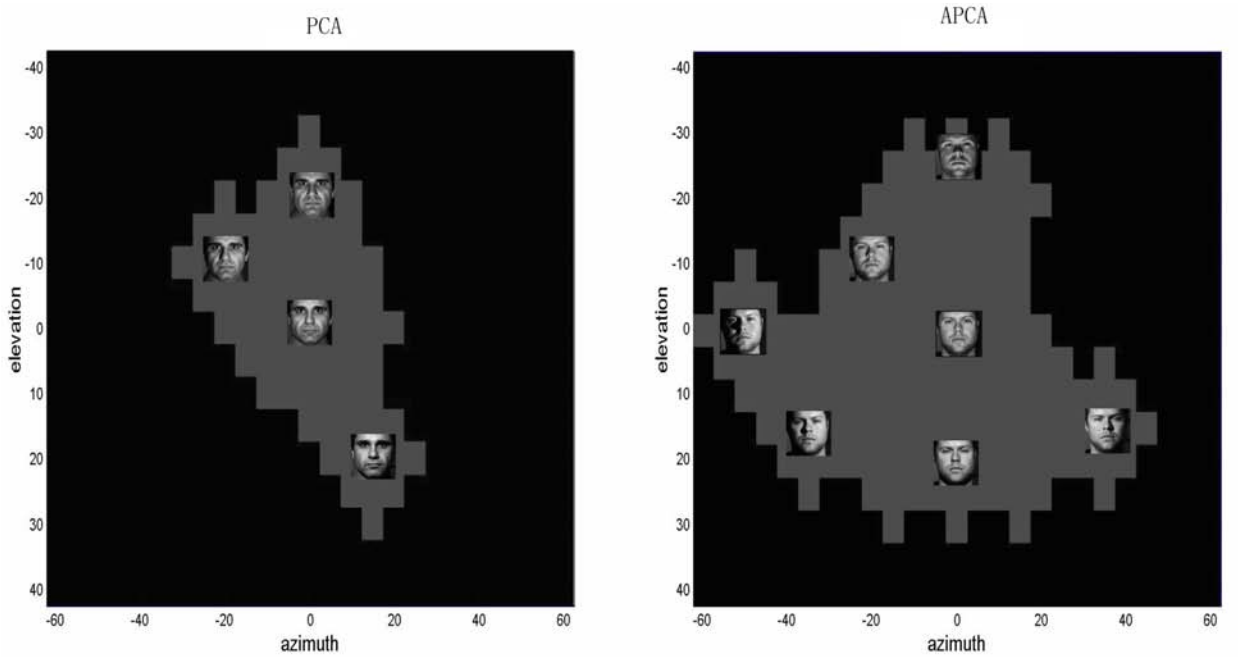
PCA is a second-order method for finding a linear representation of faces using only the covariance of the data. It determines the set of orthogonal components (feature vectors) which minimizes the reconstruction error for a given number of feature vectors. It is often used to define a face subspace with reduced dimensionality which contains the greatest covariance and yields good generalization capacity. Eigen-decomposition is normally applied to the covariance matrix C to generate eigenvectors, which are frequently called the eigenfaces and are shown as images in Figure 1. Generally, we select a small subset of eigenfaces to define a facespace which yields highest recognition performance on unseen examples of faces. For good recognition performance the required number of eigenfaces, m, is typically chosen to be of the order of 6 to 10. Nevertheless, PCA is optimized for minimizing mean square error and does not consider the classification of samples. Thus, features abstracted by PCA are preferred for representing face images, but are not the best choice for classification. Indeed some principal components may be selected that are greatly affected by within-class variation. Specifically, PCA does not provide satisfactory face recognition under different lighting conditions.

Robust PCA Recognition

The authors developed Adaptive Principal Component Analysis (APCA) to improve the robustness of PCA to nuisance factors such as lighting and expression (Chen & Lovell, 2003 and 2004). In the APCA method, we first apply PCA. Then rotate and warp the facespace

Figure 1. Typical set of eigenfaces as used for face recognition. Leftmost image is the average face.

Figure 2. Contours of 95% recognition performance for the original PCA and the proposed APCA method against lighting elevation and azimuth from Chen & Lovell (2004)



by whitening and filtering the eigenfaces according to overall covariance, between-class, and within-class covariance to find an improved set of eigenfeatures. Figure 2 shows the large improvement in robustness to lighting angle. The proposed APCA method allows us to recognize faces with high confidence even if they are half in shadow using only one gallery image. Figure 3 shows significant recognition performance gains over standard PCA when both changes in lighting and expression are present.

Pose Compensation

In 2006, the authors extended APCA to deal with face recognition under changes in pose (Shan, Lovell & Chen 2006; Sanderson, Shan & Lovell 2007). An Active Appearance Model (AAM) (Cootes, Edwards & Taylor 2001) is trained from images to learn the face shape and texture changes from different view points. A rotation model was then built to estimate pose orientation. When the pose angle is estimated, a synthesized frontal view image can be reconstructed from the model which can be used for face recognition. Figures 3 shows the recognition accuracy of APCA and PCA on face images with differing image capture conditions and Figure 4 shows reduced sensitivity to pose using the synthesized frontal face images.

After applying pose compensation to construct synthetic images, both APCA and PCA perform up to 5 times better. The method yields quite acceptable recognition rates for head rotations up to 25 degrees.

Critical Issues for Face Recognition Technology

Despite the huge number of potential applications for reliable face recognition, the need for such search capabilities in multimedia data mining, and the great strides made in recent decades, there is still much work to do before these applications become routine. Table 1 shows a summary of the critical issues for face recognition technologies.

FUTURE TRENDS

Face recognition and other biometric technologies are coming of age due to the need to address heightened security concerns in the 21st century. Privacy concerns that have hindered public acceptance of these technologies in the past are now yielding to society's need for increased security while maintaining a free society. Apart from the demands from the security sector, there

Figure 3. Recognition rates for APCA and PCA versus number of eigenfaces with variations in lighting and expression from Chen and Lovell (2003)

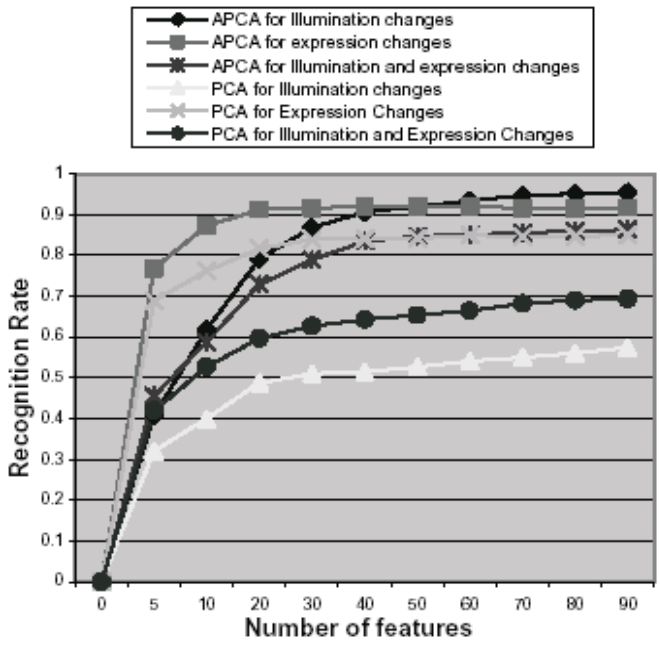


Figure 4. Recognition rate for PCA and APCA on non-frontal face images and on synthesized images from Shan, Lovell and Chen (2006)

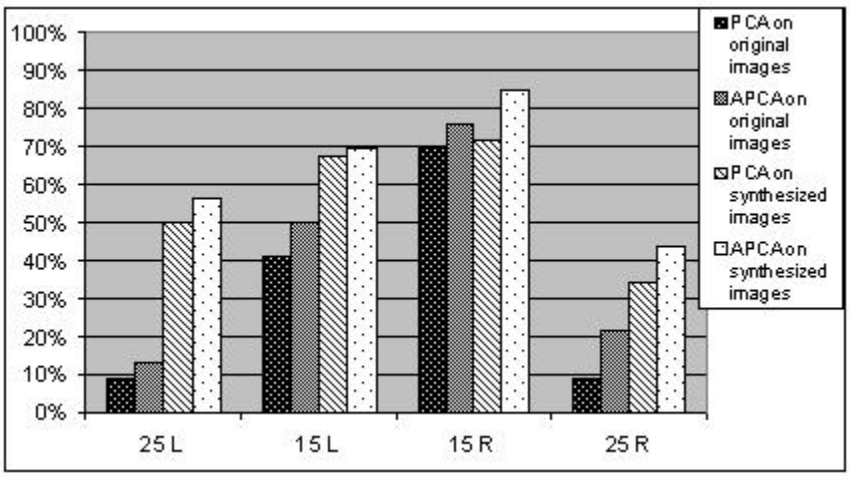

are many applications for the technology in other areas of data mining. The performance and robustness of systems will increase significantly as more researcher effort is brought to bear. In recent real-time systems there is much interest in 3D reconstruction of the head from multiple camera angles, but in data mining the focus must remain on reliable recognition from single photos.

CONCLUSION

It has been argued that by the end of the 20th century computers were very capable of handling text and numbers and that in the 21st century computers will have to be able to cope with raw data such as images and speech with much the same facility. The explosion of multimedia data on the internet and the conversion of all information to digital formats (music, speech,

Table 1. A summary of critical issues of face recognition technologies

Privacy Concerns	It is clear that personal privacy may be reduced with the widespread adoption of face recognition technology. However, since2001 and the 911 attack, concerns about privacy have taken a back seat to concerns about personal security. Governments are under intense pressure to introduce stronger security measures. Unfortunately governments' current need for robust biometric technology does nothing to improve performance in the short term and may actually damage uptake in the medium term due to unrealistic expectations.
Computational Efficiency	Face recognition can be computationally very intensive for large databases. This is a serious impediment for multimedia data mining.
Accuracy on Large Databases	Studies indicate that recognition error rates of the order of 10% are the best that can be obtained on large databases. This error rate sounds rather high, but trained humans do no better and are much slower at searching (Face Recognition Vendor Test 2006)
Sensitivity to Illumination and Other Changes	Changes in lighting, camera angle, and facial expression can greatly affect recognition performance.
Inability to Cope with Multiple Head Poses	Very few systems can cope with non-frontal views of the face. Some researchers propose 3D recognition systems using stereo cameras for real-time applications, but these are not suitable for data mining.
Ability to Scale	While a laboratory system may work quite well on 20 or 30 faces, it is not clear that these systems will scale to huge face databases as required for many security applications such as detecting faces of known criminals in a crowd or the person locator service on the planetary sensor web.

television) is driving the demand for advanced multimedia search capabilities, but the pattern recognition technology is mostly unreliable and slow. Yet, the emergence of handheld computers with built-in speech and handwriting recognition ability, however primitive, is a sign of the changing times. The challenge for researchers is to produce pattern recognition algorithms, such as face recognition, reliable and fast enough for deployment on data spaces of a planetary scale.

KEY TERMS

Biometric: A measurable, physical characteristic or personal behavioral trait used to recognize the identity, or verify the claimed identity, of an enrollee. A biometric identification system identifies a human from a measurement of a physical feature or repeatable action of the individual (for example, hand geometry, retinal scan, iris scan, fingerprint patterns, facial characteristics, DNA sequence characteristics, voice prints, and hand written signature).

Computer Vision: Using computers to analyze images and video streams and extract meaningful information from them in a similar way to the human vision system. It is related to artificial intelligence and image processing and is concerned with computer processing of images from the real world to recognize features present in the image.

Eigenfaces: Another name for face recognition via principal components analysis.

Metadata: Labeling, information describing other information.

Pattern Recognition: Pattern Recognition is the ability to take in raw data, such as images, and take action based on the category of the data.

Principal Components Analysis: Principal components analysis (PCA) is a method that can be used to simplify a dataset. It is a transform that chooses a new coordinate system for the data set, such, that that greatest variance by any projection of the data set comes to lie on the first axis (then called the first principal component), the second greatest variance on the second axis and so on. PCA can be used for reducing dimensionality. PCA is also called the Karhunen-Loève transform or the Hotelling transform.

Robust: The opposite of Brittle; this can be said of a system that has the ability to recover gracefully from the whole range of exceptional inputs and situations in a given environment. Also has the connotation of elegance in addition to careful attention to detail.

Rough Sets and Data Mining

Jerzy W. Grzymala-Busse
University of Kansas, USA

Wojciech Ziarko
University of Regina, Canada

INTRODUCTION

Discovering useful models capturing regularities of natural phenomena or complex systems until recently was almost entirely limited to finding formulae fitting empirical data. This worked relatively well in physics, theoretical mechanics, and other areas of science and engineering. However, in social sciences, market research, medicine, pharmacy, molecular biology, learning and perception, and in many other areas, the complexity of the natural processes and their common lack of analytical smoothness almost totally exclude the use of standard tools of mathematics for the purpose of data-based modeling. A fundamentally different approach is needed in those areas. The availability of fast data processors creates new possibilities in that respect. This need for alternative approaches to modeling from data was recognized some time ago by researchers working in the areas of neural nets, inductive learning, rough sets, and, more recently, data mining. The empirical models in the form of data-based structures of decision tables or rules play similar roles to formulas in classical analytical modeling. Such models can be analyzed, interpreted, and optimized using methods of rough set theory.

BACKGROUND

The theory of rough sets was originated by Pawlak (1982) as a formal mathematical theory, modeling knowledge about a universe of interest in terms of a collection of equivalence relations. Its main application areas are acquisition, analysis, and optimization of computer-processible models from data. The models can represent functional, partially functional, and probabilistic relations existing in data in the extended rough set approaches (Grzymala-Busse, 1998; Katzberg & Ziarko, 1996; Slezak & Ziarko, 2003; Ziarko, 1993). When deriving the models in the context of the rough set theory, there is no need for any additional information about data, such as, for example, probability distribution function in statistical theory, grade of membership in fuzzy set theory, and so forth (Grzymala-Busse, 1988).

The original rough set approach is concerned with investigating properties and limitations of knowledge. The main goal is forming discriminative descriptions of subsets of a universe of interest. The approach is also used to investigate and prove numerous useful algebraic and logical properties of knowledge and of approximately defined sets, called *rough sets*. The knowledge is modeled by an equivalence relation representing the ability to partition the universe into classes of indiscernible objects, referred to as *elementary sets*. The presence of the idea of approximately defined sets is a natural consequence of imperfections of existing knowledge, which may be incomplete, imprecise, or uncertain. Only an approximate description, in general, of a set (target set) can be formed. The approximate description consists of specification of lower and upper set approximations. The approximations are definable sets. The lower approximation is a union of all elementary sets contained in the target set. The upper approximation is a union of all elementary sets overlapping the target set. This ability to create approximations of non-definable, or rough, sets allows for development of approximate classification algorithms for prediction, machine learning, pattern recognition, data mining, and so forth. In these algorithms, the problem of classifying an observation into an undefinable category, which is not tractable, in the sense that the discriminating description of the category does not exist, is substituted by the problem of classifying the observation into an approximation of the category.

MAIN THRUST

The article is focused on data-mining-related extensions of the original rough set model. Based on the representative extensions, data mining techniques and applications are reviewed.

Extensions of Rough Set Theory

Developing practical applications of rough set theory revealed the limitations of this approach. For example, when dealing with market survey data, it was not possible to identify non-empty lower approximation of the target category of buyers of a product. Similarly, it often was not possible to identify non-trivial upper approximation of the target category, such as would not extend over the whole universe. These limitations follow from the fact that practical classification problems are often non-deterministic. When dealing with such problems, perfect prediction accuracy is not possible and not expected. The need to make rough set theory applicable to a more comprehensive class of practical problems inspired the development of extensions of the original approach to rough sets.

One such extension is the variable precision rough set model (VPRSM) (Ziarko, 1993). As in the original rough set theory, set approximations also are formed in VPRSM. The VPRSM criteria for forming the lower and upper approximations are relaxed, in particular by allowing a controlled degree of misclassification in the lower approximation of a target set. The resulting lower approximation represents an area of the universe where the correct classification can be made with desired probability of success, rather than deterministically. In this way, the VPRSM approach can handle a comprehensive class of problems requiring developing non-deterministic models from data. The VPRSM preserves all basic properties and algorithms of the Pawlak approach to rough sets. The algorithms are enhanced additionally with probabilistic information acquired from data (Katzberg & Ziarko, 1996; Ziarko, 1998, 2003, Ziarko & Xiao, 2004). The structures of decision tables and rules derived from data within the framework of VPRSM have probabilistic confidence factors to reflect the degree of uncertainty in classificatory decision making. The objective of such classifiers is to improve the probability of success rather than trying to guarantee 100% correct classification.

Another extension of rough set theory is implemented in the data mining system LERS (Grzymala-Busse, 1992, 1994), in which rules are equipped with three coefficients characterizing rule quality: specificity (i.e., the total number of attribute-value pairs on the left-hand side of the rule); strength (i.e., the total number of cases correctly classified by the rule during training; and the total number of training cases matching the left-hand side of the rule. For classification of unseen cases, the LERS incorporates the ideas of genetic learning, extended to use partial matching of rules and cases. The decision to which a case belongs is made on the basis of support, defined as the sum of scores of all matching rules from the class, where a score of the rule is the product of the first two coefficients associated with the rule. As indicated by experiments, partial matching is a valuable mechanism when complete matching fails (Grzymala-Busse, 1994). In the LERS classification system, the user may use 16 strategies for classification. In some of these strategies, the final decision is based on probabilities acquired from raw data (Grzymala-Busse & Zou, 1998).

Other extensions of rough set theory include generalizations of the basic concept of rough set theory—the indiscernibility relation. A survey of such methods was presented in Yao (2003).

From Data to Rough Decision Tables

When deriving models from data within the rough set framework, one of the primary constructs is a decision table derived from data referred to as *rough decision table* (Pawlak, 1991; Ziarko, 1999, 2002a). The rough decision table represents knowledge about the universe of interest and the relation between the knowledge and the target set or sets. The idea of the rough decision table was formulated in both the original framework of rough sets and in the extended VPRSM. In the latter case, the table is called *probabilistic decision table* (Ziarko, 2002a). In the table, some columns correspond to descriptive attributes used to classify objects of the domain of interest, while other columns represent target sets or rough approximations of the sets. The rows of the table represent the classes of the classification of the domain in terms of the descriptive attributes. If the decision table contains representatives of all or almost all classes of the domain, and if the relation with the prediction targets is completely or almost completely

specified, then the table can be treated as a model of the domain. Such a model represents descriptions of all or almost all objects of the domain and their relationship to the prediction target. The specification of the relationship may include empirical assessments of conditional probabilities, if the VPRSM approach is used in model derivation. If the model is complete enough, and if the data-based estimates of probabilities are relatively close to real values, then the decision table can be used as a basis of a classifier system. To ensure relative completeness and generality of the decision table model, the values of the attributes used to construct the classification of the domain need to be sufficiently general. For example, in many practical problems, rather than using precise numeric measurements, value ranges often are used after preliminary discretization of original precise values. This conversion of original data values into secondary, less precise representation is one of the major pre-processing steps in rough set-based methodology. The acquired decision table can be further analyzed and optimized using classical algorithms for interattribute dependency computation and minimal nonredundant subset of attributes (attribute reduct) identification (Pawlak, 1991; Ziarko 2002b).

From Data to Rule Sets

A number of systems for machine learning and data mining have been developed in the course of research on theory and applications of rough sets (Grzymala-Busse, 1992; Ohrn & Komorowski, 1997; Ziarko, 1998b; Ziarko et al., 1993). The representative example of such developments is the data mining system LERS, whose first version was developed at the University of Kansas in 1988. The current version of LERS is essentially a family of data mining systems. The main objective of LERS is computation of decision rules from data. Computed rule sets may be used for classification of new cases or for interpretation of knowledge. The LERS system may compute rules from imperfect data (Grzymala-Busse, 1992) (e.g., data with missing attribute values or inconsistent cases). LERS is also equipped with a set of discretization schemas to deal with numerical attributes. In addition, a variety of LERS methods may help to handle missing attribute values. LERS accepts inconsistent input data (i.e., characterized by the same values of all attributes, but belonging to two different target sets). For inconsistent data, LERS computes lower and upper approximations of all sets involved. The system is also assisted with tools for rule validation, such as leaving-one-out, 10-fold cross validation, and holdout.

LERS has proven its applicability having been used for two years by NASA Johnson Space Center (Automation and Robotics Division) as a tool to develop expert systems of the type most likely to be used in medical decision making on the board of the International Space Station. LERS also was used to enhance facility compliance under Sections 311, 312, and 313 of Title III of the Emergency Planning and Community Right to Know (Grzymala-Busse, 1993). The LERS system was used in other areas, as well (e.g., in the medical field to compare the effects of warming devices for postoperative patients, to assess preterm birth) (Woolery & Grzymala-Busse, 1994) and for diagnosis of melanoma (Grzymala-Busse et al., 2001).

FUTURE TRENDS

The literature related to the subject of rough sets exceeds well over 1,000 publications. By necessity, in what follows, we cite only some representative examples of the research works on the subject. A comprehensive up-to-date collection of references can be found online at http://rsds.wsiz.rzeszow.pl (Suraj, 2004).

Following Pawlak's original publication (Pawlak, 1991), the mathematical fundamentals of the original rough set model were published in Polkowski (2002). There exits an extensive body of literature on rough set theory applications to knowledge discovery and data mining. In particular, a comprehensive review is available in Polkowski and Skowron (1998). The basic algorithms for data mining applications using the original rough set theory were summarized in Ziarko (2002b). Since the introduction of the original RST, several extensions of the original model were proposed (Greco et al., 2000; Slezak & Ziarko, 2003; Yao & Wong 1992; Ziarko, 1993). In particular, VPRSM was published for the first time in Ziarko (1993) and was further investigated in Kryszkiewicz (1994), Beynon (2000), Slezak and Ziarko (2003), and others, and served as a basis of a novel approach to inductive logic programming (Mahesvari et al., 2001). The probabilistic decision tables were introduced in Ziarko (1998b). The LERS system was first described in Grzymala-Busse (1992). Its most important algorithm, LEM2, was presented in Chan and Grzymala-Busse (1994). Some

applications of LERS were published in Freeman, et al. (2001), Gunn and Grzymala-Busse (1994), Grzymala-Busse et al. (2001), Grzymala-Busse and Gunn (1995), Grzymala-Busse and Woolery (1994), Loupe, et al. (2001), Moradi, et al. (1995), and Woolery, et al. (1991).

It appears that utilizing extensions of the original rough set theory is the main trend in data mining applications of this approach. In particular, a number of sources reported experiments using rough set theory for medical diagnosis, control, and pattern recognition, including speech recognition, handwriting recognition, and music fragment classification (Brindle & Ziarko, 1999; Kostek, 1998; Mrozek, 1986; Peters et al., 1999; Plonka & Mrozek, 1995; Shang & Ziarko, 2003). These technologies are far from maturity, which indicates that the trend toward developing applications based on extensions of rough set theory will continue.

CONCLUSION

Data mining and machine learning applications based on the original approach to rough set theory and, more recently, on extensions and generalizations of rough set theory, have been attempted for about 20 years now. Due to space limits, this article mentions only example experimental and real-life application projects. The projects confirm the viability of rough set theory as a fundamental framework for data mining, machine learning, pattern recognition, and related application areas, and provide inspiring feedback toward continuing growth of the rough set approach to better suit the needs of real-life application problems.

KEY TERMS

Decision Rule: Specification of the relationship between collection of observations (conditions) and an outcome (a decision).

Definable Set: A set that has a description precisely discriminating elements of the set from among all elements of the universe of interest.

LERS: A comprehensive system for data mining based on rough sets.

Lower Approximation of a Rough Set: Maximum definable set contained in the rough set.

Rough Decision Table: Collection of disjoint decision rules of identical format.

Rough Set: An undefinable set.

Upper Approximation of a Rough Set: Minimum definable set containing the rough set.

Variable Precision Rough Set Model: An approach to forming lower and upper approximations of a rough set via generalized parametric definitions.

Sampling Methods in Approximate Query Answering Systems

Gautam Das
The University of Texas at Arlington, USA

INTRODUCTION

In recent years, advances in data collection and management technologies have led to a proliferation of very large databases. These large data repositories typically are created in the hope that, through analysis such as data mining and decision support, they will yield new insights into the data and the real-world processes that created them. In practice, however, while the collection and storage of massive datasets has become relatively straightforward, effective data analysis has proven more difficult to achieve. One reason that data analysis successes have proven elusive is that most analysis queries, by their nature, require aggregation or summarization of large portions of the data being analyzed. For multi-gigabyte data repositories, this means that processing even a single analysis query involves accessing enormous amounts of data, leading to prohibitively expensive running times. This severely limits the feasibility of many types of analysis applications, especially those that depend on timeliness or interactivity.

While keeping query response times short is very important in many data mining and decision support applications, exactness in query results is frequently less important. In many cases, ballpark estimates are adequate to provide the desired insights about the data, at least in preliminary phases of analysis. For example, knowing the marginal data distributions for each attribute up to 10% error often will be enough to identify top-selling products in a sales database or to determine the best attribute to use at the root of a decision tree.

For example, consider the following SQL query:

```
SELECT State, COUNT(*) as ItemCount
FROM SalesData
WHERE ProductName= 'LawnMower'
GROUP BY State
ORDER BY ItemCount DESC
```

This query seeks to compute the total number of a particular item sold in a sales database, grouped by state. Instead of a time-consuming process that produces completely accurate answers, in some circumstances, it may be suitable to produce ballpark estimates (e.g., counts to the nearest thousands).

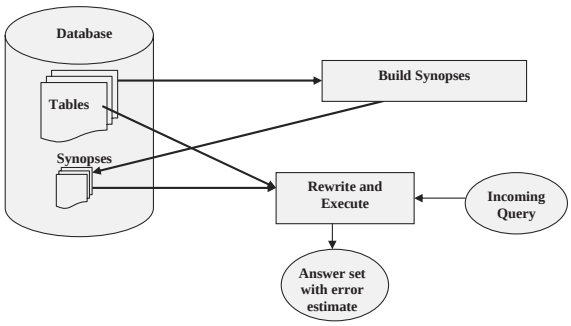
The acceptability of inexact query answers, coupled with the necessity for fast query response times, has led researchers to investigate approximate query answering (AQA) techniques that sacrifice accuracy to improve running time, typically through some sort of lossy data compression. The general rubric in which most approximate query processing systems operate is as follows: first, during the preprocessing phase, some auxiliary data structures, or data synopses, are built over the database; then, during the runtime phase, queries are issued to the system and approximate query answers quickly are returned, using the data synopses built during the preprocessing phase. The quality of an approximate query processing system often is determined by how accurately the synopsis represents the original data distribution, how practical it is to modify existing database systems to incorporate approximate query answering, and whether error estimates can be returned in addition to ballpark estimates.

BACKGROUND

Figure 1 describes a general architecture for most AQA systems. There are two components in the architecture: (1) a component for building the synopses from database relations, and (2) a component that rewrites an incoming query in order to use the synopses to answer the query approximately and report the answer with an estimate of the error in the answer.

The different approximate query answering systems that have been proposed differ in various ways: in the types of synopses proposed; whether the synopses building component is executed in a preprocessing phase or whether it executes at runtime; the ability of

Figure 1. Architecture for approximate query answering



the AQA system also to provide error guarantees in addition to the approximate answers; and, finally (from a practical point of view and perhaps the most important), the amount of changes necessary to query processing engines of commercial database management systems to incorporate approximate query answering.

The types of synopses developed for AQA systems can be divided into two broad groups: sampling-based approaches and non-sampling-based approaches. In sampling-based approaches, a small random sample of the rows of the original database table is prepared, and queries are directed against this small sample table. The non-sampling-based approaches encompass a wide variety of techniques (e.g., sophisticated data structures such as wavelets [Chakrabarti et al., 2001; Matias, Vitter & Wang, 1998] and histograms [Ioannidis & Poosala, 1999]) have been proposed as useful tools for AQA.

Work in non-sampling-based AQA techniques is of great theoretical interest, but its practical impact often is limited by the extensive modifications to query processors and query optimizers that often are needed to make use of these technologies. On the other hand, sampling-based systems have the advantage that they can be implemented as a thin layer of middleware that rewrites queries to run against sample tables stored as ordinary relations in a standard, off-the-shelf database server.

Partly for these reasons, sampling-based systems have in recent years been the most heavily studied type of AQA system. In the rest of this article, our focus is on presenting an overview of the latest developments in sampling-based AQA techniques.

MAIN THRUST

In the following section, we summarize the various sampling-based AQA technologies that have been proposed in recent years by the research community. The focus of this article is on approximately answering standard SQL queries on relational databases; other exciting work done on approximate query processing in other scenarios, such as streaming and time series data, is beyond the scope of this article.

We assume a standard data warehouse schema, consisting of a few fact tables containing the measure columns, connected to several dimension tables via foreign key relationships. Furthermore, we assume that our queries are aggregation queries with SUM, COUNT, and GROUP BY operators, either over a single fact table or over a fact table joined to several dimension tables.

Uniform Random Sampling

The essential idea is that a small precomputed uniform random sample of rows S of the database R often represents the entire database well. For a fast approximate answer at runtime, one simply has to execute the query on S and scale the result. Thus, if S is a 1% sample of the database, the scaling factor is 100. The main advantages of uniform random sampling are simplicity and efficiency of preprocessing. However, there are several critical disadvantages that have not allowed this approach to be considered seriously for AQA systems.

One disadvantage is the well-known statistical problem of large data variance. For example, suppose we wish to estimate the average salaries of a particular corporation. Uniform random sampling does badly if the salary distribution is highly skewed.

The other disadvantage is specific to database systems, and is the low selectivity problem. For example, suppose a query wishes to find the average salary of a small department of a large corporation. If we only had a uniform random sample of the entire database, then it is quite likely that this small department may not be adequately represented, leading to large errors in the estimated average salary.

To mitigate these problems, much research has been attempted using so-called biased sampling techniques, where a non-uniform random sample is precomputed, such that parts of the database deemed more important

than the rest are better represented in the sample. We discuss such techniques later in the article.

Online Aggregation

Hellerstein, Haas, and Wang (1997) describe techniques for online aggregation in which approximate answers for queries are produced during early stages of query processing and gradually refined until all the data have been processed. This framework is extended in Raman and Hellerstein (2002) to have the query processor give precedence to tuples that contribute to higher-priority parts of the query result, where priority is defined using a user-specified function. The online aggregation approach has some compelling advantages (e.g., it does not require preprocessing, and it allows progressive refinement of approximate answers at runtime until the user is satisfied or the exact answer is supplied, and it can provide confidence intervals that indicate the uncertainty present in the answer).

However, there are two important systems considerations that represent practical obstacles to the integration of online aggregation into conventional database systems. First, stored relations are frequently clustered by some attribute, so accessing tuples in a random order, as required for online aggregation, requires (slow) random disk accesses. Second, online aggregation necessitates significant changes to the query processor of the database system. This is impractical, as it is desirable for an AQA system to leverage today's commercial query processing systems with minimal changes to the greatest degree possible.

Next, we consider several biased-sampling AQA methods that are based on precomputing the samples. Toward the end, we also discuss a method that attempts to strike a balance between online and precomputed sampling.

Icicles

Recognizing the low selectivity problem, designing a biased sample that is based on known workload information was attempted in Ganti, Lee, and Ramakrishnan (2000). In this paper, the assumption was that a workload of queries (i.e., a log of all recent queries executing against the database) is a good predictor of the queries that are yet to execute on the database in the future. Thus, for example, if a query requests for the average salary of a small department in a large corporation, it is assumed that such (or similar) queries will repeat in the future. A heuristic precomputation procedure called *Icicles* was developed, in which tuples that have been accessed by many queries in the workload were assigned greater probabilities of being selected into the sample.

While this was an interesting idea based on biased sampling that leverages workload information, a disadvantage was that it focuses only on the low selectivity problem, and, furthermore, the suggested solution is rather heuristical.

Outlier Indexing

The first paper that attempted to address the problem of large data variance was by Chaudhuri, Das, Datar, Motwani, and Narasayya (2001). It proposes a technique called *Outlier Indexing* for improving sampling-based approximations for aggregate queries, when the attribute being aggregated has a skewed distribution.

The basic idea is that outliers of the data (i.e., the records that contribute to high variance in the aggregate column) are collected into a separate index, while the remaining data is sampled using a biased sampling technique. Queries are answered by running them against both the outlier index as well as the biased sample, and an estimated answer is composed out of both results. A disadvantage of this approach was that the primary emphasis was on the data variance problem, and while the authors did propose a hybrid solution for both the data variance as well as the low selectivity problem, the proposed solution was heuristical and, therefore, suboptimal.

Congressional Sampling

The AQUA project at Bell Labs (Acharya, Gibbons & Poosala, 1999) developed a sampling-based system for approximate query answering. Techniques used in AQUA included congressional sampling (Acharya, Gibbons & Poosala, 2000), which is targeted toward answering a class of common and useful analysis queries (group by queries with aggregation). Their approach stratifies the database by considering the set of queries involving all possible combinations of grouping columns and produces a weighted sample that balances the approximation errors of these queries. However, their approach is still ad hoc in the sense that even though they try to reduce the error, their scheme

does not minimize the error for any of the well-known error metrics.

Join Synopses

The AQUA project at Bell Labs also developed the join synopses technique (Acharya et al., 1999), which allows approximate answers to be provided for certain types of join queries; in particular, foreign-key joins. The technique involved precomputing the join of samples of fact tables with dimension tables, so that at runtime, queries only need to be executed against single (widened) sample tables. This is an alternate to the approach of only precomputing samples of fact tables and having to join these sample tables with dimension tables at runtime.

We mention that the problem of sampling over joins that are not foreign-key joins is a difficult problem and, under certain conditions, is essentially not possible (Chaudhuri, Motwani & Narasayya, 1999). Thus, approximate query answering does not extend to queries that involve non-foreign key joins.

Stratified Sampling (STRAT)

The paper by Chaudhuri, Das, and Narasayya (2001) sought to overcome many of the limitations of the previous works on precomputed sampling for approximate query answering and proposed a method called STRAT for approximate query answering.

Unlike most previous sampling-based studies that used ad-hoc randomization methods, the authors here formulated the problem of precomputing a sample as an optimization problem, whose goal is to minimize the error for the given workload. They also introduced a generalized model of the workload (lifted workload) that makes it possible to tune the selection of the sample, so that approximate query processing using the sample is effective, not only for workloads that are exactly identical to the given workload, but also for workloads that are similar to the given workload (i.e., queries that select regions of the data that overlap significantly with the data accessed by the queries in the given workload)—a more realistic scenario. The degree of similarity can be specified as part of the user/database administrator preference. They formulate selection of the sample for such a lifted workload as a stratified sampling task with the goal to minimize error in estimation of aggregates. The benefits of this systematic approach are demonstrated by theoretical results (where it is shown to subsume much of the previous work on precomputed sampling methods for AQA) and experimental results on synthetic data as well as real-enterprise data warehouses.

Dynamic Sample Selection

A sampling technique that attempts to strike a middle ground between precomputed and online sampling is dynamic sample selection (Babcock, Chaudhuri & Das, 2003).

The requirement for fast answers during the runtime phase means that scanning a large amount of data to answer a query is not possible, or else the running time would be unacceptably large. Thus, most sampling-based approximate query answering schemes have restricted themselves to building only a small sample of the data. However, because relatively large running times and space usage during the preprocessing phase are generally acceptable, as long as the time and space consumed are not exorbitant, nothing prevents us from scanning or storing significantly larger amounts of data during preprocessing than we are able to access at runtime. Of course, because we only are able to access a small amount of stored data at runtime, there is no gain to be had from building large auxiliary data structures, unless they are accompanied by some indexing technique that allows us to decide, for a given query, which (small) portion of the data structures should be accessed to produce the most accurate approximate query answer.

In Babcock, Chaudhuri, and Das (2003), the authors describe a general system architecture for approximate query processing that is based on the dynamic sample selection technique. The basic idea is to construct during the preprocessing phase a random sample containing a large number of differently biased subsamples, and then, for each query that arrives during the runtime phase, to select an appropriate small subset from the sample that can be used to give a highly accurate approximate answer to the query. The philosophy behind dynamic sample selection is to accept greater disk usage for summary structures than other sampling-based AQA methods in order to increase accuracy in query responses while holding query response time constant (or, alternatively, to reduce query response time while

holding accuracy constant). The belief is that for many AQA applications, response time and accuracy are more important considerations than disk usage.

FUTURE TRENDS

In one sense, AQA systems are not new. These methods have been used internally for a long time by query optimizers of database systems for selectivity estimation. However, approximate query answering has not been externalized yet to the end user by major vendors, though sampling operators are appearing in commercial database management systems. Research prototypes exist in the industry (e.g., AQP from Microsoft Research and the AQUA system from Bell Labs).

From a research potential viewpoint, approximate query answering promises to be a very fertile area with several deep and unresolved problems. Currently, there is a big gap between the development of algorithms and their adaptability in real systems. This gap needs to be addressed before AQA techniques can be embraced by the industry. Second, the research has to broaden beyond the narrow confines of aggregation queries over single table databases or multi-tables involving only foreign-key joins. It is important to investigate how to return approximations to set-valued results, AQA over multi-table databases with more general types of SQL queries, AQA over data streams, and investigations into the practicality of other non-sampling-based approaches to approximate query answering. As data repositories get larger and larger, effective data analysis will prove increasingly more difficult to accomplish.

CONCLUSION

In this article, we discussed the problem of approximate query answering in database systems, especially in decision support applications. We described various approaches taken to design approximate query answering systems, especially focusing on sampling-based approaches. We believe that approximate query answering is an extremely important problem for the future, and much work needs to be done before practical systems can be built that leverage the substantial theoretical developments already accomplished in the field.

KEY TERMS

Aggregation Queries: Common queries executed by decision support systems that aggregate and group large amounts of data, where aggregation operators are typically SUM, COUNT, AVG, and so forth.

Biased Sampling: A random sample of k tuples of a database, where the probability of a tuple belonging to the sample varies across tuples.

Decision Support Systems: Typically, business applications that analyze large amounts of data in warehouses, often for the purpose of strategic decision making.

Histograms: Typically used for representing one-dimensional data, though multi-dimensional histograms are being researched in the database field. A histogram is a division of the domain of a one-dimensional ordered attribute into buckets, where each bucket is represented by a contiguous interval along the domain, along with the count of the number of tuples contained within this interval and other statistics.

Standard Error: The standard deviation of the sampling distribution of a statistic. In the case of approximate query answering, it measures the expected value of the error in the approximation of aggregation queries.

Stratified Sampling: A specific procedure for biased sampling, where the database is partitioned into different strata, and each stratum is uniformly sampled at different sampling rates. Tuples that are more important for aggregation purposes, such as outliers, are put into strata that are then sampled at a higher rate.

Uniform Sampling: A random sample of k tuples of a database, where each subset of k tuples is equally likely to be the sample.

Workload: The log of all queries that execute on a database system. Workloads often are used by database administrators as well as by automated systems (such as AQA systems) to tune various parameters of database systems for optimal performance, such as indexes and physical design, and, in the case of AQA, the set of sample tables.

Scalable Non-Parametric Methods for Large Data Sets

V. Suresh Babu
Indian Institute of Technology-Guwahati, India

P. Viswanath
Indian Institute of Technology-Guwahati, India

M. Narasimha Murty
Indian Institute of Science, India

INTRODUCTION

Non-parametric methods like the nearest neighbor classifier (NNC) and the Parzen-Window based density estimation (Duda, Hart & Stork, 2000) are more general than parametric methods because they do not make any assumptions regarding the probability distribution form. Further, they show good performance in practice with large data sets. These methods, either explicitly or implicitly estimates the probability density at a given point in a feature space by counting the number of points that fall in a small region around the given point. Popular classifiers which use this approach are the NNC and its variants like the k-nearest neighbor classifier (k-NNC) (Duda, Hart & Stock, 2000). Whereas the DBSCAN is a popular density based clustering method (Han & Kamber, 2001) which uses this approach. These methods show good performance, especially with larger data sets. Asymptotic error rate of NNC is less than twice the Bayes error (Cover & Hart, 1967) and DBSCAN can find arbitrary shaped clusters along with noisy outlier detection (Ester, Kriegel & Xu, 1996).

The most prominent difficulty in applying the non-parametric methods for large data sets is its computational burden. The space and classification time complexities of NNC and k-NNC are $O(n)$ where n is the training set size. The time complexity of DBSCAN is $O(n^2)$. So, these methods are not scalable for large data sets. Some of the remedies to reduce this burden are as follows. (1) Reduce the training set size by some editing techniques in order to eliminate some of the training patterns which are redundant in some sense (Dasarathy, 1991)**.** For example, the condensed NNC (Hart, 1968) is of this type. (2) Use only a few selected prototypes from the data set. For example, *Leaders-subleaders* method and *l*-DBSCAN method are of this type (Vijaya, Murthy & Subramanian, 2004 and Viswanath & Rajwala, 2006). These two remedies can reduce the computational burden, but this can also result in a poor performance of the method. Using enriched prototypes can improve the performance as done in (Asharaf & Murthy, 2003) where the prototypes are derived using adaptive rough fuzzy set theory and as in (Suresh Babu & Viswanath, 2007) where the prototypes are used along with their relative weights.

Using a few selected prototypes can reduce the computational burden. Prototypes can be derived by employing a clustering method like the leaders method (Spath, 1980)**,** the *k*-means method (Jain, Dubes, & Chen, 1987), *etc.*, which can find a partition of the data set where each block (cluster) of the partition is represented by a prototype called leader, centroid, *etc*. But these prototypes can not be used to estimate the probability density, since the density information present in the data set is lost while deriving the prototypes. The chapter proposes to use a modified leader clustering method called the *counted-leader* method which along with deriving the leaders preserves the crucial density information in the form of a *count* which can be used in estimating the densities. The chapter presents a fast and efficient nearest prototype based classifier called the *counted k-nearest leader classifier (ck-NLC)* which is on-par with the conventional k-NNC, but is considerably faster than the k-NNC. The chapter also presents a density based clustering method called *l*-DBSCAN which is shown to be a faster and scalable version of DBSCAN (Viswanath & Rajwala, 2006). Formally, under some assumptions, it is shown that the number of leaders is upper-bounded by a constant which is independent of the data set size and the distribution from which the data set is drawn.

BACKGROUND

Supervised learning and *unsupervised learning* are two main paradigms of learning. Supervised learning refers to learning with a teacher, typically in situations where one has a set of training patterns whose class labels are known. The objective is to assign a label to the given test pattern. This is called pattern classification. On the other hand, unsupervised learning or learning without a teacher refers to situations where training patterns are not labeled and the typical objective is to find the natural grouping (or categories) among the given patterns. This is called pattern clustering (Jain, Murty & Flynn, 1999). Among various classification and clustering methods non-parametric methods are those which either explicitly or implicitly estimates the arbitrary density function from the data sets based on which classification or clustering tasks can be performed. Prominent non-parametric classifiers are NNC and k-NNC. Whereas DBSCAN is a popular non-parametric density based clustering method.

NNC works as follows. Let $\{(X^1, y^1),\ldots,(X^n, y^n)\}$ be the training set where y^i is the class label for the pattern X^i, for $1 \leq i \leq n$. For a given test pattern T, Let X^l be the nearest neighbor in the training set based on the given distance measure, then NNC assigns the class label of X^l *(i.e.,*y^l*)* to T. An extension of the above method is to find k nearest neighbors of the test pattern and assigning the class label to the test pattern based on a majority vote among the k neighbors. Assuming that k is a small constant when compared with n, the time required to classify a pattern, either by NNC or by k-NNC, is $O(n)$.

Density based clustering methods like DBSCAN groups the data points which are dense and connected into a single cluster. Density at a point is found non-parametrically. It is assumed that probability density over a small region is uniformly distributed and the density is given by m/nV, where m is the number of points out of n input data points that are falling in a small region around the point and V is the volume of the region. The region is assumed to be a hyper sphere of radius ε and hence threshold density can be specified by a parameter *MinPts*, the minimum number of points required to be present in the region to make it dense. Given an input dataset D, and the parameters ε and *MinPts*, DBSCAN finds a dense point in D and expands it by merging neighboring dense points. Patterns in the data set which do not belong to any of the clusters are called noisy patterns. A non dense point can be a part of a cluster if it is at distance less than or equal to ε from a dense pattern, otherwise it is a noisy outlier (Viswanath & Rajwala, 2006). The time complexity of DBSCAN is $O(n^2)$.

Many non-parametric methods suffer from the huge computational requirements and are not scalable to work with large data sets like those in data mining applications.

MAIN FOCUS

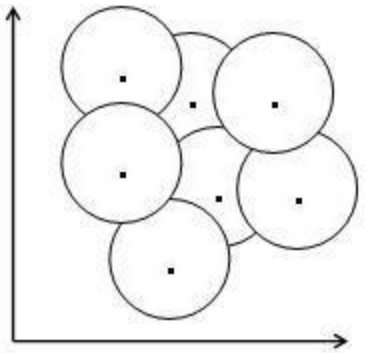
Using only a few selected prototypes from the data set can reduce the computational burden of the non-parametric methods. The prototypes need to be rich enough to compute the probability density at an arbitrary point in the feature space by using them. First, *counted-leader* method is described followed by *counted k-nearest leader classifier* and a hybrid density based clustering method which uses the counted prototypes in place of the large training data set. Finally, some experimental results are given in support of the methods in this chapter.

Counted-Leader Method

Counted-leader method which is a modified leader clustering method scans the database only once and is an incremental method. It has running time that is linear in the size of the input data set. More precisely, it can find a partition of the data set in $O(n)$ time where n is the data set size. It derives prototypes and also a count for each prototype which indicates the prototypes relative importance. The count of a prototype represents the number of patterns falling under that prototype. Conventional leader method (Spath, 1980) derives the prototypes called the leaders set. These leaders represent the semi-spherical clusters as shown in the Figure 1, and are more or less uniformly spread over some regions of the feature space. Hence by using the leaders alone it is not possible to find the probability density at a point whereas the counted leaders can be used to estimate the density at a point.

For a given threshold distance t, the counted-leader method works as follows. It maintains a set of leaders L, which is initially empty and is incrementally built. For each pattern x in D, if there is a leader l in L such that distance between x and l is less than t, then x

Figure 1. Semi spherical clusters



is assigned to the cluster represented by l and the count of the leader l is incremented. Note that, if there are many such leaders, then only one is chosen. If there is no such leader in L then x becomes a new leader which is added to the leaders set L and its count is initialized to one. The leaders and their respective counts depend on the order in which the data is scanned. But this does not affect the performance of the method which uses leaders because the cumulative count values of some of the neighboring leaders are used to estimate the density at a point. Further, when the data is drawn from a closed and bounded region of the feature space, the following theorem shows that the number of leaders is upper-bounded by a constant which is independent of the data set size and the distribution from which the data is drawn.

Theorem 1: Let the dataset D is drawn from a closed and bounded region S of the feature space. Then the number of leaders that can be derived from D using threshold distance t, such that $t > 0$, is at most $V_S / V_{t/2}$ where V_S is the volume of the region S and $V_{t/2}$ is the volume of a hyper-sphere of radius $t/2$.

Proof: Let the leaders set be L and $|L| = p$. For two distinct leaders l_1 and l_2 in L, it is guaranteed that distance between l_1 and l_2 is greater than or equal to t. Assume that at each leader l in L we replace a hyper-sphere of radius $t/2$. These hyper-spheres will not intersect each other. The total volume of these hyper-spheres is $pV_{t/2}$. Since, the data set is assumed to be drawn from a bounded region whose volume is V_S, we have $pV_{t/2} \leq V_S$. Hence $p \leq V_S / V_{t/2}$.

Counted K-Nearest Leader Classifier (ck-NLC)

The counted k-nearest leader classifier (ck-NLC) is similar to k-NNC where the selected prototypes replace the training set. A test pattern is classified based on majority cumulative count of a class among the k nearest leaders. It is described as follows. Let there are c classes *viz.*, $y^1,\ldots,y^c$. Let L_i be the prototypes derived using the *counted-leader* method using the training set for class y^i, for $i = 1$ to c. Let L be the set of all leaders. That is, $L = L_1 \cup \ldots \cup L_c$. For a given test pattern q, the k nearest leaders from L is obtained. For this k nearest leaders, the respective cumulative count for each class of leaders is obtained. Let this count for class y^i be W_i , for $i = 1$ to c. The classifier chooses the class label according to $argmax\{W_1, \ldots, W_c\}$. The method is described in Algorithm 1.

Algorithm 1 Counted k Nearest-Leader(L, q)
Step 1: Find the k-nearest leaders of q from L.
Step 2: Among the k-nearest leaders find the cumulative count of leaders that belongs to each class. Let this be W_i for class y^i, for i=1 to c.
Step 3: Find $W_x = argmax\{W_1, \ldots, W_c\}$.
Step 4: The class label assigned to q is y^x.

The domain from which a feature or attribute can take its values is almost always practically is a finite one, hence the assumption that the data set is drawn from a closed and bounded region of the feature space is not an unrealistic one. Under this assumption, the classification time of *ck-NLC* is *O(1)* only and the processing time of *l*-DBSCAN is *O(n)* only where n is the data set size. So the proposed methods are scalable. For the methods *k-NNC* and *ck-NLC*, the parameter k is found using a three fold cross validation from *{1, 2,…, 40}*.

An experimental study is done for one real time data set, *viz., Covtype.binary* available at the URL: *http://www.csie.ntu.edu.tw/cjlin/libsvmtools/datasets/binary.html* and one synthetic data set. *Covtype. binary* is a large data set consisting of 581012 patterns of 54 dimensions which belongs to two classes. The data is divided randomly into two parts consisting of 400000 and 181012 patterns, which are used as training and test sets, respectively. The synthetic data for a two dimensional two class problem is generated as follows. First class has 60000 patterns which are *i.i.d.* drawn from a normal distribution with mean as $(0,0)^T$ and covariance matrix as I_{2x2}(*i.e.*, identity matrix). Second class also is of 60000 patterns which is also *i.i.d.* drawn from a normal distribution with mean $(2.56,0)^T$ and covariance matrix as I_{2x2}. The Bayes error

rate for this synthetic data set is 10%. The data set is divided randomly into two parts consisting of 80000 and 40000 patterns which are used as training and testing sets respectively. The experimental results are summarized in Table 1 and Table 2 which shows that the proposed *ck-NLC* is a faster and efficient classifier for large data sets. Here the classifier *NLC* means the nearest leader classifier.

l-DBSCAN: A fast hybrid density based clustering method

A fast hybrid density based clustering method called *l*-DBSCAN is described below. The parameters used by *l*-DBSCAN are same as that of DBSCAN. That is, *l*-DBSCAN also uses the same ε, *MinPts* values as used by the DBSCAN method, *but l*-DBSCAN uses the set of leaders *L* and the leaders count values (which are derived by using the counted-leaders method) instead of the data set *D*. So the hybrid method primarily outputs clusters of leaders which can further be mapped into clusters of input data patterns by expanding (replacing) each leader by the pattern in *D* for which it is the representative. The key difference between the *l*-DBSCAN method and the DBSCAN method is in finding the number of points that are present in a hyper-sphere of radius ε at an arbitrary pattern of the data set. DBSCAN directly uses the data set and hence takes *O(n)* time where *n* is the data set size. But the *l*-DBSCAN method uses the set of leaders. If $l_1,\ldots,l_m$ are the leaders that are falling in the hyper-sphere, then the number of patterns in the hyper-sphere is taken to be $count(l_1) + \ldots + count(l_m)$ where count(*l*) gives the count for the leader *l*. If the total number of leaders is p, then finding $l_1,\ldots,l_m$ takes time equal to *O(p)*. Hence the total time requirement of the *l*-DBSCAN method is *O(np)*, whrereas that for the DBSCAN method is $O(n^2)$. The value of p is much smaller than n, hence *l*-DBSCAN is a faster method than DBSCAN.

Experiments are done to compare *l*-DBSCAN with DBSCAN. A *synthetic* and a standard data set are used for this purpose. The Synthetic data set called the banana data set is of a two dimensional one as shown in Figure 2 consisting of 4000 patterns. For this, the DBSCAN method with $\varepsilon = 16$ and *MinPts = 10* finds the two banana shaped clusters and also finds noisy outliers. The standard data set used is the *pendigits*

Table 1. Synthetic data set

Classifier	Classification Time(s)				Classification Accuracy(%)			
	Threshold				Threshold			
	0.25	0.20	0.15	0.10	0.25	0.20	0.15	0.10
NLC	880	1557	4137	11927	72.7	77.3	82.7	88.7
ck-NLC	1011	1744	4453	12154	74.7	78.4	84.0	90.5
NNC	1373066				94.89			
k-NNC	1373066				94.89			

Table 2. Covtype data set

Classifier	Classification Time(s)				Classification Accuracy(%)			
	Threshold				Threshold			
	0.05	0.04	0.03	0.02	0.05	0.04	0.03	0.02
NLC	54	74	105	151	75.52	77.35	79.80	82.43
ck-NLC	240	323	445	714	89.56	89.57	89.60	89.50
NNC	4692				85.17			
k-NNC	7884				89.61			

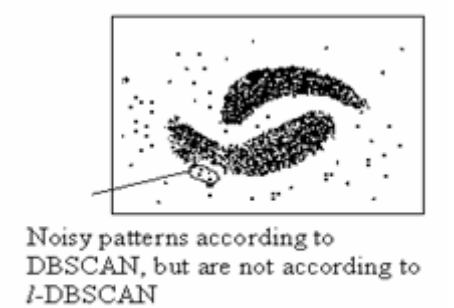
Table 3. Experimental results

Data Sets	Leaders Threshold	Rand-index	DBSCAN's execution time (s)	*l*-DBSCAN's execution time (s)
Synthetic	8	0.981	26.42	0.079
	4	0.993		0.237
	2	1		0.711
Pendigits	25	0.982923	696.86	7.58
	20	0.997139		15.33
	15	0.999988		27.52

data from the UCI machine learning repository (URL: *http://www.ics.uci.edu/mlearn/MLRepository.html*). The total number of patterns (obtained by combining the training and test data sets) is 10992. The number of dimensions is 16. The ε value used is 40 and *MinPts* is 23.

Rand-index (Rand, 1971) is used to compare the clustering outputs obtained by the DBSCAN method and the *l*-DBSCAN method. Note that, if rand-index = 1, then both clustering results are same. For the leaders threshold value 2, for the synthetic data set the rand-index obtained is 1. When the leaders threshold is 15, for the pendigits data set, the rand-index obtained is 0.999988. But the execution time of *l*-DBSCAN is less than 3% for the synthetic data set and less than 4% for the Pendigits data set when compared with that of the DBSCAN method. The results are summarized in Table 3. Figure 2 presents a situation where the leaders threshold is 8 and the clustering result of the *l*-DBSCAN is different from that of the DBSCAN.

Figure 2. The banana data set



FUTURE TRENDS

Building an index over the prototypes can reduce the computational time further. An indexing method like R-tree (Guttman, 1984) can be used for this purpose.

CONCLUSION

Non-parametric classification and clustering methods are popular and it performs very well with large data sets, but has huge computational burden. Using only a few selected prototypes which are rich enough to compute the probability density can reduce the computational time requirement. The chapter proposed to use a modified leaders clustering method where along with the leaders, the number of patterns grouped with the leader called the leader's count are preserved. The leaders set is used instead of the given data set with a nearest neighbor based classifier and with a density based clustering method. The classifier proposed is the counted *k* nearest leader classifier (ck-NLC) and the clustering method proposed is a faster version of the DBSCAN method called the *l*-DBSCAN method. The proposed methods are experimentally demonstrated to perform well and are shown to be scalable to work with large data sets like those in data mining applications.

S

KEY TERMS

Clustering of a dataset: The process of grouping data set into subsets whose union is equal to the dataset such that patterns in the same group are similar and the patternswhich are in different groups are dissimilar.

Cross Validation: It is a process of finding unknown parameters of a model by partitioning the training data set into several groups where each part in turn is used to test the model fitted by using the remaining parts.

Pattern: An object either physical or abstract which can be represented using a set of feature values. Normally a pattern is seen as a point in a feature space.

Partition of a Dataset: A collection of subsets of the dataset such that every pair of distinct subsets are disjoint and the union of the collection is equal to the dataset.

Prototype Selection: The process of selecting a few representative samples from the given training set suitable for the given task.

Rand-Index: If P and Q are two partitions of a data set, then *Rand-Index(P,Q)* which measures the similarity between P and Q is $(a+b)/d$, where a is the number of pairs (x,y) in the data set that x and y are present in a block of P and x and y are present in a block of Q, b is the number of pairs (x,y) in the data set such that x and y are not present in a block according to P and also not present in a block according to Q, and d is the total number of pairs present in the data set.

Training Set: The set of patterns whose class labels are known and which is used by the classifier in classifying a given pattern.

Scientific Web Intelligence

Mike Thelwall
University of Wolverhampton, UK

INTRODUCTION

Scientific Web Intelligence (SWI) is a research field that combines techniques from data mining, web intelligence and scientometrics to extract useful information from the links and text of academic-related web pages, using various clustering, visualization and counting techniques. Its origins lie in previous scientometric research into mining offline academic data sources such as journal citation databases, in contrast to Web Science, which focuses on engineering an effective Web (Berners-Lee et al., 2006). Typical scientometric objectives are either evaluative: assessing the impact of research; or relational: identifying patterns of communication within and between research fields. From scientometrics, SWI also inherits a need to validate its methods and results so that the methods can be justified to end-users and the causes of the results can be found and explained.

BACKGROUND

The term 'scientific' in Scientific Web Intelligence has a dual meaning. The first meaning refers to the scope of the data: it must be academic-related. For example, the data may be extracted from university web sites, electronic journal sites, or just pages that mention or link to academic pages. The second meaning of 'scientific' alludes to the need for SWI research to use scientifically defensible techniques to obtain its results. This is particularly important when results are used for any kind of evaluation.

Scientific Web Intelligence is young enough that its basic techniques are not yet established (Thelwall, 2005c). The current emphasis is on methods rather than outputs and objectives. Methods are discussed in the next section. The ultimate objectives of typical developed SWI studies of the future can be predicted, however, from research fields that have used offline academic document databases for data mining purposes. These fields include bibliometrics, the study of academic documents, and scientometrics, the measurement of aspects of science, including through its documents (Borgman & Furner, 2002).

Evaluative scientometrics develops and applies quantitative techniques to assess aspects of the value of academic research or researchers. An example is the Journal Impact Factors (JIF) of the Institute for Scientific Information (ISI) that are reported in the ISI's journal citation reports. JIFs are calculated for journals by counting citations to articles in the journal over a fixed period of time and dividing by the number of articles published in that time. Assuming that a citation to an article is an indicator of impact (because other published research has used the article in order to cite it), the JIF assesses the average impact of articles in the journal. By extension, 'good' journals should have a higher impact (Garfield, 1979), so JIFs could be used to rank or compare journals. In fact the above argument is highly simplistic. Scientometricians, whilst accepting the principle of citations as a useful impact proxy, will argue for more careful counting methods (e.g., not comparing citation counts between disciplines), and a much lower level of confidence in the results (e.g., taking them as indicative rather than definitive) (van Raan, 2000). Evaluative techniques are also commonly used for academic departments. For example, a government may use citation-based statistics in combination with peer review to conduct a comparative evaluation of all of the nation's departments within a given discipline (van Raan, 2000). Scientific Web Intelligence may also be used in an evaluative role, but since its data source is only web pages, which are not the primary outputs of most scientific research, it is unlikely to ever be used to evaluate academics' web publishing impact. Given the importance of the web in disseminating research (e.g., Lawrence, 2001), it is reasonable to measure web publishing, however.

Relational scientometrics seeks to identify patterns in research communication. Depending upon the scale of the study, this could mean patterns of interconnections of researchers within a single field, of fields or journals within a discipline, or of disciplines within the whole of science. Typical outputs are graphs of the relationships, although dimension-reducing statistics such as factor analysis are also used. For example, an investigation into how authors within a field cite each other may yield an author-based picture of the field that usefully identifies sub-specialisms, their main actors and interrelationships (Lin, White, & Buzydlowski, 2003). *Knowledge domain visualisation* (Börner, Chen, & Boyack, 2003) is a closely related research area, but one that focuses on the design of visualisations to display relationships in knowledge domains. Relationship identification is likely to be a common outcome for future SWI applications. An advantage of the web over academic journal databases is that it can contain more up to date information, which could help produce more current domain visualisations. The disadvantage, however, is that the web contains a wide variety of information that is loosely related to scholarly activity, if at all, even in university web sites. The challenge of SWI, and the rationale for the adoption of web intelligence and data mining, is to extract useful patterns from this mass of mainly useless data. Successful SWI will be able to provide early warning of new research trends, within and between disciplines.

MAIN THRUST OF THE CHAPTER

Scientific Web Intelligence uses methods based upon web links (web structure mining) and text (web content mining). A range of relevant web content and structure mining techniques are described below.

Academic Web Structure Mining

Modelling

Early academic web structure mining sought to assess whether counts of links to university or department web sites could be used to measure their online impact. This originated in the work of Ingwersen (1998). In brief, the results of this line of research indicated that links between university web sites, unlike citations, almost never represented knowledge transfer within the context of research. For example, few of these links point to online journal or conference articles. Nevertheless, it seems that about 90% of links are related in some way to academic activities (Wilkinson et al., 2003), and counts of links to universities correlate significantly with measures of research productivity for universities (Thelwall & Harries, 2004) and departments in some disciplines (Li et al., 2003; Tang & Thelwall, 2003). These results are consistent with web publishing being a natural by-product of research activity: people who do more research tend to create more web pages, but the chances of any given web page being linked to does not depend upon the research capabilities of its author, on average. In other words, more productive researchers tend to attract more links, but they also tend to produce more content and so the two factors cancel out (see also Barjak & Thelwall, 2007).

A little more basic information is known about academic web linking. Links are related to geography: closer universities tend to interlink more (Thelwall, 2002). Links are related to language: universities in countries sharing a common language tend to interlink more, at least in Europe, and English accounts for at least half of international linking pages in European universities in all countries except Greece (Thelwall, Tang & Price, 2003).

Data Cleansing

An important, but unexpected, outcome of the research described above was the need for extensive *data cleansing* in order to get better results from link counting exercises. This is because, on a theoretical level, link counting works best when each link is created independently by human experts exercising care and judgement. In practice, however, many links are created casually or by automated processes. For example, links within a web site are often for navigational purposes and do not represent a judgement of target page quality. Automatically generated links vary from the credit links inserted by web authoring software to links in navigation bars in web sites. The following types of link are normally excluded from academic link studies.

- All links between pages in the same site.
- All links originating in pages not created by the hosting organisation (e.g., mirror sites).

Note that the second type requires human judgements about ownership, and that these two options do not address the problem of automatically generated links. Some research has excluded a proportion of such links (e.g., Thelwall & Wilkinson, 2003) but an alternative more automated approach devised to solve this problem is to change the method of counting.

Several new methods of counting links have been devised. These are deployed under the umbrella term of Alternative Document Models (ADMs) and are, in effect, data cleansing techniques (Thelwall & Wilkinson, 2003). The ADMs were inspired by the realisation that automated links tended to originate in pages within the same directory. For example, a mini web site of 40 pages may have a web authorising software credit link on each page, but with all site pages residing in the same directory. The effect of these links can be reduced if links are counted between directories instead of between pages. In the example given, the 40 links from 40 pages would be counted as one link from a directory, discarding the other 39 links, which are now duplicates. The ADMs deployed so far include the page ADM (which is standard link counting) the directory ADM, the domain ADM and the whole site ADM. The choice of ADM depends partly upon the research question and partly on the data. A purely data-driven selection method has been developed (Thelwall, 2005a), designed to be part of a much more automated approach to data cleansing, namely Multiple Site Link Structure Analysis (MSLSA).

Subject Similarity and Clustering

A key SWI goal is to be able to automatically cluster academic web pages by academic subject. The ability to cluster web pages by (the more general concept of) topic has been investigated in the past, employing both text-based and link-based approaches. For example, the research of Chakrabarti et al. (2002) and Menczer (2005) shows that pages about the same topic tend to interlink more than with pages on different topics. It is logical to conclude that links will be helpful for subject clustering in academic webs.

A pair of web pages can be directly linked or may be indirectly connected by links if another page is joined to both by links. Direct links are not more reliable as indicators of subject than indirect connections, but indirect connections are far more numerous (Thelwall & Wilkinson, 2004). Hence, academic subject clustering should use both types.

There are many link-based clustering algorithms, but one that is fast and scalable is the Community Identification Algorithm (Flake et al., 2002). This accepts any number of interlinked pages as input and returns their community, based solely upon link structures. This 'community' is, loosely speaking, a collection of pages that tend to link to each other more than they link to pages outside of the community. Research with this algorithm on academic webs has shown that it is capable of identifying communities for the page, directory and domain ADM, but heavily linked pages negatively affect its results (Thelwall, 2003). Data cleansing to remove these pages is recommended.

Academic Web Content Mining

Academic web content mining is less developed than academic web structure mining, but is beginning to evolve. As with structure mining, a key goal is to be able to cluster academic web spaces by subject. There is some overlap between the two, for example in the need for ADMs and similar data cleansing.

Exploratory analysis of the text in university web sites has revealed the existence of many non-subject-specific high frequency words, such as computer and internet-related terms. Low frequency words were found to be predominantly not errors. The lesson for text mining is that low frequency words could not be ignored but that a strategy must be developed to filter out unwanted high frequency words (Thelwall, 2005b). Such a strategy, Vocabulary Spectral Analysis (VSA), has been developed (Thelwall, 2004). VSA is a technique based upon the standard vector space model and k-means clustering that identifies words that are highly influential in clustering document sets, and also words that are helpful for clustering document sets in ways that they do not naturally follow. This latter capability was developed in response to the realisation that academic web sites did not naturally cluster by subject, but in other ways, including university affiliation. Further research with low frequency words (Price & Thelwall, 2005) confirmed them to be helpful for subject clustering: removing them from the documents reduced their subject clustering tendency.

Knowledge Domain Visualisation

The field of Information Visualisation has been able to develop rapidly in recent years with the improved

speed and graphical power of PCs. Its newer subfield, *Knowledge Domain Visualisation* (KDViz) uses scientometric data and develops special purpose visualisations. These visualisations are for use by researchers to orient themselves within their own discipline, or to see how other fields or disciplines fit together or relate to each other. Although the typical data sources have been journal citation databases or journal text collections, these have similarities to web links and web content that make KDViz tools a logical starting point for Scientific Web Intelligence visualisations. A discussion of some KDViz research serves to highlight the visualisation capabilities already present.

- PNASLINK is a system that treats visualisations from articles published in the Proceedings of the National Academy of Sciences (White et al., 2004). It uses pathfinder networks (a technique for selecting the most important connections to draw for large network visualizations), and self-organising maps (a clustering technique that can plot documents on a two-dimensional map) to display information to users in order to help them select terms with which to search the digital library. Both text and citations are used by the algorithms.
- Cross maps is a technique for visualising overlapping relationships in journal article collections, (Morris & Yen, 2004). It produces two-dimensional graphs cross mapping authors and research fronts, more of a mainstream scientometrics application than PNASLINK.
- CITESPACE implements features that are designed to help users identify key moments in the evolution of research fields (Chen, 2004). It works by tracking the evolution of collections of papers in a field through citation relationships. Particularly important nodes in the generated network can be identified through the visualisations. Key moments in the time for the evolution of the network can also be revealed; these are called "turning points".

To apply all of the above visualisation techniques to SWI data is a future task, although some interesting progress has already been made (Heimeriks & van den Besselaar, 2006; Ortega, Aguillo, Cothey, & Scharnhorst, forthcoming). The main current challenge is to process web data in ways that make it possible to get useful results from visualisations.

FUTURE TRENDS

The immediate goal of SWI research is effective subject clustering of collections of academic web sites. This is likely to involve a fusion of link-based and text-based clustering approaches. Success will be dependent upon developing more effective data cleansing techniques. Perhaps initially these techniques will be only semi-automated and quite labour-intensive, but a longer-term goal will be to make them increasingly more automated. This prediction for a focus on data cleansing does not rule out the possibility that advanced web intelligence techniques could be developed that bypass the need for data cleansing.

The medium-term SWI goal is to harness academic web data to visualisations in order to give web information to users in a practical and effective way.

The long-term SWI goals are to develop applications that extend those of scientometrics and KDViz, to branch out into different web data sets, and to incorporate more web intelligence techniques (Zhong, Liu, & Yao, 2003) in order to extract new types of useful information from the data.

CONCLUSION

Scientific Web Intelligence has taken the first steps towards maturity as an independent field through the harnessing of techniques from scientometrics, web structure mining and web content mining. To these have been added additional techniques and knowledge specific to academic web spaces. Many of the new discoveries relate to data cleansing, recognition that web data is far 'noisier' than any data set previously used for similar purposes. The future is promising, however, particularly in the longer term if the techniques developed can be applied to new areas of web information – perhaps even to some that do not yet exist.

KEY TERMS

Alternative Document Model: A conceptual rule for grouping together web pages into larger units, such as sites and domains, for more effective data mining, particularly useful in web structure mining.

Knowledge Domain Visualisation: A subfield of Information Visualisation that is concerned with creating effective visualisations for specific knowledge domains.

Multiple Site Link Structure Analysis: A technique for identifying the alternative document model that best fits a collection of web pages.

Scientific Web Intelligence: A research field that combines techniques from data mining, web intelligence and scientometrics to extract useful information from the links and text of academic related web pages, principally concerning the impact of information and the relationships between different kinds of information.

Scientometrics: The quantitative study of science and scientists, particularly the documentary outputs of science.

Vocabulary Spectral Analysis: A technique using the vector space model and k-means clustering to identify words that are highly influential in clustering document sets.

Web Structure Mining: Data mining the web primarily through its link structure.

Web Content Mining: Data mining the web primarily through the contents of web pages, and ignoring interlinking between pages.

Seamless Structured Knowledge Acquisition

Päivikki Parpola
Helsinki University of Technology, Finland

INTRODUCTION

Some parts of this text, namely "Co-operative Building, Adaptation, and Evolution of Abstract Models of a KB" and most subsections in "Performing Reasoning in SOOKAT According to a KB", have appeared in an article (DOI:10.1007/s10115-004-0181-6) published in the 'Knowledge And Information Systems' journal (Parpola, 2004).

A knowledge base (KB) contains data and instructions for using it (e.g., as a rule base). A KB containing knowledge possessed by experts can be used in an expert system. It can solve problems requiring expert knowledge, explain its decisions and deal with uncertainty. An expert system can be used as a basis for a larger system, called a knowledge-based system (KBS).

Knowledge acquisition (KA) that is the development and maintenance of KBs, (e.g. an expert system), can be divided into several phases, performed sequentially and iteratively. Some phases may be performed in parallel with other phases. The most commonly recognised phases are requirements definition, analysis, design, and implementation.

Disintegration, or the gap between phases of development, especially between abstract and executable descriptions, was recognised during the early stages of KA (Marcus, 1988a; Motta, Rajan and Eisenstadt, 1988). It complicates the development of KBs and hinders traceability between parts of abstract and executable descriptions. •

BACKGROUND

Seamless Structured Knowledge Acquisition (SeSKA) (Parpola, 1998; Parpola, 1999a; Parpola, 1999b; Parpola, 2000) is a methodology for as well the development and maintenance of KBs as performing reasoning in them. It is designed to enhance integration of the KA process.

During KB construction, a series of models, including the (combined) dependency graph, the domain model, the inference model, together with analysis, design and implementation descriptions, is created and possibly modified. The structure of the knowledge base is based on the logical structure of the domain which has been noticed to be more stable than the component structure (Jacobson et al., 1992).

Related work concerning the use of metaobjects and metalevels in KA includes the following:

- Protégé-2000 (Fridman Noy, Ferguson and Musen, 2000) uses a metaobject protocol (Steele, 1990; Kiczales, des Riviers and Bobrow, 1991) to describe a model, for example, the CommonKADS model of expertise (Schreiber, Crubézy and Musen, 2000). This allows applications to be presented as instantiations of the model.
- OIL (Ontology Inference Language) (Fensel, van Harmelen, Decker, Erdmann and Klein, 2000) is a proposal, based on OKBC (Open Knowledge Base Connectivity), XOL (Ontology Exchange Language), and RDF (Resource Description Framework), for a joint standard for specifying and exchanging ontologies over the Internet. Modelling ontologies in OIL distinguishes three separate layers, the object level the first metalevel, and the second metalevel. The structure consists of several components. Rule bases, classes and slots, and types, as well as slot constraints and inheritance, are used. OIL is a frame-based system, using, for example, rule bases.

MAIN FOCUS OF THE CHAPTER

Models used in SeSKA

A domain model (DM) contains a somewhat stable componential structure of a domain. Knowledge is described through a network of relations between domain or abstract concepts with attributes. These attributes in the DM are selected according to what is needed in the dependency graph (DG).

Initial dependency graphs (DG) are acquired from different sources. DGs present inferential dependencies between attributes of DM concepts. Descriptions can be attached to dependencies. The actual DG is a combination of initial DGs. A DG contains dynamic knowledge described through a network of concept attributes and dependencies.

An inference structure (IS) presents the structure of possible inference sequences performed. The IS is shared among three sets of descriptions. Collections of analysis, design and implementation descriptions are attached to inferences in the IS. The result is called the inference model (IM).

These models can be described in terms of ontologies and natural language analysis (Parpola, 2000). The DM and the DG can be produced using several different KA techniques (Parpola, 1999b). Heterogeneous vocabulary can also be harmonised. The domain model and inference model can be instantiated to form the value model and execution model. This enables performing inferences.

Managing Change through Seamless Transformations

When constructing a KB with SeSKA, integration of a structured set of models can be produced through seamless transformations that is predefined ways of getting from objects in one model to objects in another model (Jacobson et al., 1992; Parpola, 1998). The KB structure is also maintained using the constructed shared skeleton: The inference structure (IS) describes the structure of possible inference sequences through a network of roles and inference steps. The former refer to concept attributes, and the latter have attached analysis, design, and implementation descriptions:

- The major logical components of abstract descriptions,
- Their formal descriptions, and
- Executable rules or functions, respectively.

The collections of different descriptions of all inference steps, in combination with the inference structure, form the analysis, design, and implementation models. The possibility of performing inferences, described in the models, requires instantiation of domain and inference models.

The idea of being able to describe a KB via models is proposed in the SeSKA methodology and implemented in the SOOKAT tool, described later.

The Knowledge Base Construction Process

Initial Formation of the Models Describing the Domain

The initial domain model and dependency graphs are formed on the basis of default value suggestions for, and dependency suggestions between, concept attributes, acquired from several knowledge sources that may give differing values.

Combining Dependencies and Attribute Values

Complementary dependency graphs can be processed using joining and simplification rules (Parpola, 1998). These rules allow different fragments of knowledge to be brought together, even before building a KB, and make it possible to show how they might be combined. Combination rules may accelerate the construction of a KB. To cope with contradictory or multiple attribute values, SeSKA defines combination heuristics (Parpola, 1999b).

Network of Roles and Inferences

A role in the IS is formed of concept attributes that a certain attribute depends on. Inferences between roles and descriptions associated with the inferences can be created on the basis of dependencies between attributes.

Several different dependency graphs can produce the same analysis model. One way to form such a dependency graph is to take the roles connected by an inference and set all the concepts referenced by the conclusion role to depend on all concepts referenced by the premise role. The analysis description of the inference can be attached to all dependencies.

Analysis descriptions are formalised to implementation descriptions, possibly via semi-formal design descriptions. The process is iterative and modular.

Managing Change through Seamless Transformations

Often, a need for change is acknowledged during the development or maintenance of a KB through imple-

mentation errors or other instabilities in the design or implementation models. The corresponding parts of the analysis model are traced using the shared inference structure. It may frequently be the practice to describe changes that have already been carried out, but it is important to keep the logical description up to date.

Possible Implementations of SeSKA

To implement SeSKA, an implementation paradigm should be able to define and modify entities with properties, relations between entities, inheritance, and instances. These facilities enable the presentation of metalevel constructions. At least the object-oriented (OO) approach, and conceptual graphs (CG) (Sowa, 1984) can be used. Either formalism is suitable for SeSKA, since they can be used for presenting both stable knowledge in the DM and dynamic knowledge in the DG, also supporting metalevel constructs. The tool SOOKAT has been built for testing different features of SeSKA.

Overview of the SOOKAT tool

A series of OO models is created and partially modified during the iterative development process.

Construction of a KB

SOOKAT uses two metaobject protocols, for domain and inference models, in order to be able to:

- Present and modify application instances and their attributes,
- At run time, create and modify concepts with instances, so that the modifications transfer to instances, and
- Use instantiations of the inference structure to apply abstract rules defined in the inference model to application instances of concept attributes.

Instantiation models are created in order to complete use of metaobject protocols. Taking full advantage of using the metaobject protocols means being able to simultaneously modify and use the knowledge base. The tool is implemented in the Java programming language, which does not inherently contain a metaobject protocol, unlike, for example, the Common Lisp programming language.

Architecture of SOOKAT

The class DomainModel contains an inheritance hierarchy of Concept metaclasses in the domain. The class ConceptAttribute can manage both the multiple values acquired from different knowledge sources and the default values worked out. A Concept contains instances of ConceptAttribute.

The class DependencyGraph refers to instances of the classes AttributeReference and Dependency. An AttributeReference contains a reference to a Concept in the domain model, as well as the name of a ConceptAttribute. A Dependency describes an inferential, (i.e., logical dependency between attributes of domain concepts). Dependencies of one or several types can be used. The type of a dependency is indicated by referring to an instance of a suitable subclass of the class DependencyType. A description is attached to each dependency.

Restricted views, showing only selected concepts, can be created for applications. This implements the Remove combination rule for DGs, without deleting information, as discussed earlier.

The model, managed through the class InferenceModel, is based on a network called the inference structure, which describes the structure of possible inferences through instances of the metaclasses Role and Inference. Inference defines, for each description level, a separate aggregate attribute:

- An analysis-level description is an abstract textual description. The initial analysis-level description of an inference is formed as a combination of descriptions of the dependencies the inference is based on. The description may be presented as a table.
- A design-level description is a semi-formal presentation of the analysis-level description. In SOOKAT, it is implemented as a rule table.
- An implementation-level description is composed of abstract descriptions of executable rules, implemented using the class Rule, containing three attributes, namely
  a. A premise expression that is, an instance of the class BooleanExpression, defining a logical operator, as well as operands that may be Expressions, RoleAttributeReferences, acting as variables, or arithmetic (integer) or logical (boolean) constants and references

to variables evaluating to primitive types,

b. A reference to the *conclusion attribute* that is, a RoleAttributeReference instance, and
c. A formula for obtaining the conclusion value that is an instance of the class ValueExpression which is a subclass of the class ArithmeticExpression. The conclusion attribute reference and the conclusion value form a BooleanExpression with an 'IS' operator.

In the value model, application instances are represented by instances of the Java class ConceptInstance. The values of their attributes are the possibly variable given values and the different possible conclusion values from the inferences. The latter depend on the execution model, in addition to the inference model.

The execution model contains instances of the Java classes RoleInstance and InferenceInstance. Messages are sent between these application instances in an order controlled by an instance of some subclass of the class ControlObject.

InferenceInstance instances adjust abstract rules. RoleAttributeReferences are replaced with corresponding values or references to attributes of application instances in the value model.

Co-Operative Building, Adaptation, and Evolution of Abstract Models of a KB

Suggestions for attribute values of concepts can be inserted in an arbitrary order by different knowledge sources. All suggestions are stored in instances of the class ConceptAttribute, a subclass of the class Attribute.

To eliminate heterogeneity in AttributeReference names, Concepts can be selected from among the ones in the domain model, as well as an attribute name from among those in a selected Concept. DependencyTypes can be selected from among the instances of it or its subclasses.

The combination of dependency graphs acquired from different sources is implicit in SOOKAT. Combination rules (Parpola, 1998) can be used incrementally, even when several knowledge sources are considered in parallel, assuming the context to be the same (Parpola, 2002; Parpola, 2001). Dependencies are joined automatically. Simplification is performed semi-automatically when SOOKAT collects dependencies. SOOKAT simply joins descriptions of varying dependencies and the user can remove duplicate descriptions. The descriptions and sources of the original dependencies are maintained. Descriptions of dependencies can also be augmented with lists of suitable contexts.

The dependency graph, with its descriptions, is used in forming the initial inference model, called the analysis model, consisting of the inference structure and abstract descriptions taken directly from dependencies. Inference structure formation is triggered from the user interface.

The informal, semi-informal, and formal descriptions are stored as attributes of instances of the class Inference, giving abstract descriptions of inferences in the inference model. Thus, formal and informal descriptions can be stored contiguously, as different descriptions can simultaneously be at different stages of development. Transformations between different descriptions of an inference are performed semi-automatically.

Different models can be modified in the user interface of SOOKAT, and models can be saved in a format that can be exported. Changes made can to some extent be propagated to other models (Parpola, 1999b).

Performing Reasoning in SOOKAT According to a KB

Instantiation of Models

In order to be able to perform inferences in an application, the domain model and inference model have to be instantiated to form the value model and execution model.

The Concepts in the domain model are gone through by the tool in order to remind the user of the items to be instantiated. For the desired concepts, the user can create one or more application instances with specific names and attribute values.

Roles in the inference model will be instantiated with selected collections of attribute instances. InferenceInstance instances between RoleInstance instances trigger rules of Inference metaobjects, applied to the ConceptInstance instance attributes, indicated by the RoleInstance instances.

A reason for defining Inference as a metaobject is that it provides a handy way of collecting together a group of InferenceInstances using the same rules. In this way, modifying a rule in a subclass of Inference affects all of its InferenceInstances at a time.

The Message Sending and Assignment Mechanism

Inferences are performed according to principles that have been adopted from the KADS methodology (Hesketh and Barrett, 1989; Schreiber, Akkermans, Anjewierden, de Hoog, Shadbolt, Van de velde and Wielinga, 1999) and modified. InferenceInstance instances between RoleInstance instances trigger rules of corresponding Inference instances, applied to the desired ConceptInstance attributes.

Assignments are made to values of Attributes of ConceptInstance instances in the value model, considered as variables to which either values of, or references to, the actual application instance attributes are assigned by InferenceInstance instances.

It has been proved that reasoning through the assignment of concept values holds the power of first-order logic (Wetter, 1990). Replacing concepts with attributes of concepts makes only a small addition to the proof.

The structure of possible inferences is defined by the instantiated inference structure.

Control Objects

A ControlObject (CO), specific to the chosen inference strategy, is used to control message sending between RoleInstance and InferenceInstance instances.

Actual inferencing takes place when COs for different inference strategies also guide the overall process as individual tasks. Message sending among CO, RoleInstance, and InferenceInstance instances (i.e. objects) are controlled by the CO. Suitable actions in RoleInstance and InferenceInstance objects are also triggered by the CO. The actual order of inferences to be performed is determined by the inference strategy used.

Using Protocols for Reasoning

Here a protocol means a documented series of reasoning stages that are gone through when a solution based on some premise values is reached (Ericsson and Simon, 1984). In other words, a protocol goes through an instantiation of one possible path (a sequence of inference steps, i.e., reasoning stages) through the inference structure. Reasoning stages are called protocol phases.

In SOOKAT, protocols are presented using dependencies. Each protocol phase depends on the attribute(s) reasoned during it, and on the previous phase. In other words, a DependencyGraph can describe the ordering of reasoning steps, in addition to logical dependencies between attributes.

The metaclass Protocol is defined as a subclass of the metaclass Concept. The class ProtocolPhase is, in turn, defined as a subclass of the class ConceptAttribute. As Protocol is a metaclass, the following are possible:

a. Dynamic creation of Protocol instances,
b. Inheritance among Protocol instances, and
c. Instantiation of Protocol instances (e.g. MineralClassificationProtocol instances).

The use of the second or third possibilities could increase the flexibility of the system through enabling the association of different and alternative COs to instances of Protocols.

Inference Using PSMs

Inferences can also be performed according to some problem-solving methods (PSMs) such as cover-and-differentiate (Eshelman, 1988) or propose-and-revise (Marcus, 1988b; Leo, Sleeman and Tsinakos, 1994).

FUTURE TRENDS

In the SeSKA and SOOKAT domain in the future, control objects (COs) for different problem-solving methods (PSMs) will be implemented, and their use investigated.

Mechanisms for transferring metaobjects, objects and their properties, as well as descriptions of PSMs and COs over the Internet between applications should be integrated in SOOKAT. OIL (Ontology Inference Language) mentioned in the section *BACKGROUND* is an interesting tool for this. Using Semantic Web to connect to and even discover knowledge in services or other applications is also a very interesting possibility (Hepp, 2005; Lopez, Sabou and Motta, 2006; Sabou and Pan, 2007).

CONCLUSION

The SeSKA (seamless structured knowledge acquisition) methodology has been developed to reduce

disintegration in the knowledge acquisition (KA) process. SeSKA does this by using *uniform formalisms* in the models used in KA phases, using automatic and semi-automatic *seamless transformations* between the models, facilitating traceability by linking them with different types of inference descriptions in the common inference structure (IS), inferencing in the models, using metaobject protocols to simultaneously modify and use knowledge bases (KB). Parts of the above means have been used in existing knowledge acquisition (KA) tools to overcome the disintegration problem, whereas SeSKA combines them.

KEY TERMS

Knowledge Base: Combination of both knowledge (facts about the world) and instructions of using the knowledge (inference, i.e., reasoning rules).

Knowledge Acquisition: Acquiring from possibly multiple experts, using multiple acquisition techniques, values of items of a knowledge base.

Natural Language Analysis: Analysing language (or signs presenting it), used (produced) by human beings, with special methods.

Object-Oriented: A way of describing the world or a part of it through active entities, called objects, that can be specialisations or parts of other objects.

Reasoning: Obtaining values of concept attributes, marked to be conclusion attributes, based on performing reasoning on concept attributes, marked to be premises.

Metaobject Protocol: Contains objects on three levels of abstraction:

- A Metaclass is a class, the instances of which are themselves classes.
- Class attributes with types describe a group of objects. Behaviour is defined through methods. Classes form an inheritance hierarchy.
- An Instance is an instance of another class than a metaclass.

SeSKA Methodology: The knowledge acquisition methodology SeSKA (seamless structured knowledge acquisition) has been developed to reduce disintegration between informal and formal descriptions of a knowledge base.

SOOKAT Tool: Implementation of the SeSKA methodology, used to test the methodology.

Search Engines and their Impact on Data Warehouses

Hadrian Peter
University of the West Indies, Barbados

Charles Greenidge
University of the West Indies, Barbados

INTRODUCTION

Over the past ten years or so *data warehousing* has emerged as a new technology in the database environment. "A data warehouse is a global repository that stores pre-processed queries on data which resides in multiple, possibly heterogeneous, operational or legacy sources" (Samtani et al, 2004).

Data warehousing as a specialized field is continuing to grow and mature. Despite the phenomenal upgrades in terms of data storage capability there has been a flood of new streams of data entering the warehouse. During the last decade there has been an increase from 1 terabyte to 100 terabyte and, soon to be 1 petabyte, environments. Therefore, the ability to search, mine and analyze data of such immense proportions remains a significant issue even as analytical capabilities increase.

The data warehouse is an environment which is readily tuned to maximize the efficiency of making useful decisions. However the advent of commercial uses of the Internet on a large scale has opened new possibilities for data capture and integration into the warehouse.

While most of the data necessary for a data warehouse originates from the organization's internal (operational) data sources, additional data is available externally that can add significant value to the data warehouse. One of the major reasons why organizations implement data warehousing is to make it easier, on a regular basis, to query and report data from multiple transaction processing systems and/or from external sources. One important source of this external data is the Internet.

A few researchers (Walters, 1997; Strand & Olsson, 2004; Strand & Wangler, 2004) have investigated the possibility of incorporating external data in data warehouses, however, there is little literature detailing research in which the Internet is the source of the external data. In (Peter & Greenidge, 2005) a high-level model, the Data Warehousing Search Engine (DWSE), was presented. However, in this article we examine in some detail the issues in search engine technology that make the Internet a plausible and reliable source for external data. As John Ladley (Ladley, 2005) states "There is a new generation of Data Warehousing on the horizon that reflects maturing technology and attitudes". Our long-term goal is to design this new generation Data Warehouse.

BACKGROUND

Data warehousing methodologies are concerned with the collection, organization and analysis of data taken from several heterogeneous sources, all aimed at augmenting end-user business function (Berson & Smith, 1997; Wixom & Watson, 2001; Inmon, 2003). Central to the use of heterogeneous data sources is the challenge to extract, clean and load data from a variety of operational sources. External data is key to business function and decision-making, and typically includes sources of information such as newspapers, magazines, trade publications, personal contacts and news releases.

In the case where external data is being used in addition to data taken from disparate operational sources, this external data will require a cleaning/merge/purge process to be applied to guarantee consistency (Higgins, 2003; Walters, 1997). The Web represents a large and growing source of external data but is notorious for the presence of bad, unauthorized or otherwise irregular data (Kim, 2003). Thus the need for cleaning and integrity checking activities increases when the web is being used to gather external data.

External data has the following advantages (Strand & Olsson, 2004) and disadvantages (Strand & Wangler, 2004):

Advantages

- Ability to compare internal data with external data
- Helps with the acquisition of data related customers
- Helps with the acquisition of additional data about the marketplace

Disadvantages

- Ensuring the quality of the external data
- Making users trust the external data
- Physically integrating the external data with the internal data
- Conceptually mapping the external data with the internal data

Given that the focus of this article is the use of external data (accessed from the web) in the data warehouse, it is in our interest to highlight the advantages and minimize or, if possible, eliminate the disadvantages mentioned above. We believe that one way of doing so is to use the appropriate search engine(s) to access the data from the Internet. Figure 1 illustrates the role played by external data in the decision-making process.

MAIN THRUST

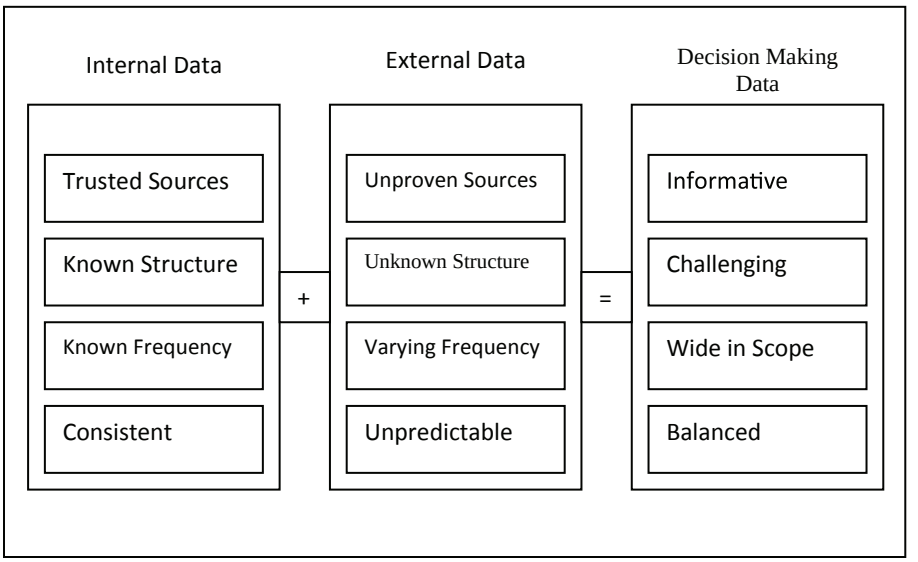
Search Engines: Comparison and Background Information

The literature is replete with examples of search engines for accessing external data from the Internet. In this section we examine a number of search engines and compare their characteristics.

There are substantial limitations to Search Engines. Most of them rely on crawler programs that go through a process of indexing web pages during a search (Butler, 2000). Most search engines only cover a fraction of the web, because vast amounts of data and documents stored in databases cannot be accessed by the current versions of web crawlers. These search engines are therefore unfortunately incapable of extracting information from the deep web or invisible web where much useful external data resides.

A long-standing shortcoming of search engines is that they provide only one way of organizing their search – by *salience (confidence, or certainty)* value (Bean, 2007). This value indicates how likely it is that a returned result matches the query. Such shortcomings

Figure 1. Merits of internal/external data



provide the motivation for a better approach to searching.

Another feature of conventional search engines is that they use algorithms and simple heuristics to rank web pages, and most of them only associate the text of a link with the page the link is on. However, newer search engines such as Google (see www.google.com) exploit the many links between web pages, and rank web pages based on *authorities* – web pages with many links pointing to them.

Given the obvious limitations of most search engines, and the sophistication of users, who are becoming more knowledgeable and demanding, the need for advanced search technologies is very urgent.

A number of research efforts have led to search engines with features that make them conducive to accessing external data. One approach is to use dedicated, specialized search engines. Examples are HotBot (Butler, 2000) which lets users search only academic sites with the domain name ending in ".edu", and NEC's ResearchIndex (now CiteSeer) (see http://citeseer.ist.psu.edu/citeseer.html) – a search engine designed specifically for scientists. Unlike most search engines Citeseer retrieves PDF and Postscript files. It uses simple rules based on the formatting of a document.

Advances in Artificial Intelligence (AI) technology promise better tools for web search. Techniques such as natural language, object recognition, and statistical machine learning are promising. Examples of new search engines that utilize AI techniques are MedStory, Powerset and Riya (Olsen, 2006). Powerset uses AI to train computers to make connections between words and make inferences. MedStory is a search engine focusing on health and is said to outdo Google, with a superior relevancy ranking. It uses a new approach to searching called *clustering*, and its strength lies "in the conceptual overview provided for each search topic and in the options provided for refining and focusing a search" (Anderson, 2007). The strength of Riya is that it is an "image" search engine. That is, it uses visual search to find images on the web. Details about how the search is performed can be accessed at http://www.ehow.com/how_2105171_visual-search-riya.html and http://www.techcrunch.com/2006/11/08/riyas-like-com-is-first-true-visual-image-search/.

Another class of search engines is designed for accessing data from the invisible or deep Web. Glenbrook Networks (2001) has developed a search engine that extracts data from multiple databases in the deep Web and then allows it to be searched from a single site. The method used is the analysis of a set of forms on a web page and then the use of AI techniques to sift through complicated web forms. Other examples of invisible Web search engines are BrightPlanet's Completeplanet (see www.Completeplanet.com) and Kartoo (see

http://websearch.about.com/od/enginesanddirectories/a/kartoo.htm

Another interesting search engine is Kenjin (Yurko, 2000) which uses neural networks and pattern matching technology. It reads and analyzes text on the screen, picks out major themes, and then searches the Internet for links related to those subjects.

The search technology, Clever (Butler, 2000), has taken the issue of relevancy to a new level. It enables search engines to automatically identify and display the most relevant sites it has crawled on the web. For most conventional search engines this can only be achieved by human intervention.

Inquirus (Lawrence & Giles, 1998) is a meta search engine which has been introduced to address some of the shortcomings of conventional search engines in searching the web. Meta search engines search the Web by making requests to multiple search engines. The major advantages of meta search engines are (a) ability to combine results of multiple search engines, and (b) ability to provide a consistent user interface for searching these search engines.

Desirable Features of Search Engine

The desirable features of a new search engine can be listed under the following headings:

(a) User-Interface design

- A better interface is probably a good thing for a new search engine – however, it has to be simple enough and give more information than any of the current solutions.
- Introduction of XML (Nassis, 2004), successor of HTML, for coding web pages should make it possible to restrict search

(b) Search box

- Most search engines provide only 2 levels of detail for users to input keywords – a simple text box and a formatted advanced search page with a few input fields.

A simple text box is great for most searches, however, the advanced search pages which are available do not allow users to adequately control input choices.

Suggestion: Have a more user-controlled advanced search page which allows users to:

(a) add or subtract search parameters and save these preferences, (b) have personalized search pages.
- Need for **semantic search** where search engine figures out what I mean from my keywords and can return results with the same meaning**.** It is frustrating and time-consuming to search the Internet for information and not be able to find it because of *semantics.*

(c) How results are presented
- Search is contextual – a small personal AI program running on the user's desk/web top should interface with the SE rather than natural language-based solutions.
- A search engine where one can see how changing the search criteria, changes the results on the fly.
- Develop a trend where users are focused on the quality of the information they receive and how reliable it is. Need for user-defined and AI-powered "TrustedSources" that can be used as a basis for ranking or filtering results.

(d) Relevancy
- Speed and relevance are required features of an efficient search engine.
- Need for "oracle capabilities" (or "magical mirror capabilities")
  - for example, if I am searching for "good restaurants for dinner", it would be good if I am given a list of potential restaurants next to where I live – this (intelligent) search should be based on my **IP address**. In other words the search engine should utilize *local context.*
- Automated technologies should help people to frame queries to maximize the relevance of search terms
- It would be useful if the search engine could answer with the most relevant website, instead of a webpage for user queries

(e) Specific versus general
- Highly personalized search portals that bring information one needs with regular updates. Also specialist search engines such as ones focused on, say, science or nature.
- Tackling a specific body of knowledge is more economical and efficient

Enhanced Active Search Engine (EASE)

The prevalence of so much data on the Internet means that it is potentially a superior source of external data for the data warehouse. Since such data typically originates from a variety of sources (sites) it has to undergo a merging and transformation process before it can be used in the data warehouse. The existence of the so called "invisible web", and ongoing efforts to gain access to these untapped sources, suggest that the future of external data retrieval will enjoy the same interest as that shown in internal data (Smith, 2001; Inmon, 2002; Sherman & Price, 2003).

The need for reliable and consistent external data provides the motivation for an intermediate layer between raw data gathered from the Internet (by search engines) and external data storage areas lying within the domain of the data warehouse (Agosta, 2000). This layer, which provides a data extraction/cleaning functionality, is called the *Meta-Data Engine* (M-D.E), and is a major component of the *Data Warehouse Search Engine* (D.W.S.E) Model (Peter & Greenidge, 2005). Figure 2 shows the structure of the D.W.S.E model.

The M-D.E enhances queries coming from the warehouse, and also captures, merges and formats information returned by the search engine (Lawrence & Giles, 1998; Peter & Greenidge, 2005). The M-D.E combined with the Search Engine component is called the *Enhanced Active Search Engine* (EASE).

EASE works as follows:

1. A query originates in the warehouse environment, and is modified by the M-D.E so that it is specific and free of "nonsense" words. A word that has a high occurrence in a text but conveys little specific information about the subject of the text is deemed to be a *nonsense* or *noise* word (Belew, 2000).

2. The modified query is transmitted to the search engine that performs its operations and retrieves its results documents.
3. The documents returned are analysed by the M-D.E and information is prepared for return to the warehouse.
4. The information relating to the answer to the query is returned to the warehouse environment.

The design of both search engine and data warehouse are skill-intensive and specialized tasks.

EASE: The Search Engine Component

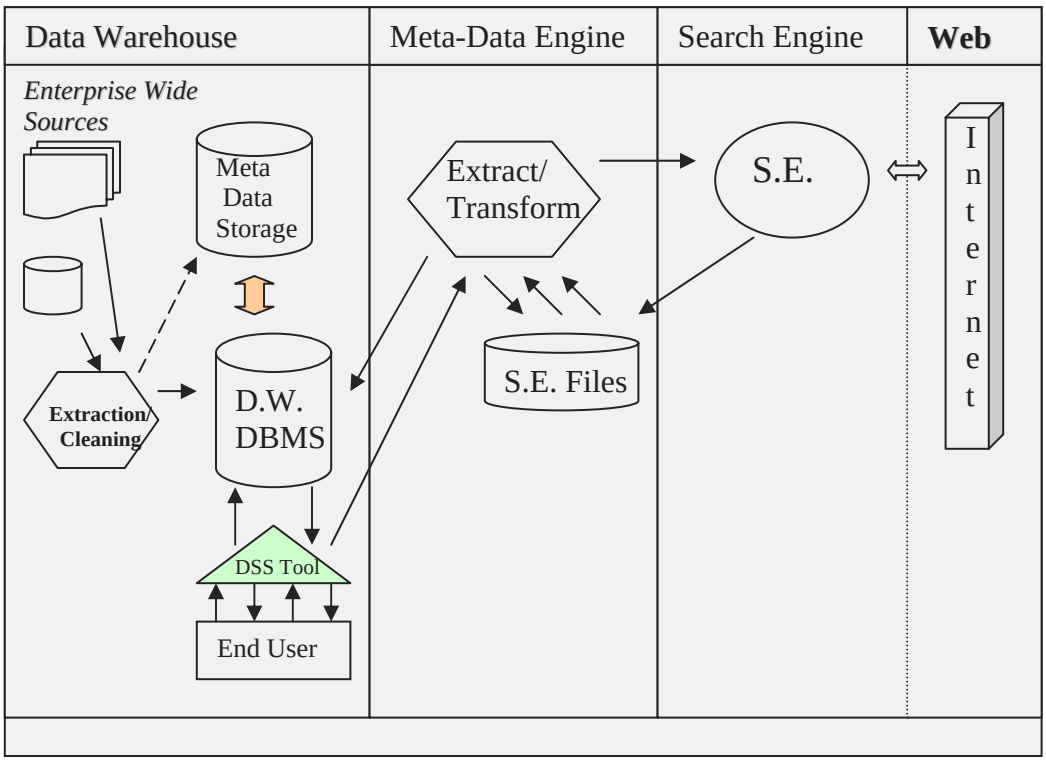
The search engine component of EASE is an important component, and has a major impact on the quality of the external data accessed from the Web. Accordingly, we are in the process of incorporating a number of features in that component – features we think will address some of the shortcomings of typical conventional search engines. Our search engine component is intended to have the following functionalities:

(a) The ability to conduct intelligent (semantic) searches using AI techniques (Olsen, 2006) such as natural language processing, machine learning, and neural networks (Yurko, 2000).
(b) The ability to access the invisible web.
(c) The ability to extract relevant data (Butler, 2000) from the Web.

EASE: The Meta-Data Engine Component

To cope with the radical differences between the search engine and data warehouse components we propose a Meta-Data Engine component to coordinate all activities. Typical commercial search engines are composed of a crawler (spider) and an indexer (mite). The indexer is used to codify results into a database for easy querying. Our approach reduces the complexity of the search engine by moving the indexing tasks to the meta-data engine. The meta-data engine seeks to form a bridge between the diverse search engine and data warehouse environments. The purpose of the meta-data engine is

Figure 2. The D.W.S.E. Model



to facilitate an *Automatic Information Retrieval* mode (see Figure 2).

The following are some of the main functions of the Meta-Data Engine

(a) Capture and transform data arising from the search engine - for example, handle HTML, XML, .pdf and other document formats
(b) Index words retrieved during search engine crawls
(c) Manage the scheduling and control of tasks arising from the operation of both DW and SE
(d) Provide a neutral platform so that SE and DW operational cycles and architectures cannot interfere with each other.

ANALYSIS OF MODEL

The model that we have provided in this article incorporates sophisticated search engine technology to ensure that external web data used to populate the data warehouse is of a high level of relevance. The following strengths of the model are identified:

- **Load sharing:** Since the meta-data engine component relieves the search engine component of tasks normally associated with information search engines, overloading is minimized.
- **Value added approach:** additional value is provided to the data warehouse, because the web data supplied by the sophisticated search engine EASE, is of a high level of relevance.
- The three-component architecture allows for a high degree of modularity, resulting in high levels of integrity and security in the external data.

A potential weakness of the model is that, with the rapid change in technologies, the two components of EASE have to be upgraded frequently.

FUTURE TRENDS

The changing nature of software makes it difficult to predict the future in the software industry. However, given the material provided in this article, the following are likely to be the relevant trends in the next few years in search engine and data warehouse technology:

- The use of ontologies in searching the Web (Corcho, 2006; Zhang et al, 2004).
- Design of more search engines to access the invisible web.
- Use of the technology in new search engines such as Swoogle (see http://swoogle.umbc.edu).
- Maturing of the Data Warehouse tools and techniques (Agosta, 2000; Inmon, 2002; Schwartz, 2003)
- The design and use of more dedicated and sophisticated search engines.
- Design the meta-data engine component to query multiple search engines (Lawrence & Giles, 1998) and, in so doing, speed up the search process.

We are confident that our D.W.S.E. model will gain prominence as practitioners realize the benefits of three distinct and architecturally independent layers.

CONCLUSION

In this article we presented a new approach to searching the (surface and deep) Web for relevant external data, which is subsequently integrated in the data warehouse. Our approach is based on a three-tiered model called the D.W.S.E model.

We believe that our model has the potential for harnessing the Web as a major source of information that can subsequently be used in the decision-making process. It is, however, important that we demonstrate the superiority of our model by comparing the results obtained using our approach with those obtained using the traditional external data approaches.

Although "relevance" remains a thorny issue, we have reason to believe that advances in Semantic Web developments – in particular, the use of ontologies – will help to address questions of relevance on the Internet.

KEY TERMS

Authority: A web page with many links pointing to it.

Data Integration: The process of combining data residing at different sources and providing the user with a unified view of these data.

Decision Support System (DSS): An interactive arrangement of computerized tools tailored to retrieve and display data regarding business problems and queries.

Deep (Invisible) Web : Denotes those significant portions of the web where data is stored which are inaccessible or cannot be readily indexed by the major search engines. The deep web represents an often ignored/neglected source of potential online information.

External Data: A broad term indicating data that is external to a particular company. Includes electronic and non-electronic formats.

Internal Data: Previously cleaned warehouse data which originated from the daily information processing systems of a company.

Information Retrieval: Denotes the attempt to match a set of related documents to a given query using semantic considerations. For example, Library catalogue systems often employ information retrieval techniques.

Metadata: Data about data; in the data warehouse it describes the contents of the data warehouse.

Search Situations and Transitions

Nils Pharo
Oslo University College, Norway

INTRODUCTION

Several studies of Web information searching (Agosto, 2002, Pharo & Järvelin, 2006, Prabha et al. 2007) have pointed out that searchers tend to satisfice. This means that, instead of planning for optimal search outcomes based on the best available knowledge, and on choosing the best information sources for their purpose, they aim at obtaining satisfactory results with a minimum of effort. Thus it is necessary to study other factors than the information needs and sources to explain Web search behaviour. Web information search processes are influenced by the interplay of factors at the micro-level and we need to understand how search process related factors such as the actions performed by the searcher on the system are influenced by various factors, e.g. those related to the searcher's work task, search task, knowledge about the work task or searching etc. The Search Situation Transition (SST) method schema provides a framework for such analysis.

BACKGROUND

Studies of information seeking and retrieval (IS&R) have identified many factors that influence the selection and use of sources for information seeking and retrieval. Web information searching often seems to be a rather haphazard behaviour where searchers seem to behave irrationally, i.e., they do not follow optimal textbook prescriptions (e.g., Ackermann & Hartman, 2003).

Other than the actual information need factors related to the searcher's personal characteristics, search task, work task, and social/organisational environment influence the searcher during his selection and use of information sources. These factors have been classified and discussed in great detail in the literature, and the SST method schema focuses specifically on the search process and how it is affected by external factors.

Early studies of Web searching to a large degree used log analysis (see review in Jansen and Pooch, 2001 and a summary in Spink and Jansen, 2004) or surveys (e.g., GVU's WWW user surveys (2001)) as their data collection methods. Log analysis can provide researchers with data on large numbers of user-system interactions focusing on users' actions. One common use has been to see how searchers formulate and reformulate queries (e.g., Spink et al, 2001). The user surveys have focused on demographics of web users and collected information on the use of different kinds of web resources, time spent on web use, e-shopping etc. Both these kinds of methods may reveal important information about how and why people use the Web, but they are unable to point out what causes the searcher to perform the actions he/she does. To learn how work tasks, search tasks, and searcher's personality directly affect Web information search processes the SST method schema (Pharo, 2002; Pharo & Järvelin, 2004) was developed.

MAIN THRUST OF THE CHAPTER

To present a method (e.g. Bunge, 1967), as well as a method schema (Eloranta, 1979), one needs to define its domain, procedure and justifications (Newell, 1969, Pharo, 2002). Both the domain and procedure is presented below to clarify the usability of the SST method schema.

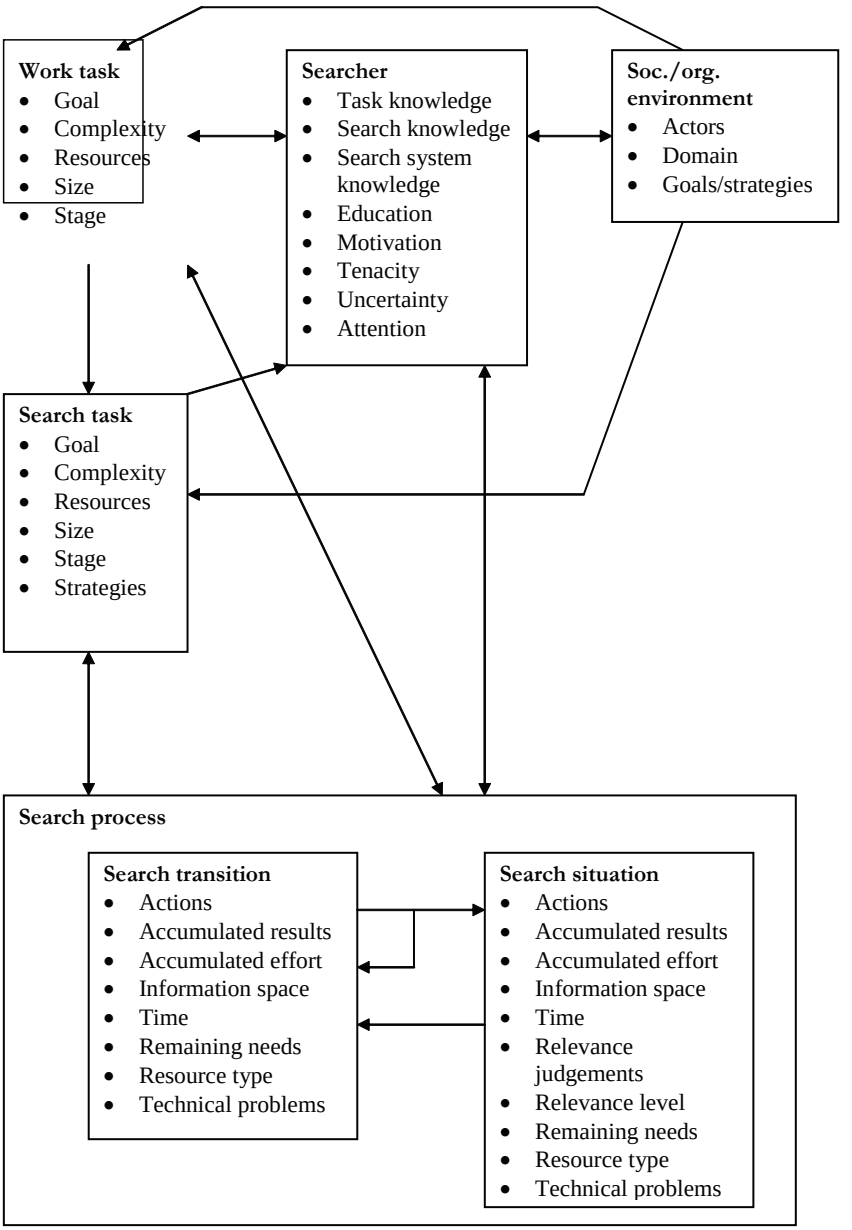
The Method Schema's Domain

The problem statement, or *domain*, which is used in the following, states the properties of the problem the method is intended for and their relationships. This designates how general it is possible to make the procedure for handling the problem.

Figure 1 is a representation of the framework's five *categories* and the relationships existing between them.

The *search process* category consists of two subcategories; *search situation* and *search transition*. The

Figure 1. The conceptual framework - the domain of the method schema



search process category will be emphasised here, the other categories and their attributes are well known from the IS&R literature (for details see Pharo, 2002).

Search *situations* are the periods during a search process when the searcher examines a resource in order to find information that may be of help in executing his work task. Situations may take place in the same kind of resources as transitions depending on the search task; if the searcher wants to learn more about the structuring of subject indices it would be natural to examine such resource types for that purpose.

Search *transitions* are executed in order to find resources in which the searcher believes there may be information that can help execute his task. The transitions

consist of source selection and inter-source navigation. An alternative way of explaining this is to say that while situations represent interaction with real information the transitions deal with *meta*-information.

Action is used to describe the moves made by the searcher during a situation/transition. In web interaction this includes the following of links, entering of queries, and reading of pages. The actions may be influenced, e.g., by a search task strategy.

The *accumulated results* refer to the information already found. This includes information found in previous situations as well as information found in the current one. Accumulated results relate to the completion of the information need (or the futility of trying this).

The *accumulated efforts* refer to how much work the searcher has had to invest from the start of the present session (or in prior sessions) up to the current position. In addition it can refer specifically to effort invested in the current situation.

The *information space* refers to the part of the Web that the searcher has navigated, as well as the information space anticipated by the searcher. The searcher has developed a cognitive model of the information space based on his knowledge about the Web and the existing resources on the Web, but also on his knowledge about institutions and organisations that he expects to be represented on the Web.

Time can be used to specify how the total amount of time spent during a search process influences the current situation, but it can also relate to the specific time used in that situation.

The *remaining needs* refer to what the searcher has planned to search for in the continuation of the search process and possibly in subsequent search processes.

Web *resource types* differ from each other with respect to content and format. Some are known from the world of paper-based publishing, such as newspapers, scientific journals, dissertations, novels, and collections of poems, but there are many new genres that have originated on the Web (home pages, blogs, wikis etc.) (Shepherd & Watters, 1998).

"Technical problems" is used to describe problems caused by the software in use, both on the client and server sides of interaction. Lack of bandwidth may also cause problems, for example in accessing resources that heavily depend on transmission of large amounts of data. Web pages that have disappeared also cause this kind of problem.

Situations and transitions share many attributes. Two unique attributes are only present in situations: relevance judgement and relevance level.

Relevance judgement relates to the searcher's evaluation of the pages found, which may be of use to him in different degrees. No predefined categories for relevance judgements are stated, in many studies binary (relevant or not relevant) or ternary (adding "partially relevant" to the former two) relevance measures have been used.

Relevance level signifies that the criteria used for evaluation may be related to the work task, which is what Saracevic (1996) calls situational relevance, but also be related to other levels, e.g., when an intermediary judges a resource's relevance for a (potential) user. Relevance judgements are also made in accordance with the organisational preferences, thus socio-cognitive relevance (Cosijn & Ingwersen, 2000) may also affect the judgements.

The Method Schema's Procedure

Log analysis and surveys are the most common data collection methods in Web IS&R. In general the problem with:

- Survey-type of web information searching (WIS) analysis is that neither the specific work tasks/ search tasks nor the specific processes are captured. Ex post facto findings in surveys provide only overviews of individuals' conceptions of WIS in general;
- Log analysis-type of data on WIS analysis is that it is not informed by anything happening in front of the computer screen.

In fact, even if one combines these types of analyses, one cannot analyse the processes properly for the effects of characteristics of work tasks, search tasks, or specific processes because the primary determinants are missing from the study setting. The use of triangulation as a general approach for data collection is necessary to capture the interplay of the various factors.

The procedure suggest the use of the following data collection methods for the domain described above:

- The search process can be captured using a multitude of methods such as transaction logs, screen captures from video logs, observation

and interviews. This kind of data will provide information on all of the proposed attributes of situations and transitions discussed above. It will also provide data on the other categories. Each attribute can be identified as follows:

- Actions are observable from transaction logs and screen captures.
- Accumulated results can be identified in the transaction logs and screen captures, but also through the use of pre- and post-search interviews.
- Accumulated efforts can be identified by searchers comments during the transactions and post-search interviews.
- Information space is dynamically changing during the search process and will be identified by analysing searchers comments, transaction logs and combining answers from pre- and post-search interviews.
- Time will be tracked in the transaction and video logs.
- Remaining needs can be identified through the interviews and the comments made by searchers during transactions.
- Resource types are easiest categorised from the video logs, but transaction logs can also be used.
- Technical problems can be observed using the video and transaction logs as well as the searchers' comments. Also post-search interviews should be addressed to collect this kind of information.
- Relevance judgements are identified by searchers bookmarking in transaction logs, but also from observation of their non-screen activities and post-search interviews. It is also possible to derive this from identifying what sources are listed in the references in, e.g., a report or thesis.
- Relevance level can be identified by the post-search-processing of the collected material. Are the sources used directly or indirectly in the searchers' output (reports etc)? The comments made by searchers during transactions and post-search interviews are also usable for identifying relevance level.

- The work task can be captured using a combination of interviews and output data, such as, e.g., theses, articles, reports and other written material.
- The search task can be identified from the interviews as well as utterances made by the searcher during the process (observation and video logs)
- The searcher can provide information about him/herself in interviews and questionnaires/surveys
- The social/organisational environment can be described through interviews, annual reports, and other written material documenting the organisation's activities and policies

The core data is usually collected using some kind of screen capturing or video recording of the computer screen during the processes. This, however, should be combined with simultaneous recordings of the searcher's utterances, and the searchers should be instructed to talk aloud (Ericsson & Simon, 1996) during searching. Alternatively Web transaction logs can be used alone, but then it would be difficult to capture non-action-related features of the process, e.g., to determine whether the searcher is actually reading a page or whether she is taking a coffee break.

The Method Schema's Justification

A method based on this schema was used to analyse real WIS interactions (Pharo, 2002) with encouraging results, in Pharo and Järvelin (2006) it was used to analyse the difference between textbook prescription of search strategies and searchers actual search strategies.

FUTURE TRENDS

The continuing growth, and hence importance, of the World Wide Web will make a better understanding of the complex interplay taking place during search processes even more important. The Web will doubtless be an important factor affecting interaction in various "environments" (business, education on all levels, research, public affairs etc). The need to analyse what takes place in different setting advocates the need for tools for holistic analysis, such as the SST method schema.

CONCLUSION

There is a large body of research literature on Web information searching (WIS). One approach to WIS research is log analysis, which is based on log contents and furnishes researchers with easily available massive data sets. However, the logs do not represent the user's intentions and interpretations. Another common approach to WIS is based on user surveys. Such surveys may cover issues like the demographics of users, frequencies of use, preferences, habits, hurdles to WIS etc. However, being ex post facto studies, they do not supply knowledge on how the searchers act in concrete WIS processes.

To understand and explain WIS processes, one needs to closely look at concrete processes in context. The literature of IS&R suggests several factors or categories like work task, search task, the searcher him/herself, and organisational environment as affecting information searching. A promising way to understand/explain WIS is through these categories. The current approaches to WIS, however, cannot shed light on what the effects are, if any. The SST method schema is developed to address these issues.

KEY TERMS

Information System: A collection of sources containing potential information. Information systems can be of variable structure and size, from small bibliographic catalogues to the Web itself.

Method: A procedure for handling a set of problems. Methods can be categorised as "quantitative", which is, for example, the case for various statistical ways of data handling, or "qualitative", which may be exemplified by grounded theory. A method (and thus a method schema) consists of the following three parts: (1) a problem statement or *domain* modelling the phenomenon under study, (2) a *procedure* for collecting and analysing data to understand the phenomenon, and (3) a *justification*, e.g. by showing its ability to solve designated problems of the domain.

Method Schema: Any representation defined for one or more methods, where one or more aspects of the method have been left uninterpreted and represented only through their plain name, and where some aspects of the methods may have been left out (even lacking their naming). Method schemas take the format of a method, but it contains unspecified components that need to be specified if it is to reach the level of a method. In other words a method schema is an abstract representation of one or more methods – a generic model. The difference between a method and a method schema can be said to be a continuum of generality.

Search Process: The period during which a searcher interacts with an information system. The structure of a search process is dialectic; it switches between search situations and search transitions.

Search Situations: The periods of a search process during which the searcher interacts with sources potentially containing information related to his/her search task.

Search Transitions: The periods of a search process during which the searcher interacts with sources containing meta-information

SST Method Schema: A method schema developed to analyse search processes by identifying what external and internal factors interplay with the search process during, before, and after the process.

Secure Building Blocks for Data Privacy

INTRODUCTION

Rapid advances in automated data collection tools and data storage technology have led to the wide availability of huge amount of data. Data mining can extract useful and interesting rules or knowledge for decision making from large amount of data. In the modern world of business competition, collaboration between industries or companies is one form of alliance to maintain overall competitiveness. Two industries or companies may find that it is beneficial to collaborate in order to discover more useful and interesting patterns, rules or knowledge from their joint data collection, which they would not be able to derive otherwise. Due to privacy concerns, it is impossible for each party to share its own private data with one another if the data mining algorithms are not secure.

Therefore, privacy-preserving data mining (PPDM) was proposed to resolve the data privacy concerns while yielding the utility of distributed data sets (Agrawal & Srikant, 2000; Lindell.Y. & Pinkas, 2000). Conventional PPDM makes use of Secure Multi-party Computation (Yao, 1986) or randomization techniques to allow the participating parties to preserve their data privacy during the mining process. It has been widely acknowledged that algorithms based on secure multi-party computation are able to achieve complete accuracy, albeit at the expense of efficiency.

BACKGROUND

In recent years, PPDM has emerged as an active area of research in the data mining community. Several traditional data mining algorithms have been adapted to become privacy-preserving that include decision trees, association rule mining, *k*-means clustering, SVM, Naïve Bayes, and Bayesian network. These algorithms generally assume that the original data set has been horizontally and/or vertically partitioned with each partition privately held by one party. In privacy-preserving data mining algorithms, data are horizontally and/or vertically partitioned in order to spread the data across multiple parties so that no single party holds the overall data.

In this chapter, we focus on current work in privacy-preserving data mining algorithms that are based on Secure Multi-party Computation (Yao, 1986). In secure multi-party computation, there are two models that classify adversarial behaviors (Goldreich, 2002): the semi-honest model and the malicious model. Loosely speaking, a party in a semi-honest model follows the protocol properly but it keeps a record of all the intermediate computations during the execution. After the protocol, a party attempts to compute additional information about other honest parties. A party in the malicious model is allowed to diverge arbitrarily from the protocol. To force a malicious party to follow the protocol, zero-knowledge proofs can be applied. Zero-knowledge proofs as introduced by authors in (Goldwasser, Micali, & Rackoff, 1989) are proofs of the validity of an assertion made by a party without disclosing additional information.

MAIN FOCUS

In this section, we review current work on privacy-preserving data mining algorithms that are based on secure multi-party computation (Yao, 1986).

Privacy-Preserving Decision Trees

In (Lindell & Pinkas, 2000), the authors proposed a privacy-preserving ID3 algorithm based on cryptographic techniques for horizontally partitioned data involving two parties. The authors in (Du & Zhan, 2002) addressed the privacy-preserving decision tree

induction problem for vertically partitioned data based on the computation of secure scalar product involving two parties. The scalar product is securely computed using a semi-trusted commodity server. In the model, a semi-trusted third party helps two parties to compute scalar product; the third party will learn nothing about the parties' private data and is required not to collude with any of them. The authors in (Vaidya & Clifton, 2005a) extended the privacy-preserving ID3 algorithm for vertically partitioned data from two parties to multiple parties using the secure set intersection cardinality protocols.

Privacy-Preserving Association Rule Mining

In (Kantarcioglu & Clifton, 2004), the authors proposed a method to securely mine association rules for horizontally partitioned data involving three or more parties. The method incorporates cryptographic techniques to reduce the information disclosed. The authors in (Vaidya & Clifton, 2002) presented a privacy-preserving association rule mining algorithm for vertically partitioned data using secure scalar product protocol involving two parties. A secure scalar product protocol makes use of linear algebraic techniques to mask private vectors with random numbers. Solutions based on linear algebraic techniques are believed to scale better and perform faster than those based on cryptographic techniques. To extend association rule mining algorithm for vertically partitioned data to multiple parties, the authors in (Vaidya & Clifton, 2005b) proposed a secure set intersection cardinality protocol using cryptographic techniques. The communication and computation complexities of the protocol are O(mn) and $O(mn^2)$, where m and n are the length of private vectors and the number parties respectively.

Privacy-Preserving Clustering

The authors in (Vaidya & Clifton, 2003) presented a method to address privacy-preserving k-means clustering for vertically partitioned data involving multiple parties. Given a sample input that is partially held by different parties, determining which cluster the sample is closest must be done jointly and securely by all the parties involved. This is accomplished by a secure permutation algorithm (Du & Atallah, 2001) and a secure comparison algorithm based on the circuit evaluation protocol (Yao, 1986). The authors in (Geetha Jagannathan & Wright, 2005) proposed a new concept of arbitrarily partitioned data that is a generalization of horizontally and vertically partitioned data. They provided an efficient privacy preserving protocol for k-means clustering in an arbitrarily partitioned data setting. To compute the closest cluster for a given point securely, the protocol also makes use of secure scalar product protocols. The authors in (G. Jagannathan, Pillaipakkamnatt, & Wright, 2006) presented a simple I/O-efficient privacy-preserving k-clustering algorithm. They claimed that cluster centers produced by their algorithm are more accurate than those produced by the iterative k-means algorithm. The algorithm achieved privacy using secure scalar product protocols and Yao's circuit evaluation protocol (Yao, 1986). The authors in (Lin, Clifton, & Zhu, 2005) presented a technique that uses EM mixture modeling to perform clustering on horizontally partitioned distributed data securely. In the protocol, each partition is computed locally based on local data points. The global sum of the partitions from all parties is then computed without revealing the individual values by secure sum.

Privacy-Preserving Support Vector Machine

The authors in (Yu, Vaidya, & Jiang, 2006) proposed a privacy-preserving SVM classification algorithm for vertically partitioned data. To achieve complete security, the generic circuit evaluation technique developed for secure multiparty computation is applied. In another paper (Yu, Jiang, & Vaidya, 2006), the authors securely constructed the global SVM classification model using nonlinear kernels for horizontally partitioned data based on the secure set intersection cardinality protocol (Vaidya & Clifton, 2005b). The authors in (Laur, Lipmaa, & Mielikainen, 2006) proposed secure protocols to implement the Kernel Adaption and Kernel Perception learning algorithms based on cryptographic techniques without revealing the kernel and Gramm matrix of the data.

Privacy-Preserving Naïve Bayes

In (Kantarcioglu & Clifton, 2003), the authors presented a privacy-preserving Naïve Bayes classifier for horizontally partitioned data using secure sum—an instance the Secure Multi-party Computation (Yao, 1986). The

authors in (Vaidya & Clifton, 2004) developed privacy-preserving Naïve Bayes classifier for vertically partitioned data. Secure scalar products protocols are used to give the appropriate probability for the data while preserving data privacy. The same authors summarized the above two protocols for different partitioned data and published them in (Vaidya, Kantarcioglu, & Clifton, 2007). The authors in (Wright & Yang, 2004) presented a privacy-preserving Bayesian network computation for vertically distributed data involving two parties. They showed an efficient and privacy-preserving version of the *K2* algorithm to construct the structure of a Bayesian network for the parties' joint data based on secure scalar product protocols.

Privacy-Preserving Gradient Descent Paradigm

The authors in (Du, Han, & Chen, 2004) proposed secure versions of multivariate linear regression and multivariate classification for vertically partitioned data involving two parties. They developed a practical security model based on a number of building blocks, such as the secure matrix product protocol and the secure matrix inverse protocol. In (Barni, Orlandi, & Piva, 2006), the authors presented a privacy-preserving neural network involving two parities under the scenario where one party holds private data and the other party only has a private neural network that is used to process the private data. The protocol preserves the privacy of two parties using secure scalar product protocols, private polynomial evaluation, and so on. In (Wan, Ng, Han, & Lee, 2007), the authors proposed a generic formulation of gradient descent methods for secure computation by defining the target function as a composition. They demonstrated its feasibility in specific gradient descent methods, such as linear regression, and neural network. The privacy is preserved using secure scalar product protocols.

Other Recent Privacy-Preserving Data Mining Algorithms

In (Han & Ng, 2007a), the authors proposed a protocol for secure genetic algorithms for the following scenario: Two parties, each holding an arbitrarily partitioned data set, seek to perform genetic algorithms to discover a better set of rules without disclosing their own private data. The challenge for privacy-preserving genetic algorithms is to allow the two parties to securely and jointly evaluate the fitness value of each chromosome using each party's private data without compromising their data privacy. They proposed a new protocol to address this challenge that is correct and secure. The protocol preserves the privacy of two parties using secure scalar product protocol.

In (Han & Ng, 2007b), the authors proposed a protocol for privacy-preserving self-organizing map for vertically partitioned data involving two parties. Self-organizing map (SOM) is a widely used algorithm for transforming data sets to a lower dimensional space to facilitate visualization. The challenges in preserving data privacy in SOM are (1) to securely discover the inner neuron from data privately held by two parties; (2) to securely update weight vectors of neurons; and (3) to securely determine the termination status of SOM. The authors proposed protocols to address the above challenges using secure scalar product protocols. They proved that these protocols are correct and privacy-preserving. Also, they proved that the intermediate results generated by these protocols do not violate the data privacy of the participating parties.

FUTURE TRENDS

As shown in the above sections, much work has been done to equip conventional algorithms with the privacy-preserving feature. There are other directions of research in privacy-preserving data mining. One direction of inquiry asks the question: "What is the definition of privacy?" The authors in (Clifton, Kantarcioglu, & Vaidya, 2002) provided a definition for privacy and presented some metrics to evaluate the degree to which privacy is preserved. Most of the current work in privacy preserving data mining focuses on preserving the privacy of privately held data values from other parties. The definition and coverage of privacy also extends to the names of attributes, as the sharing of attribute names among multiple parties is a potential form of privacy violation. In order to achieve "perfect" security; i.e., to preserve the privacy of all possible private information, the definition of privacy for privacy-preserving data mining algorithms should be appropriately stretched. Is it possible for privacy-preserving data mining algorithms to fulfill the "perfect" security requirement?

Another direction is secure-satisfiability protocols: A protocol that is secure in one model (e.g., semi-honest model) may be insecure in another model (e.g., malicious model). So far the protocols proposed in the malicious model are more secure than the ones in the semi-honest model. However, as shown by the author (Goldreich, 2002), there are three problems that cannot be avoided even in the current malicious model:

- *Parties refusing to participate in the protocol (when the protocol is first invoked).* It is impossible to force the malicious parties to participate in the protocol.
- *Parties aborting the protocol prematurely (e.g., before sending their last message).* It is hard to prevent the malicious party from suspending or aborting the execution of the protocol. In particular, the malicious party may abort at the first moment when it obtains the desired result.
- *Parties substituting their local input (and entering the protocol with an input other than the one provided to them).* The malicious party may modify its local input to attack the private data of the honest parties. The protocol in the current malicious model cannot prevent the malicious party from giving the false data. But if the malicious party is allowed to give *arbitrary* false inputs, it is possible to probe the private inputs of the honest parties.

When the problems occur to the honest parties, it is an interesting research topic whether the privacy of the honest parties is violated. To address these problems, more researches are required to build a more secure model for data mining algorithms.

Third direction is whether what is done to preserve 100% of the privacy based on SMC is necessary or not. The most important reason is that the performance of data mining algorithms based on SMC is much worse than ones based on randomization technique. Sometimes, the performance may be more important for the parties. To achieve the high performance for privacy-preserving data mining algorithms while preserving the high privacy, the hybrid technique may be a solution. In the privacy-preserving data mining algorithms based on SMC, we use the randomization technique to preserve the privacy for less important data to increase the performance. But how to realize the idea in the specific data mining algorithms is another interesting research topic.

Finally most of the current privacy-preserving data mining algorithms focus on the algorithms in data mining domain. However, other algorithms in other domains, such as machine learning, computational intelligence, and so on, have been proposed to be privacy-preserving. For enabling the algorithms in these domains to be privacy-preserving, the main problems are (1) how to preserve the privacy between two for the iterative algorithms and (2) how to utilize the efficiency for the iterative privacy-preserving algorithms.

CONCLUSION

Since the first papers on privacy preserving data mining appeared in 2000, the data mining community has lent much attention to the area. Numerous extensions have been proposed to enable existing machine learning and data mining algorithms with the privacy-preserving feature. Work has also been done to enhance existing privacy-preserving data mining algorithms using the semi-honest model to securely work in the malicious model. This chapter presents the state-of-the-art in privacy-preserving data mining algorithms. The techniques covered include decision trees, association rule mining, clustering, naïve Bayes, support vector machines, and gradient descent algorithms.

KEY TERMS

Horizontally Partitioned Data: In horizontally partitioned data, two or more parties hold different disjoint set of objects (tuples) all having the same set of attributes.

Malicious Model: A party in the malicious model is allowed to behave arbitrarily and deviate from the protocol.

Privacy-Preserving Data Mining: Privacy-preserving data mining seeks to allow the cooperative execution of data mining algorithms while preserving the data privacy of each party concerned.

Randomization: A party randomizes its private value by adding to it a random shift. The shift values are independently and identically distributed random variables.

Secure Multi-Party Computation: A set of parties each holding private inputs wishes to jointly compute a function or a computation of their inputs. After the computation, they only know the correct joint output and nothing about the other parties' private data.

Semi-Honest Model: Stated informally, a party in the semi-honest model follows and executes a designated protocol properly. However, it may keep a record of the intermediate results of the execution and use them to compute additional information about the private inputs of other honest parties.

Vertically Partitioned Data: In vertically partitioned data, two or more parties hold different disjoint set of attributes for the same set of objects (tuples).

Secure Computation for Privacy Preserving Data Mining

Yehuda Lindell
Bar-Ilan University, Israel

INTRODUCTION

The increasing use of data mining tools in both the public and private sectors raises concerns regarding the potentially sensitive nature of much of the data being mined. The utility to be gained from widespread data mining seems to come into direct conflict with an individual's need and right to privacy. Privacy preserving data mining solutions achieve the somewhat paradoxical property of enabling a data mining algorithm to use data *without* ever actually "seeing" it. Thus, the benefits of data mining can be enjoyed, without compromising the privacy of concerned individuals.

BACKGROUND

A classical example of a privacy preserving data mining problem is from the field of medical research. Consider the case that a number of different hospitals wish to jointly mine their patient data, for the purpose of medical research. Furthermore, let us assume that privacy policy and law prevents these hospitals from ever pooling their data or revealing it to each other due to the confidentiality of patient records. In such a case, classical data mining solutions cannot be used. Fortunately, privacy preserving data mining solutions enable the hospitals to compute the desired data mining algorithm on the union of their databases, without ever pooling or revealing their data. Indeed, the only information (provably) learned by the different hospitals is the output of the data mining algorithm. This problem whereby different organizations cannot directly share or pool their databases, but must nevertheless carry out joint research via data mining, is quite common. For example, consider the interaction between different intelligence agencies in the USA. These agencies are suspicious of each other and do not freely share their data. Nevertheless, due to recent security needs, these agencies must run data mining algorithms on their combined data. Another example relates to data that is held by governments. Until recently, the Canadian Government held a vast federal database that pooled citizen data from a number of different government ministries (this database was called the "big brother" database by some). The Canadian government claimed that the database was essential for research. However, due to privacy concerns and public outcry, the database was dismantled, thereby preventing that "essential research" from being carried out. This is another example of where privacy preserving data mining could be used to balance between real privacy concerns and the need of governments to carry out important research.

Privacy preserving data mining is actually a special case of a long-studied problem in cryptography: *secure multiparty computation*. This problem deals with a setting where a set of parties with private inputs wish to jointly compute some function of their inputs. Loosely speaking, this joint computation should have the property that the parties learn the correct output and nothing else, even if some of the parties maliciously collude to obtain more information.

MAIN THRUST

In this short chapter, we will provide a succinct overview of secure multiparty computation, and how it can be applied to the problem of privacy preserving data mining. Our main focus will be on how security is formally defined, why this definitional approach is adopted, and what issues should be considered when defining security for privacy preserving data mining problems. Due to space constraints, the treatment in this chapter is both brief and informal. For more details, we refer the reader to (Goldreich, 2003) for a survey on cryptography and cryptographic protocols.

Security Definitions for Secure Computation

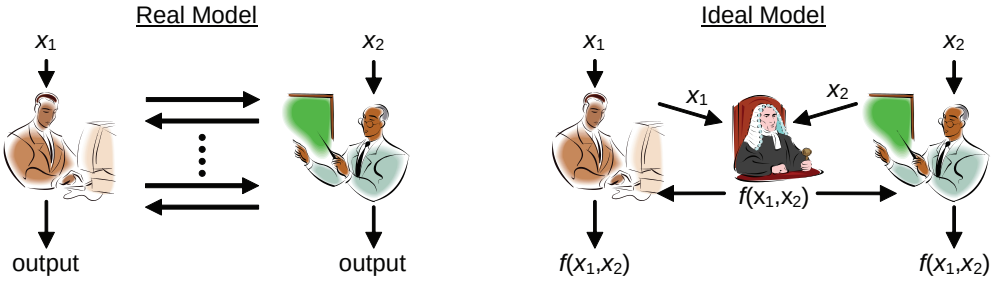
The aim of a secure multiparty computation task is for the participating parties to *securely* compute some function of their distributed and private inputs. However, what does it mean for a computation to be *secure*? One way of approaching this question is to provide a list of *security properties* that should be preserved. The first such property that often comes to mind is that of *privacy* or *confidentiality*. A naïve attempt at formalizing privacy would be to require that each party learns nothing about the other parties' inputs, even if it behaves maliciously. However, such a definition is usually unattainable because the defined output of the computation itself typically reveals some information on other parties' inputs. (For example, a decision tree computed on two distributed databases reveals some information about both databases.) Therefore, the privacy requirement is usually formalized by saying that the only information learned by the parties in the computation (again, even by those who behave maliciously) is that specified by the function output. Although privacy is a primary security property, it rarely suffices. Another important property is that of *correctness*; this states the honest parties' outputs are correctly distributed even in the face of adversarial attack. A central question that arises in this process of defining security properties is: *when is our list of properties complete*? This question is, of course, application-dependent and this essentially means that for every new problem, the process of deciding which security properties are required must be re-evaluated. We stress that coming up with the right list of properties is often very difficult, and it can take many years until we are convinced that a definition truly captures the security requirements that are needed. Furthermore, an incomplete of properties may easily lead to real security failures.

The Ideal/Real Model Paradigm

Due to these difficulties, the standard definitions of secure computation today follow an alternative approach called the *ideal/real model paradigm*. This has been the dominant paradigm in the investigation of secure computation in the last fifteen years; we refer the reader to (Canetti, 2000) for the formal definition and references therein for related definitional work. Loosely speaking, this paradigm defines the security of a real protocol by comparing it to an *ideal computing scenario* in which the parties interact with an external trusted and incorruptible party. In this ideal execution, the parties all send their inputs to the trusted party (via ideally secure communication lines). The trusted party then computes the function on these inputs and sends each party its specified output. Such a computation embodies the goal of secure computation, and it is easy to see that the properties of privacy and correctness hold in the ideal model. In addition to the fact that these and other security properties are preserved in an ideal execution, the simplicity of the ideal model provides an intuitively convincing security guarantee. For example, notice that the only message that a party sends in an ideal execution is its input, and so the only power that a corrupted party has is to choose its input (something which is typically legitimate anyway).

So far, we have defined an ideal execution in an ideal world. However, in the *real world*, the parties run a protocol without any trusted help. Despite this, a secure real protocol should somehow "emulate" an ideal execution. That is, we say that a real protocol that is run by the parties (in a world where no trusted party exists) is ***secure***, if *no adversary* can do more harm in

Box 1.



a real execution than in an execution that takes place in the ideal world. Stated differently, for *any adversary* carrying out a successful attack on a real protocol, there exists an adversary that successfully carries out the same attack in the ideal world. This suffices because, as we have seen, *no successful attacks* can be carried out in an ideal execution. Thus, no successful attacks can be carried out on the real protocol, implying that it is secure. See Box 1 for a diagram of the real and ideal models.

We stress that security is required to hold for *every* adversary carrying out *any feasible attack* (within the parameters defined for the adversary, as discussed next).

Defining the Model

The above informal description of the ideal/real model paradigm expresses the intuition that a real execution should behave just like an ideal execution. In order to obtain a complete and formal definition, it is crucial that both the ideal and real models are fully defined. Among other things, this involves defining the real network model and the adversary's power, including any assumptions on its behavior. We stress that a secure protocol only provides real-world security guarantees if the mathematical definition of the real computation and adversarial models accurately reflects the real network and adversarial threats that exist.

We now briefly discuss a number of parameters that are considered when defining the network model and the adversary (this list is far from comprehensive). Two central considerations that arise when defining the network model relate to the communication channels and whether or not any trusted setup phase is assumed. It is typically assumed that all parties are connected via point-to-point *authenticated* channels (meaning that the adversary cannot modify messages sent between honest parties). We note that this can be implemented assuming a public-key infrastructure for digital signatures. Other parameters to consider are whether the communication over the network is synchronous or asynchronous, and whether or not messages that are sent between honest parties are guaranteed to arrive. Finally, the question of what (if any) other protocols are running simultaneously in the network must also be addressed. This issue is referred to as *protocol composition* and is currently a very active research subject in the cryptographic community. When defining the adversary, a number of possibilities arise. We now describe some of these:

1. **Complexity:** Given that the widely accepted notion of efficient or feasible computation is *probabilistic polynomial-time*, the natural choice is to limit an adversary to this complexity. However, there are also protocols that are secure against *unbounded* adversaries.
2. **Number of corrupted parties:** In a general multiparty setting, we assume that the adversary controls some subset of the participating parties; these parties are called corrupted. The allowed size of this subset must also be defined (typical choices are assuming that less than one third or one half are corrupted, and not assuming any limitation on the number of corrupted parties).
3. **Corruption strategy:** This parameter relates to whether or not the adversary is *static* (meaning that the set of corrupted parties is fixed ahead of time), or *adaptive* (meaning that the adversary can "break into" parties during the protocol execution).
4. **Allowed adversarial behavior:** In our discussion above, we implicitly referred to *malicious* adversaries who are allowed to arbitrarily deviate from the protocol specification. However, the adversary's behavior is sometimes restricted. For example, a *semi-honest* adversary is assumed to follow the protocol but may attempt to learn secret information from the messages that it receives.

The above very partial list of parameters for defining the adversary begs the question: how do we decide which adversarial model to take? A conservative approach is to take the most powerful adversary possible. However, being overly conservative comes at a price. For example, it is impossible to obtain security for unbounded adversaries in the case that half or more of the parties are corrupted. Furthermore, it is often the case that more efficient protocols can be constructed for weaker adversaries (specifically, highly efficient protocols for many tasks are known for the semi-honest adversarial model, but this is not the case for the malicious model). In general, a good approach is to consider malicious polynomial-time adversaries who may adaptively corrupt any number of the participants. However, in some cases, the semi-honest adversarial model is reasonable. For example, in the medical data-

base example provided in the Introduction, the hospitals are not believed to be malicious; rather, the law prevents them from revealing confidential patient data. In such a case, the protection provided by semi-honest adversarial modeling is sufficient. We stress, however, that in many cases the semi-honest model is not realistic, and malicious adversaries must be considered.

In summary, two central guiding principles when defining security are that: **(a)** the definition must accurately and conservatively model the real-world network setting and adversarial threats, and **(b)** all aspects of the model must be fully and explicitly defined. These conditions are necessary for obtaining a mathematical definition of security that truly implies that protocols executed in the real world will withstand all adversarial attacks.

The Feasibility of Secure Multiparty Computation

The aforementioned security definition provides very strong guarantees. An adversary attacking a protocol that is secure is essentially limited to choosing its input (because this is all that it can do in the ideal model). However, can this definition actually be achieved, and if yes under what conditions? A fundamental result of the theory of cryptography states that under certain parameters and assumptions, *any* efficient multiparty functionality can be securely computed. This result is comprised of a number of different theorems, depending on the model and the number of corrupted parties. We will describe the basic results for the stand-alone model (where only a single protocol execution is considered), and the computational setting (where the adversary is limited to polynomial-time). The basic results for the information-theoretic setting can be found in (Ben-Or et al., 1988) and (Chaum et al., 1988).

The first basic theorem states that when a majority of the parties are honest, *any multiparty functionality* can be securely computed in the presence of malicious, static adversaries (Yao, 1986; Goldreich et al., 1986). Extensions to the case of adaptive adversaries can be found in (Beaver and Haber, 1992) and (Canetti et al., 1996).

The second basic theorem relates to the case that any number of parties may be corrupted, and so there is not necessarily an honest majority. In this case, it is impossible to construct protocols that meet the definition as described above. The reason for this is that the definition implies that all parties receive output together; however, this cannot be achieved without an honest majority (Cleve, 1986). We therefore explicitly relax the security definition and allow the adversary to prevent the honest parties from receiving their output, even in the ideal model; this relaxed definition is called *security with abort*. As above, it has been shown that even when any number of parties may be corrupted, *any multiparty functionality* can be securely computed in the presence of malicious, static adversaries (Yao, 1986; Goldreich et al., 1986).

As we have mentioned, the above results all refer to the *stand-alone model* of computation, where it is assumed that the secure protocol being analyzed is run once in isolation. Feasibility results have also been shown for the case of protocol composition where many different protocols run concurrently; for example, see (Canetti, 2001) and (Canetti et al., 2002). A brief survey on known results for the setting of composition can be found in (Lindell, 2003).

The importance of the above results is that they demonstrate that under an appropriate choice of parameters and assumptions, *any* privacy preserving data mining problem can be solved, *in principle*. Therefore, the challenge remaining is to construct protocols that are efficient enough for practical use.

Secure Protocols for Privacy Preserving Data Mining

The first paper to take the classic cryptographic approach to privacy preserving data mining was (Lindell and Pinkas, 2002). The paper presents an efficient protocol for the problem of distributed decision tree learning; specifically, how to securely compute an ID3 decision tree from two private databases. The paper considered *semi-honest* adversaries only. This approach was adopted in a relatively large number of works that demonstrate semi-honest protocols for a wide variety of data mining algorithms; see, for example, (Clifton et al., 2003). In our opinion, these results serve as a "proof of concept" that highly efficient protocols can be constructed, even for seemingly complex functions. However, in many cases, the semi-honest adversarial model does *not* suffice. Therefore, the malicious model must also be considered.

Other work on the problem of privacy preserving data mining has followed what is often called the "data perturbation" approach, as introduced by (Agrawal &

Srikant, 2000). We remark that the development of rigorous security definitions that appropriately model security in settings considered by this approach seems to be a very difficult task. We remark that naïve definitions of security have been shown to be completely insecure; see (Dinur and Nissim, 2003) for just one example.

FUTURE TRENDS

As we have shown, there exist secure solutions for all privacy preserving data mining problems. However, these solutions are usually not efficient enough for use in practice. Thus, the main problem of privacy preserving data mining is to find protocols that can realistically be run, even on very large databases. Until now, most work has focused on the semi-honest adversarial model, which often does not provide a sufficient level of security. It is therefore of great importance to begin developing tools and techniques for constructing highly efficient protocols that are secure against malicious adversaries. We note that achieving this goal may involve finding new definitions that are more relaxed than those described here, yet still accurately model the real security concerns. This is a very non-trivial research task due to the subtle nature of security and security definitions.

CONCLUSIONS

The history of cryptography shows very clearly that when protocols are not proven secure, or when the adversarial models are not explicitly defined, real attacks are very often discovered. Furthermore, the task of coming up with mathematical definitions that accurately model real adversarial threats is a very difficult task. Indeed, slight modifications to existing definitions can render them completely useless; see (Canetti, 2000) for some discussions on this issue. In this short article, we have described the real/ideal model paradigm for defining security. This definitional approach has been the fruit of many years of cryptographic research, and protocols that meet this definition provide very powerful security guarantees. In order to provide efficient solutions for privacy preserving data mining problems, it may be necessary to find new definitions that provide both rigorous security guarantees and can be met by highly efficient protocols. This is perhaps the ultimate challenge of this new and exciting field of research.

KEY TERMS

Corrupted Parties: parties that participate in a protocol while under the control of the adversary.

Functionality: the task that the parties wish to jointly compute.

Ideal Model: a virtual setting where all parties interact with an incorruptible trusted party who carries out the joint computation for them.

Malicious Adversary: an adversary who may arbitrarily deviate from the protocol specification (and so is unlimited in its attack strategy).

Real Model: the setting where a real protocol is run (without any trusted help).

Secure Multiparty Computation: the problem of computing any distributed task so that security is preserved in the face of adversarial attacks.

Semi-Honest Adversary: an adversary who follows the protocol specification, but may try to learn private information by analyzing the messages that it receives during the protocol execution. (This models the inadvertent leakage of information even during legitimate protocol executions.)

Segmentation of Time Series Data

Parvathi Chundi
University of Nebraska at Omaha, USA

Daniel J. Rosenkrantz
University of Albany, SUNY, USA

INTRODUCTION

Time series data is usually generated by measuring and monitoring applications, and accounts for a large fraction of the data available for analysis purposes. A time series is typically a sequence of values that represent the state of a variable over time. Each value of the variable might be a simple value, or might have a composite structure, such as a vector of values. Time series data can be collected about natural phenomena, such as the amount of rainfall in a geographical region, or about a human activity, such as the number of shares of Google™ stock sold each day. Time series data is typically used for predicting future behavior from historical performance. However, a time series often needs further processing to discover the structure and properties of the recorded variable, thereby facilitating the understanding of past behavior and prediction of future behavior. Segmentation of a given time series is often used to compactly represent the time series (Gionis & Mannila, 2005), to reduce noise, and to serve as a high-level representation of the data (Das, Lin, Mannila, Renganathan & Smyth, 1998; Keogh & Kasetty, 2003). Data mining of a segmentation of a time series, rather than the original time series itself, has been used to facilitate discovering structure in the data, and finding various kinds of information, such as abrupt changes in the model underlying the time series (Duncan & Bryant, 1996; Keogh & Kasetty, 2003), event detection (Guralnik & Srivastava, 1999), etc.

The rest of this chapter is organized as follows. The section on **Background** gives an overview of the time series segmentation problem and solutions. This section is followed by a **Main Focus** section where details of the tasks involved in segmenting a given time series and a few sample applications are discussed. Then, the **Future Trends** section presents some of the current research trends in time series segmentation and the **Conclusion** section concludes the chapter. Several important terms and their definitions are also included at the end of the chapter.

BACKGROUND

A time series is simply a sequence of data points. In a segmentation of a given time series, one or more consecutive data points are combined into a single *segment* and represented by a single data point or a model for the data points in the segment. Given a time series T of n data points, segmentation of T results in a sequence of m segments, where each segment represents one or more consecutive data points in T. The number of segments m is typically much less than n. The input to a given instance of the segmentation problem is usually a time series and an upper bound on the number of segments.

Since the data points in a segment are represented by a single point or model, there is usually some error in the representation. Formally, the segmentation problem can be defined as follows. Given time series T and integer m, find a minimum error segmentation of T consisting of at most m segments. A specific version of this problem depends on the form of the data and how the segmentation error is defined. There are several approaches in the literature for addressing the segmentation problem. An *optimum* solution for the segmentation problem can be found by a dynamic programming based approach. (Duncan & Bryant, 1996; Gionis & Mannila, 2005; Himberg, Korpiaho, Mannila, Tikanmaki & Toivonen, 2001). A dynamic programming algorithm for solving this optimization problem runs in $O(n^2m)$ time, and so may not be practical for long time series with thousands of data points. There are more efficient heuristics that can be used to construct a segmentation of a given time series. However, these heuristics generally produce a suboptimal segmentation (Himberg, Korpiaho, Mannila, Tikanmaki & Toivonen,

2001; Keogh, Chu, Hart & Pazzani, 2004). There are also Bayesian based, fuzzy clustering, and genetic algorithm approaches to the segmentation problem (Oliver & Forbes, 1997; Abonyi, Feil, Nemeth, & Arva, 2005; Tseng, Chen, Chen & Hong, 2006). Methods have also been developed where a time series is segmented by converting it into a sequence of discrete symbols (Chung, Fu, Ng & Luk, 2004).

References (Chundi & Rosenkrantz, 2004a; Chundi & Rosenkrantz, 2004b) discuss segmentation algorithms for time series where each data point is a set of documents, each containing a set of keywords or key phrases. Reference (Siy, Chundi, Rosenkrantz & Subramaniam, 2007) gives an application of segmentation for time series where each data point is a set of items. References (Cohen, Heeringa & Adams, 2002; Gionis & Mannila, 2005) discuss segmentation algorithms for time series where each data point is a single symbol from an alphabet.

MAIN FOCUS

The main focus of a segmentation algorithm is to find the best segmentation to represent the given time series. There are *two primary* tasks in the segmentation process: constructing the representation of a given segment, and constructing the overall segmentation.

Representation of a Given Segment

The data representation of a given segment is computed from the time series data points in the segment, and can be viewed as representing a model of a process that may have generated these data points. The representation of a segment depends on the type of the data points in the time series, and the kind of model to be used. The usual goal in constructing the representation of a given segment is to minimize the error between the representation and the data points in the segment. Each data point in a time series can be a single numeric value (Keogh & Kasetty, 2003; Keogh, Chu, Hart & Pazzani, 2004), a vector of numeric values (McCue & Hunter, 2004), a set of items (Siy, Chundi, Rosenkrantz & Subramaniam, 2007) , a set of documents (Chundi & Rosenkrantz, 2004a), or some other type of value.

When each time series data point is a single numeric value, the model underlying a segment is typically a curve fitted to the points in the segment. This curve is constructed from the data points in the segment, usually with the goal of minimizing the error between the sequence of values of the data points in the segment, and the sequence of values implied by the segment representation. This segment error is usually computed by combining the difference between the value of each data point and the value assigned to that time point by the segment representation. These differences are often combined using an L_p metrics. L_1 is the Manhattan distance, i.e., the sum of the magnitude of the differences. L_2 is the Euclidean distance, based on the sum of the squares of the differences. In addition to the L_p metrics, local PCA methods have been used to measure error (Abonyi, Feil, Nemeth & Arva, 2005).

The curve for a given segment may be a single number (piecewise constant representation), a linear function (piecewise linear representation), a quadratic function, or a polynomial of even higher degree. A piecewise constant representation is a single numeric value that minimizes the segment error. For the L_1 error metric, this value is the median of the data points in the segment, and for the L_2 metric, it is the average of the data points (Gionis & Mannila, 2005). A piecewise linear representation fits a straight line to the data points (Keogh & Kasetty, 2003), usually with the goal of minimizing the L_2 error metric (Edwards, 1976). A piecewise constant or piecewise linear representation can be computed more efficiently than a quadratic or higher degree representation (Lamire, 2007). Sometimes the segments in a segmentation have different types of representation; e.g., some segments may have a linear representation, and some may have a quadratic representation, etc. (Lamire, 2007; Pednault, 1991).

When each data point is a vector of numeric values, a segment may be represented as a vector of constant values (McCue & Hunter, 2004), a vector of line segments (Abonyi, Feil, Nemeth & Arva, 2005), a vector of quadratics, etc.

When each data point is a set of documents, each of which contains a set of keywords or key phrases, the segment error is a measure of how closely the keywords (or key phrases) for the segment correspond to those for the documents in the time points of the segment (Chundi & Rosenkrantz, 2004a; Chundi & Rosenkrantz, 2004b).

Best Plan for Overall Segmentation

Several parameters must be specified to construct a segmentation for a given time series. Some of the commonly provided parameters are the desired number of segments, any constraints on individual segments, and the optimality criterion. An aspect ratio constraint may also be provided, specifying an upper bound on ratio of the length of the segmentation's longest segment to the length of its shortest segment.

A segmentation of a time series consists of multiple segments, and each segment error contributes to the overall error in segmentation. This overall segmentation error may be defined to be the sum of the individual segment errors, an average of these errors, or the maximum of these errors. It is also possible that future applications will consider some other means of combining the segment errors.

The simplest segmentation that can be built for a given time series is a *uniform segmentation*, where all segments are of the same size (Lavrenko, Schmill, Lawrie, Ogilvie, Jensen & Allan, 2000; Lent, Agrawal & Srikant, 1997). A straightforward way to construct a uniform segmentation is to combine all data points that fall in a given period of time (such as the same day, week, month, quarter, year, etc.) into a single segment. Or, given a specification that there should be m segments, one can make each of these segments be a sequence of n/m consecutive points from the time series (with suitable modification if n/m is not an integer).

The segmentation optimization problem requires construction of a segmentation that minimizes the overall segmentation error. Since a uniform segmentation is constructed without looking at the actual data values in the time series, there is no particular reason why it would minimize the overall error, or even be a good approximation to an optimum segmentation. Indeed, it is easy to construct time series where a uniform segmentation has an arbitrarily larger overall segmentation error than an optimum segmentation with the same number of segments.

Several methods have been developed to construct an optimum segmentation. In addition, several heuristics have been developed that do not necessarily construct an optimum segmentation, but construct acceptably good segmentations in many cases. Further research is needed to provide quality of approximation guarantees or otherwise characterize how well the segmentations produced by these heuristics do in terms of overall segmentation error, in comparison with an optimum segmentation.

Dynamic programming based schemes are commonly employed to construct optimal segmentations (Duncan & Bryant, 1996; Himberg, Korpiaho, Mannila, Tikanmaki & Toivonen, 2001; Keogh & Kasetty, 2003; Pavlidis & Horowitz, 1974). Given a time series T with n data points, an upper bound m on the number of segments, and the segment error of each possible segment of T, a dynamic programming based scheme constructs a segmentation whose overall error is minimal. Let (i, j) denote the segment of T consisting of data points i through j. The scheme typically maintains a table R to record the minimal error value possible in covering time points 1 through j with k segments. (Variable k ranges between 1 and the maximum of m and j.) For $k = 1$, entry $R[j, 1]$ of the table is set to the segment error of segment $(1, j)$. For $k > 1$, entry $R[j, k]$ is constructed from other values in R. In the following example, the optimization goal is to minimize the sum of the individual segment errors. Accordingly, $R[j, k]$ is set based on the idea that if in an optimum k segment covering of time points 1 through j, the first $k-1$ segments cover time points 1 through x, then these segments provide a minimum total cost covering of these time points by $k-1$ segments.

$$R[j, k] = min_{k-1 \le x < j} \{R[x, k-1] + \text{segment error of segment } (x+1, j)\}$$

The Reference (Chundi & Rosenkrantz, 2004b) presents a dynamic programming algorithm where the parameters include a constraint on the size, and/or variability of the size, of segments in a segmentation.

Dynamic programming based segmentation methods run in time $O(n^2m)$ time, where n is the number of data points in the time series and m is the desired number of segments. For many applications, where time series data may contain hundreds of thousands of data points, dynamic programming based methods are too slow. In such cases, a user may opt for suboptimal segmentations. There are heuristic methods that take less time than dynamic programming methods to produce a segmentation. Three popular heuristic schemes are sliding window, top-down, and bottom-up methods (Keogh, Chu, Hart & Pazzani, 2004; Lamire, 2007). These heuristic methods save time by considering only

some possible segments to hopefully find a good segmentation, whereas dynamic programming considers all $O(n^2)$ segments to find an optimal segmentation. Consequently, heuristic based methods may not find the best segmentation.

In addition to the above methods, fuzzy clustering based methods have also been studied to construct segmentations of time series data (Abonyi, Feil, Nemeth & Arva, 2005) where segments are identified as fuzzy sets and the hyper planes of local PCA models are used to measure segment errors.

Sample Applications

Segmentation methods have been employed in many domains. We describe several recent applications. There has been recent interest in temporal analysis of software version histories. Such histories contain a wealth of information about development activities of a software project. A software version history contains, among other information, the identity of files that have changed at a given time point and the developers that made the changes (Siy, Chundi, Rosenkrantz & Subramaniam, 2007). This information is represented as a time series where each data point is a set of discrete items, such as files and developers. Then, several dynamic-programming based segmentations as well as uniform segmentations of varying sizes the time series are constructed. Dynamic-programming based segmentation performed better by capturing more of the temporal content of the time series than uniform segmentations. Time segments in a dynamic-programming based segmentation corresponded to natural stages in the history of the paper. In addition, the study identified developers that were actively changing files in a time segment and discovered that changes to files made by active developers in a time segment leads to fewer fixes in the future.

Segmentation methods have also been employed to identify temporal information from unstructured text documents (Chundi & Rosenkrantz, 2004a; Chundi & Rosenkrantz, 2004b). The time of creation/publication is used to create a time series over documents, where each data point is a set of documents and keywords (or key phrases) occurring in those documents. Segmentation of a document set time series has been used to remove noise from data and analyze trends in topics.

FUTURE TRENDS

Segmentation of time series data continues to be an active area of research, as it is central to understanding and mining temporal data. We outline a few recent research issues here. Time series segmentation methods are being extended to applications where data points are non-numeric; they may be sets of discrete items, sets of sets, or some kind of a nested structure. Definitions of segment errors, overall errors and other functions appropriate to various applications must be suitably defined, so that current segmentation methods can be adapted to new kind of data. Traditionally a time series is considered to consist of a finite number of observations, all available before a segmentation is constructed. However, it is often more natural to think of a time series as an unending stream of observations, obtained as a natural or man-made phenomenon is monitored. For such streaming data, a segmentation may need to be constructed incrementally, as observations become available. Finally, methods are being designed where the polynomial degree of different segment representations in a segmentation may vary, with a higher degree polynomial used only for those segments where it has a major effect on reducing the overall error.

CONCLUSION

Time series data is pervasive in many domains, including financial, scientific, and healthcare domains, and is very useful for understanding past information and predicting future trends. Time series segmentation is an important problem since data mining methods are often applied to a segmented time series to discover useful information. Therefore, it is important to ensure that the segmentation of a time series provides an accurate representation of the underlying time series data. Time series segmentation is still an active area of research, including developing approaches for streaming data and scaling segmentation algorithms to long time series (with millions of data points).

KEY TERMS

Optimum Segmentation: An optimum segmentation for a given time series, with a given constraint *m* on the number of segments, is a segmentation with a minimum segmentation error among all segmentations containing at most *m* segments.

Segment: A segment is a sequence of one or more consecutive points from a time series, represented as a value or a model fitted to the data in these time points.

Segmentation: A segmentation of a given time series is a representation of the time series as a sequence of segments.

Segmentation Error: The segmentation error of a given segmentation is a measure of the overall difference between the representation of the segments in the segmentation and the data points in the time series.

Segment Error: The segment error of a given segment is a measure of the difference between the segment representation and the data points in the segment.

Time Series: A time series is a sequence of data points that represent the state of a variable, possibly having a composite structure, over consecutive points in time.

Uniform Segmentation: A uniform segmentation of a given time series is a segmentation all of whose segments are of the same length.

Segmenting the Mature Travel Market with Data Mining Tools

INTRODUCTION

The graying of America is one of the most significant demographic changes to the present and future of the United States (Moisey & Bichis, 1999). As more baby boomers enter their 50s and 60s, the mature travel market becomes a fast-growing market segment and starts to attract attention from many tourism researchers and professionals. The significant increases in size and wealth of the older population make the mature travel market a strong component of the general travel market (Reece, 2004). Understanding the mature market as well as mature travelers' motivations are vital to the success of the travel industry (Brewer, Poffley, & Pederson, 1995; Hsu, Cai, & Wong, 2007).

Today's mature travel market can be generalized as being "different, diverse and demanding" (Harssel, 1994, p. 376). Faranda and Schmidt (1999) suggest that mature tourism marketers must recognize three critical components: the aging process comprehended from multiple disciplines, the acknowledged "heterogeneity and dynamic nature" of the mature market, and the "necessity for sound segmentation methods" (p. 24). It is not a simple task for marketers to fully understand the mature travel market.

In order to better understand and serve the diverse market, tourism professionals will have to use data mining (DM) tools and techniques to discover the hidden patterns and characteristics of the mature travel market. According to Pyo, Uysal, and Chang (2002), DM can be applied to many areas in tourism research. These areas include destination quality control and perceptions, environmental scanning and optimization, travel behavior, tourism forecasting, and market segmentation and positioning. Therefore, the purpose of this study is to review and analyze the segmentation methods reported in the literature during the past seven years on the mature travel market and to explore the application of DM tools regarding the segmentation of the mature travel market in the near future.

BACKGROUND

A diversity of segmentation variables have been documented in the literature of the mature travel market. The segmentation efforts usually focus on socio-demographic variables (e.g., age, gender, and employment status) and psychographic variables (e.g., motivations and constraints). Demographic and behavioral profiles are then developed and compared based on subgroups or segments, with the help of data analytical tools.

A Priori Segmentation

A priori segmentation approach has been widely used in tourism studies (Dolnicar, 2004). Most tourism researchers use geographic and demographic characteristics to analyze the market (Hsu & Lee, 2002). Socio-demographic variables, such as age, gender, and retirement, are already known before conducting statistical analyses. The number of segments is known and determined by pre-selected variables.

Age. Mature travelers' biological age is always used as a categorical variable to distinguish different subgroups within the mature travel market. Various terms are employed to describe different age subgroups, such as "age cycles," "first cycle" and "next cycle" (Fleischer & Pizam, 2002), and "young old," "old," and "very old" (Hong, Kim, & Lee, 1999). The age subgroups are found different regarding to psychographic, behavior, and other sociodemographic variables. For example, younger senior travelers (55-64) reported a conservation/protection attitude rather than the consumptive attitude reported by the older senior travelers. Older senior travelers were more likely to visit friends and relatives than younger senior travelers (Backman, Backman, & Silverberg, 1999). Hong, Kim, and Lee (1999) found from a study of three age subgroups: young-old (55-64), old (65-74), and very old (75+) that race, education, marital status, and economic factors determined the decision to travel (i.e., whether or not to travel), while age, health care expenditures, and household income were found significant in predicting tourism expenditure.

Age cycles were associated with the effect of the constraints on the number of vacation days (Fleischer and Pizam, 2002). In the first cycle (55-65), the number of vacation days was positively correlated with leisure time and household income; while in the next cycle (65+), declining incomes and deteriorating health were found to cause a decrease of the vacation length.

Different from the traditional categorization based on chronological or objective age, Muller and O'Cass (2001) focused on the subjective age of older adults. Measured in felt age and activities age, subjective age was recognized as a valuable segmentation tool. The young-at-heart seniors sought fun and enjoyment in life, traveled for physical stimulation and a sense of accomplishment, and had high expectations of their vacation trips. The subjectively older seniors, those less young at heart, were concerned about security and they tended to worry about having trouble with travel arrangements, getting hurt or being in danger, and becoming ill on vacation. They preferred traveling with a group of friends or with their family, which distinguished them from the young-at-heart seniors.

Gender. The travel behavior based on gender in the context of mature tourism research has been rarely studied (Lehto, O'Leary, & Lee, 2001). Lehto et al. (2001) identified significant differences between male and female mature travelers in terms of preferences for destination attributes and travel products and services. Women were more drawn to people-oriented activities than male travelers. Older female travelers were also found interested in long-haul travel in general; however, they had strong preferences for shorter duration trips. Issues, such as personal safety, package or guided tours, and availability of comprehensive tourist information, were highly important to female travelers. Older male travelers paid attention to the utility or functional aspects of a travel destination.

Employment Status. Blazey (1992) investigated the relationship between pre- and post-retirement status, as well as key issues related to older adult travel activity. Four separate analyses examined the relationship between retirement status and constraints to travel activity, use of various forms of travel information, travel characteristics, and participation in travel related activities. Retirees were likely to be constrained by health conditions, physical energy, perception of age, and disability.

A Posteriori (Data-Driven) Segmentation

As noted by Hsu and Lee (2002), a posteriori approach is most likely used based on psychographic variables, such as motivations, constraints, and perceived benefits. In contrast to priori segmentation, researchers have no prior knowledge of the desired travel market segments regarding travelers' psychographic characteristics. DM analytical tools are required to generate the market segments.

Gerontologists proposed that as people reached their mature stage of life, they became more preoccupied with self-utilization. Cleaver, Muller, Ruys, and Wei (1999) stressed the strategic usefulness of identifying travel-motive segments for tourism product development. Seven travel-motive segments were determined with factor analyses, namely, Nostalgics, Friendlies, Learners, Escapists, Thinkers, Status-Seekers, and Physicals.

You and O'Leary (1999) examined the diversity and heterogeneity of the older UK outbound travelers' market and segmented it based on travel push and pull factors. The older market was categorized into three distinct groups, namely, passive visitors, the enthusiastic go-getters, and the culture hounds. The three segments exhibit distinct differences in demographics as well as their destination participation patterns,

travel philosophies, trip frequencies and other travel characteristics.

MAIN FOCUS

A total of seven journal articles published since 2000 in six different sources (i.e., Activities, Adaptation & Aging, Journal of Hospitality & Leisure Marketing, Journal of Travel Research, Journal of Travel & Tourism Marketing, Journal of Vacation Marketing, and Tourism Management) were selected and included in this study. All the articles focused on segmenting the mature travel market from a data-driven approach. A review of the sample size, segmentation variables, DM methods used to segment the market, as well as the results was summarized in Table 1.

As shown in Table 1, most of the recent literature on segmentation of the mature travel market was data-driven. Variables such as travel motives and benefits were commonly used to segment the mature travel market. Traveler attributes (i.e., age, gender, marital status, income, companions) and travel frequency were applied to a priori segmentation approach. More studies employ a posteriori segmentation to depict the heterogeneity of the market.

Due to its interdisciplinary nature, cluster analysis was the single DM technique that has been widely used in the recent segmentation literature except in Kim, Wei, and Ruys' (2003) study, although there were a wide variety of grouping techniques (Wedel & Kamakura, 1998). The fundamental idea of cluster analysis is to divide a number of survey respondents into some subgroups according to a pre-defined and pre-determined criterion. The similarity of individuals within the subgroups and the dissimilarity between them are assumed to be achieved to their maximum (Dolnicar, 2002).

Factor analysis and/or discriminant analysis were often used to accompany cluster analysis; for example,

Table 1. Summary of the Mature Travel Market Segmentation Studies

Study	Sample	Segmentation Variables	DM Methods	Segmentation Results
Guinn & Vincent (2003)	50+ visitors to a Winter destination in Texas (n=154)	Monthly means frequency of activity participation	Hierarchical cluster analysis; Stepwise discriminant analysis	- high involvement - low involvement
Hsu & Lee (2002)	55+ motorcoach travelers (n=817)	Motorcoach tour selection attributes	Factor analysis; Cluster analysis; Stepwise discriminant analysis ANOVA, Chi-square	- dependents - sociables - independents
Kim, Wei, & Ruys (2003)	50+ Australian (n=200)	Traveler attributes (age, gender, marital status, income, companions)	Kohonen's self-organizing maps (SOM, an artificial neural network)	- active learner - relaxed family body - careful participant - elementary vacationer
Lehto, O'Leary, & Lee (2001)	50+ French travelers	Traveler attributes	Cluster analysis; ANOVA	- independent eco-tourists - enthusiastic female experiencers - budget conscious relaxation seekers
Littrell, Paige, & Song (2004)	50+ Caucasian travelers (n=146)	Travel activities	Principle component factor analysis; K-means cluster analysis; ANOVA	- active outdoor/cultural tourists - cultural tourists - moderate tourists
Sellick (2004)	50+ members of the National Seniors Association in Australia (n=986)	Motives; Benefits; Value & lifestyle	Factor analysis; Cluster analysis; Multiple discriminant analysis	- discovery and self-enhancement - enthusiastic connectors - reluctant travelers - nostalgic travelers
Shoemaker (2000)	Pennsylvania residents 55+ (n=234)	Motivation	ANOVA; *K*-means clustering; Discriminant analysis	- escape and learn group - the retirees - active storytellers

two articles employed all the three DM tools (Hsu & Lee, 2002; Sellick, 2004), two studies used discriminant analysis to supplement cluster analysis (Guinn & Vincent, 2003; Shoemaker, 2000), and only one study conducted factor analysis (Littrell, Paige, & Song, 2004). Factor analysis was usually used first to reduce and purify the dimensionality of the selected attributes, and therefore to enhance the ability to classify and generate distinct subgroups within the mature travel market. A stepwise discriminant analysis was often conducted as a supplementary tool to further identify distinguishing attributes between the subgroups (Hsu & Lee, 2002).

FUTURE TRENDS

One of the emerging trends of data mining in the field of mature tourism is the application of various segmentation tools to the mature tourism research, such as neural network modeling. As discussed by Kim, et al. (2003), Kohonen's self-organizing maps (SOM) is capable of combining vector quantization and projection and therefore providing a visual data map of the subgroups. A two-dimensional Kohonen network possesses a layer of strongly interrelated neurons (e.g., features and attributes), which enables the implementation of a nonlinear and multidimensional mapping. Kim, et al. employed Kohonen's SOM to segment the motivations and concerns of the travelers based on older adults' traveler attributes and characteristics. The deployment of the neural network models enhances the travel market professionals' understanding of changing behavior among tourists within and between the macrosegments (Bloom, 2005).

The second trend is the employment of a diversity of the combined DM tools, as demanded by the urgent need for combined segmentation variables, for example, a combination of psychographic and demographic variables. A behavioral profile of the male and female subgroups based on a wide array of motivations is more accurate and persuasive in predicting travel trends than a profile purely based on gender differences. Therefore, to develop a series of the combined DM tools is necessary to advance the research in segmenting the mature travel market.

Exploring DM tools to investigate non-traditional segmentation variables that are relevant to the nature of the mature travel market is the third trend. Two types of variables can contribute to an enhanced understanding of market segmentation. First of all, it is necessary to add gerontographic variables to the segmentation process (Shoemaker, 2000). The gerontographic factors can depict the picture of the mature travelers to its full extent. For example, Moschis (1996) developed a gerontographic life stage model, which classifies older adults into four segments based on the amount and type of aging events and health problems they have experienced. These groups (i.e., healthy indulgers, healthy hermits, ailing outgoers, and freail recluses) are hypothesized to possess different attitudes toward travel. Secondly, a close connection between destination and travel decision makes it critical to include destination attributes into the market segmentation process. After defining the position of a destination, a profile of the target market should be proposed and developed by considering the destination attractions (Pyo, et al., 2002).

CONCLUSION

A review of the most recent segmentation studies in mature tourism revealed the overwhelming usage of cluster analysis and the emergence of other segmentation tools, for example, neural network modeling. With the increasing magnitude and diversification of the older population, the segmentation of the mature travel market is a promising field to which many DM tools and techniques may be practiced and applied. The employment of various DM tools, in turn, will enhance the tourism researchers' ability to understand and segment the mature travel market.

KEY TERMS

A Posteriori Segmentation (Data-Driven or Post Hoc Segmentation): Quantitative techniques of data analysis are used to derive a grouping based on psychographic and behavioral segmentation variables.

A Priori Segmentation: A conceptual approach when the relevant dimensions for grouping respondents in an empirical study are felt to be known in advance, except for the fact that both uni- and multidimensional approaches are used (Dolnicar, 2002).

Baby Boomers: People who were born between 1946 to 1964 in the United States, as well as in Australia, Canada, and United Kingdom.

Data Mining (DM): A "discovery-oriented data analysis technology, which automatically detects hidden important information in the data warehouse" (Pyo, et al., 2002, p.397).

Market Segmentation: The process of dividing a total marketing into distinct subgroups, with shared characteristics within the subgroups.

Mature Travel Market: The travel market that is composed of older travelers, usually aged 50 and above.

Tourism: The activities of persons traveling to and staying in places outside their usual environment for not more than one consecutive year for leisure, business and other purposes (an official definition provided by the United Nations World Tourism Organization).

Travel Constraints: The factors that prevent people from traveling or from enjoying traveling (Fleischer & Pizam, 2002).

Travel Motivation: The reasons that make a person engaged in a tourism-related activity.

Semantic Data Mining

INTRODUCTION

Over the past few decades, data mining has emerged as a field of research critical to understanding and assimilating the large stores of data accumulated by corporations, government agencies, and laboratories. Early on, mining algorithms and techniques were limited to relational data sets coming directly from On-Line Transaction Processing (OLTP) systems, or from a consolidated enterprise data warehouse. However, recent work has begun to extend the limits of data mining strategies to include "semi-structured data such as HTML and XML texts, symbolic sequences, ordered trees and relations represented by advanced logics." (Washio and Motoda, 2003)

The goal of any data mining endeavor is to detect and extract patterns in the data sets being examined. Semantic data mining is a novel approach that makes use of graph topology, one of the most fundamental and generic mathematical constructs, and semantic meaning, to scan semi-structured data for patterns. This technique has the potential to be especially powerful as graph data representation can capture so many types of semantic relationships. Current research efforts in this field are focused on utilizing graph-structured semantic information to derive complex and meaningful relationships in a wide variety of application areas-- national security and web mining being foremost among these.

In this article, we review significant segments of recent data mining research that feed into semantic data mining and describe some promising application areas.

BACKGROUND

In mathematics, a graph is viewed as a collection of vertices or nodes and a set of edges which connect pairs of those nodes; graphs may be partitioned into sub-graphs to expedite and/or simplify the mining process. A tree is defined as an acyclic sub-graph, and trees may be ordered or unordered, depending on whether or not the edges are labeled to specify precedence. If a sub-graph does not include any branches, it is called a path.

The two pioneering works in graph-based data mining, the algorithmic precursor to semantic data mining, take an approach based on greedy search. The first of these, SUBDUE, deals with conceptual graphs and is based on the Minimum Description Length (MDL) principle. (Cook and Holder, 1994) SUBDUE is designed to discover individual concepts within the graph by starting with a single vertex, which represents a potential concept, and then incrementally adding nodes to it. At each iteration, a more "abstract" concept is evaluated against the structure of the original graph, until the algorithm reaches a stopping point which is defined by the MDL heuristic. (Cook and Holder, 2000)

The second of the seminal graph mining works is called Graph Based Induction (GBI), and like SUBDUE, it is also designed to extract concepts from data sets. (Yoshida, Motoda, and Inokuchi, 1994) The GBI algorithm repeatedly compresses a graph by replacing each found sub-graph or concept with a single vertex. To avoid compressing the graph down to a single vertex, an empirical graph size definition is set to establish the size of the extracted patterns, as well as the size of the compressed graph.

Later researchers have applied several other approaches to the graph mining problem. Notable among these are the Apriori-based approach for finding frequent sub-graphs (Inokuchi, Washio, and Motoda, 2000; Kuramochi and Karypis, 2002), Inductive Logic Processing (ILP), which allows background knowledge to be incorporated in to the mining process; Inductive Database approaches which have the advantage of practical computational efficiency; and the Kernel Function approach, which uses the mathematical kernel function measure to compute similarity between two graphs. (Washio and Motoda, 2003)

Semantic data mining expands the scope of graph-based data mining from being primarily algorithmic, to include ontologies and other types of semantic information. These methods enhance the ability to systematically extract and/or construct domain specific features in data.

MAIN THRUST OF CHAPTER

Defining Semantics

The effectiveness of semantic data mining is predicated on the definition of a domain-specific structure that captures semantic meaning. Recent research suggests three possible methods of capturing this type of domain knowledge:

- Ontologies
- Semantic Associations
- Semantic Metadata

In this section, we will explore each of these in depth.

An ontology is a formal specification in a structured format, such as XML or RDF, of the concepts that exist within a given area of interest and the semantic relationships among those concepts. The most useful aspects of feature extraction and document classification, two fundamental data mining methods, are heavily dependent on semantic relationships. (Phillips and Buchanan, 2003) For example, a news document that describes "a car that ran into a gasoline station and exploded like a bomb" might not be classified as a terrorist act, while "a car bomb that exploded in a gasoline station" probably should be. (Gruenwald, McNutt and Mercier, 2003) Relational databases and flat documents alone do not have the required semantic knowledge to intelligently guide mining processes. While databases may store constraints between attributes, this is not the same as describing relationships among the attributes themselves. Ontologies are uniquely suited to characterize this semantic meta-knowledge. (Phillips and Buchanan, 2003)

In the past, ontologies have proved to be valuable in enhancing the document clustering process. (Hotho, Staab, and Strumme, 2003) While older methods of text clustering were only able to relate documents that used identical terminology, semantic clustering methods were able to take into account the conceptual similarity of terms such as might be defined in terminological resources or thesauri. Beneficial effects can be achieved for text document clustering by integrating an explicit conceptual account of terms found in ontologies such as WordNet. For example, documents containing the terms "beef" and "chicken" are found to be similar, because "beef" and "chicken" are both sub-concepts of "meat" and, at a higher level, "food". However, at a more granular clustering level, "beef" may be more similar to "pork" than "chicken" because both can be grouped together under the sub-heading of "red meat". (Hotho, Staab, and Strumme, 2003)

Ontologies have also been used to augment the knowledge discovery and knowledge sharing processes. (Phillips and Buchanan, 2003) While in the past, prior knowledge had been specified separately for each new problem, with the use of an ontology prior knowledge found to be useful for one problem area can be reused in another domain. Thus, shared knowledge can be stored even in a relatively simple ontology, and collections of ontologies can be consolidated together at later points in time to form a more comprehensive knowledge base.

At this point it should be noted that that the issues associated with ontology construction and maintenance are a research area in and of themselves. Some discussion of potential issues is presented in (Gruenwald, McNutt and Mercier, 2003) and (Phillips and Buchanan, 2003), but an extensive examination of this topic is beyond the scope of the current article.

In addition to ontologies, another important tool in extracting and understanding meaning is semantic associations. "Semantic associations lend meaning to information, making it understandable and actionable, and provide new and possibly unexpected insights." (Aleman-Meza, 2003) Looking at the Internet as a prime example, it becomes apparent that entities can be connected in multiple ways to other entities by types of relationships that cannot be known or established a priori. For example, a "student" can be related to a "university", "professors", "courses" and "grades" but she can also be related to other entities by different relations like financial ties, familial ties, neighborhood, etc. "In the Semantic Web vision, the RDF data model provides a mechanism to capture the meaning of an entity or resource by specifying how it relates to other entities or classes of resources" (Aleman-Meza, et. al., 2003) – each of these relationships between entities is a "semantic association" and users can formulate queries against them. For example, semantic association queries in the port security domain may include the following:

1. Are any passengers on a ship coming into dock in the United States known to be related by blood to one or more persons on the watch list?
2. Does the cargo on that ship contain any volatile or explosive materials, and are there any passengers on board that have specialized knowledge about the usage of those materials?

Semantic associations that span several entities and these constructs are very important in domains such as national security because they may enable analysts to uncover non-obvious connections between disparate people, places and events.

In conjunction with semantic associations, semantic metadata is an important tool in understanding the meaning of a document. Semantic metadata, in contrast to syntactic metadata, describes the content of a document, within the context of a particular domain of knowledge. For example, documents relating to the homeland security domain may include semantic metadata describing terrorist names, bombing locations, etc. (Sheth, et. al., 2002)

Methods of Graph Traversal

Once the semantic structures for a given domain have been defined, an effective method of for traversing those structures must be established. One such method that is coming into recent prominence, in addition to the algorithmic graph mining methods mentioned earlier in this chapter, is link mining. "Link mining is a newly emerging research area that is the intersection of the work in link analysis, hypertext and web mining, relational learning and inductive logic programming, and graph mining." (Getoor, 2003) Link mining is an instance of multi-relational data mining, in its broadest sense, and a field that is coming into prominence as the issues around graph traversal become paramount.

Link mining encompasses a range of tasks including both descriptive and predictive modeling. The field also introduces new algorithms for classification and clustering for the linked relational domain, and with the increasing prominence of links new mining tasks come to light as well. (Getoor, 2003) Examples of such new tasks include predicting the number of links between two entities, predicting link types, inferring the existence of a link based on existing entities and links, inferring the identity of an entity, finding co-references, and discovering sub-graph patterns. Link mining areas currently being explored are: link-based classification, which predicts the category of an object, link based cluster analysis, which clusters linked data based on the original work of SUBDUE, and several approaches on finding frequently occurring linking patterns. (Getoor, 2003).

Relative Importance and Ranking

There is increasing interest in developing algorithms and software tools for visualization, exploratory and interpretive analysis of graph-structured data, such the results of the semantic mining process. "While visualization techniques such as graph-drawing can be very useful for gleaning qualitative information about the structure of small graphs, there is also a need for quantitative tools for characterizing graph properties beyond simple lists of links and connections, particularly as graphs become too large and complex for manual analysis." (White and Smyth, 2003) In the area of web graphs, a number of ranking algorithms have been proposed, such as HITS (Kleinberg, 1999)

and PageRank (Brin and Page, 1998) for automatically determining the "importance" of Web pages.

One way of determining the relative importance of a result set might be to use a standard, global algorithm to rank all nodes in a sub-graph surrounding the root nodes of interest. The aforementioned PageRank algorithm is one such example. However, the problem with such an approach is that the root nodes are not given preferential treatment in the resulting ranking—in effect, one is ranking the nodes in the local sub-graph, rather than being ranked globally.

Another approach is to apply semantic methods themselves to the relevance and ranking problem. In order to determine the relevance of semantic associations to user queries, it becomes critical to capture the semantic context within which those queries are going to be interpreted and used, or, more specifically, the domains of user interest.

(Aleman-Meza, 2003) proposes that this can be accomplished "by allowing a user to browse an onotology and mark a region (sub-graph) of an RDF graph of nodes and/or properties of interest." The associations passing through these regions that are considered relevant are ranked more highly in the returned result set than other associations, which may be ranked lower or discarded.

FUTURE TRENDS

One of the most high-profile application areas for semantic data mining is in the building and mining of the Semantic Web, which associates the meaning of data with web content. The SCORE system (Semantic Content Organization and Retrieval Engine), built at the University of Georgia, is one example that uses semantic techniques to traverse relationships between entities. (Sheth, et. al., 2002) Designed as a semantic engine with main-memory based indexing, SCORE provides support for context sensitive search, browsing, correlation, normalization and content analysis. Once the semantic search engine determines the context of information described in the document, it can explore related entities through associations. By navigating these associations or relationships, the engine can access content about these entities.

Another critical domain for the application of semantic data mining, as mentioned previously, is national security. In this area, one of the most difficult aspects of the mining process is creating an ontology to be used for the duration of the task. "In classification of a terrorist incident we must identify violent acts, weapons, tactics, targets, groups and perhaps individuals." (Gruenwald, McNutt and Mercier, 2003) While many domains are topic-driven and focus on only a single classification area, the national security inherently requires a focused search across multiple topics in order to classify a document as terrorism related. Specifically, a document must be identified as being semantically related to multiple branches in a terrorism hierarchy to be positively marked as relevant to the national security domain. (Gruenwald, McNutt and Mercier, 2003)

The prototypical Passenger Identification, Screening and Threat Analysis Application (PISTA), developed at the University of Georgia is an example of the application of the semantic mining approach to the national security domain. "PISTA extracts relevant metadata from different information resources, including government watch-lists, flight databases, and historical passenger data." (Sheth, et. al., 2003) Using a semantic association based knowledge discovery engine, PISTA discovers suspicious patterns and classifies passengers into high-risk, low-risk and no-risk groups, potentially minimizing the burden of an analyst who would have to perform further investigation. While PISTA restricts its focus to flight security, a similar approach might be applied to other aspects of national security and terrorism deterrence, such as port security and bomb threat prediction.

One relatively novel area to which semantic mining techniques have recently been applied is in Money Laundering Crimes. (Zhang, Salerno, and Yu, 2003) Money laundering is considered a major federal offense, and with the development of the global economy and internet commerce, it is predicted that Money Laundering will become more prevalent and difficult to detect. The investigation of such crimes involves analyzing thousands of text documents in order to generate crime group models. These models group together a number of people or entities linked by certain attributes. These "attributes" typically are identified by the investiga-

tors based on their experiences and expertise, and consequently are very subjective and/or specific to a particular situation. (Zhang, Salerno and Yu, 2003) The resulting structure resembles a semantic graph, with the edges defined by the aforementioned attributes. Once this graphical model of the crime group model has been generated graph traversal and semantic query techniques may be used to automatically detect potential investigation scenarios.

CONCLUSION

Today, semantic data mining is a fast growing field due to the increasing interest in understanding and exploiting the entities, attributes, and relationships in graph-structured data, which occurs naturally in many fields. In this review article, we have presented a high-level overview of several important research areas that feed into semantic mining, as well as describing some prominent applications of specific techniques. Many accomplishments have been made in this field to date, however, there is still much work to be done. As more and more domains begin to realize the predictive power that can be harnessed by using semantic search and association methods, it is expected that semantic mining will become of the utmost importance in our endeavor to assimilate and make effective use of the ever-increasing data stores that abound in today's world.

KEY TERMS

Graph: In mathematics, a set of vertices or nodes which are connect by links or edges. A pair of vertices that are connected by multiple edges yield a multi-graph; vertices that are connected to themselves via looping edge yield a pseudo-graph.

Graph-Based Data Mining: A method of data mining which is used to find novel, useful, and understandable patterns in graph representations of data.

Link Mining: A method of data mining that combines techniques from link analysis, hypertext and web mining, relational learning and inductive logic programming, and graph mining. Link mining places primary emphasis on links, and is used in both predictive and descriptive modeling.

Ontology: A formal specification in a structured format, such as XML or RDF, of the concepts that exist within a given area of interest and the semantic relationships among those concepts.

Semantic Associations: "The associations that lend meaning to information, making it understandable and actionable, and providing new and possibly unexpected insights" (Aleman-Meza, 2003)

Semantic Context: The specification of the concepts particular to a domain that help to determine the interpretation of a document.

Semantic Data Mining: A method of data mining which is used to find novel, useful, and understandable patterns in data, and incorporates semantic information from a field into the mining process.

Semantic Metadata: Metadata that describes the content of a document, within the context of a particular domain of knowledge. For example, for documents relating to the homeland security domain, semantic metadata may include terrorist names, group affiliations, etc.

Semantic Web: An extension of the current World Wide Web, proposed by Tim Berners-Lee, in which information is given a well-defined meaning. The Semantic Web would allow software agents, as well as humans, to access and process information content.

Syntactic Metadata: Metadata that describes a document's structure and/or format. For example, document language, document size, and MIME type might all be included as elements of syntactic metadata.

Semantic Multimedia Content Retrieval and Filtering

INTRODUCTION

Several consumer electronic devices that allow capturing digital multimedia content (like mp3 recorders, digital cameras, DVD camcorders, smart phones etc.) are available today. These devices have allowed both the amateur and the professional users to produce large volumes of digital multimedia material, which, together with the traditional media objects digitized recently (using scanners, audio and video digitization devices) form a huge distributed multimedia information source. The multimedia material that is available today is usually organized in independent multimedia information sources, developed on top of different software platforms.

The Internet, the emergence of advanced network infrastructures that allow for the fast, efficient and reliable transmission of multimedia content and the development of digital multimedia content services on top of them form an open multimedia consumption environment. In this environment, the users access the multimedia material either through computers or through cheap consumer electronic devices that allow the consumption and management of multimedia content. The users of such an open environment need to be able to access the services offered by the different vendors in a transparent way and to be able to compose the different atomic services (like, for example, multimedia content filtering) into new, composite ones. In order to fulfill this requirement, *interoperability* between the multimedia content services offered is necessary.

Interoperability is achieved, at the syntactic level, through the adoption of standards. At the semantic level, interoperability is achieved through the integration of domain knowledge expressed in the form of domain *ontologies*. An ontology is a logical theory accounting for the intended meaning of a formal vocabulary, i.e. its ontological commitment to a particular conceptualization of the world (Guarino, 1998).

The standard that dominates in multimedia content description is the *MPEG-7* (Salembier, 2001), formally known as *Multimedia Content Description Interface*. It supports multimedia content description from several points of view, including media information, creation information, structure, usage information, textual annotations, media semantics, and low-level visual and audio features. Since the MPEG-7 allows the structured description of the multimedia content semantics, rich and accurate semantic descriptions can be created and powerful *semantic retrieval and filtering* services can be built on top of them.

It has been shown, in our previous research (Tsinaraki, Fatourou and Christodoulakis, 2003), that domain ontologies capturing domain knowledge can be expressed using pure MPEG-7 constructs. This way, domain knowledge can be integrated in the MPEG-7 semantic descriptions. The domain knowledge is subsequently utilized for supporting semantic personalization, retrieval and filtering and has been shown to enhance the retrieval precision (Tsinaraki, Polydoros and Christodoulakis, 2007).

Although multimedia content description is now standardized through the adoption of the MPEG-7 and semantic multimedia content annotation is possible, multimedia content retrieval and filtering (especially *semantic* multimedia content retrieval and filtering), which form the basis of the multimedia content services, are far from being successfully standardized.

We focus in this chapter on MPEG-7 based semantic multimedia retrieval and filtering and we introduce the *MPEG-7 Query Language (MP7QL)* and its compatible user preference model, which aim to provide standardized support to such services. The rest of the chapter is structured as follows: In the *Background*

section we present the state of the art in MPEG-7 based multimedia content retrieval and filtering; In the *Main Focus* section we introduce the MP7QL query language and its compliant user preference model; In the *Future Trends* section we outline the future research directions in semantic multimedia content retrieval and filtering and we conclude in the *Conclusions* section.

BACKGROUND

In this section we present the state of the art in MPEG-7 based multimedia retrieval and filtering. It has been mentioned in the introduction that MPEG-7 allows the creation of rich multimedia content descriptions, based on the different aspects of the content. Powerful retrieval and filtering capabilities can be built on top of these descriptions.

Several research groups have been working on MPEG-7 based multimedia content retrieval and filtering, exploiting different features of the MPEG-7 descriptions. The systems offering MPEG-7 based multimedia content retrieval and filtering are classified in three categories:

1. Systems that exploit the textual annotations together with the media-related elements of the MPEG-7 descriptors for retrieval and filtering support (Graves and Lalmas, 2002; Rogers, Hunter and Kosovic, 2003; Tseng, Lin and Smith, 2004). Multimedia content filtering in these systems utilizes the MPEG-7 *Filtering and Search Preferences (FASP)*, which allow the users to specify their preferences regarding multimedia content retrieval and filtering.
2. Systems that exploit the *MPEG-7 Visual* (ISO/IEC, 2001a) and *Audio* (ISO/IEC, 2001a) *Descriptors* in order to support multimedia content retrieval based on the low-level MPEG-7 features (Eidenberger and Breiteneder, 2003; Bertini, del Bimbo and Nunziati 2006). These systems cannot be transparently integrated with the MPEG-7 FASP for multimedia content filtering, because the MPEG-7 FASP do not allow the expression of the user preferences regarding the MPEG-7 low-level visual and audio features.
3. Systems that exploit the semantic metadata descriptions formed according to the Semantic DS of the MPEG-7 *Multimedia Description Schemes (MDS)* (ISO/IEC, 2003a) for semantic multimedia retrieval and filtering (Hammiche, Lopez, Benbernou, Hacid and Vakali, 2006; Tsinaraki, Fatourou and Christodoulakis, 2003; Tsinaraki, Polydoros and Christodoulakis, 2007). These systems cannot be fully exploited using the MPEG-7 FASP for multimedia content filtering, because the MPEG-7 FASP allow only the keyword-based expression of the user preferences regarding the multimedia content semantics.

The major limitation of the above research efforts is that each of them exploits some of the features of the MPEG-7 multimedia content descriptions, but none of them provides a uniform and transparent MPEG-7 retrieval and filtering framework. The most important efforts in the direction of MPEG-7 based retrieval and filtering that transparently exploits all the features of the MPEG-7 descriptions are the following:

- The use of plain XQuery (Chamberlin et al., 2005) on top of an XML repository for MPEG-7 based multimedia content retrieval (Lee et al., 2003). This approach does not take into account the peculiarities of the MPEG-7 description elements. Thus, the different MPEG-7 metadata description elements cannot be fully exploited. This happens because both the MPEG-7 semantic model and the domain knowledge integrated in the semantic MPEG-7 descriptions are expressed in an involved way and cannot be successfully exploited if they are accessed in the same way with the textual and the media-related elements of the MPEG-7 metadata descriptions. The low-level visual and audio features also need special treatment. It is difficult for the average user to express, using plain XQuery, query conditions on the semantics and/or the low-level features and even more difficult to combine such query conditions with textual and media-related query conditions. Finally, XQuery does not support queries with preference values, which allow the users to state which query conditions are more important for them.
- The use of the existing MPEG-7 FASP in order to allow multimedia content filtering and retrieval. The limitations of this approach are the following:

- Several MPEG-7 description elements are not present in the MPEG-7 FASPs. The most important among these elements are the semantic elements and the low-level visual and audio features;
- The boolean operators (AND/OR/NOT), as well as the comparison operators (equals, greater, less) cannot be explicitly specified in the MPEG-7 FASPs.

These limitations do not allow the expression of queries for every aspect of the MPEG-7 descriptions. In addition, due to the lack of semantic support, they cannot support semantic multimedia content retrieval and filtering.

In order to overcome the limitations of the existing approaches, a language for querying MPEG-7 descriptions is needed, with clear, MPEG-7 specific semantics (instead of the generic semantics of the XQuery). In response to this need, the International Organization for Standardization (ISO) has recently issued the *MPEG-7 Query Format Requirements (MP7QF)* (ISO/IEC, 2006), in order to guide the MPEG-7 query format standardization. The MP7QL query language, which is presented in the next section, is a query language that fulfils the ISO MPEG-7 Query Format Requirements.

MAIN FOCUS

In this section we introduce the *MPEG-7 Query Language (MP7QL)* (Tsinaraki and Christodoulakis, 2007), a powerful query language that we have developed for querying MPEG-7 descriptions. The MP7QL has the MPEG-7 as data model and satisfies the MP7QF Requirements. It allows for querying every aspect of an MPEG-7 multimedia content description, including semantics, low-level visual features and media-related aspects. It also allows for the exploitation of domain knowledge encoded using pure MPEG-7 constructs. In addition, the MP7QL allows the explicit specification of both boolean operators and preference values in order to allow both the combination of the query conditions according to the user intentions and the expression of the importance of the individual conditions for the users.

The MP7QL queries may utilize the user preferences and the usage history as context, thus allowing for personalized multimedia content retrieval and filtering. The user preferences regarding multimedia content retrieval and filtering may be expressed either according to the MPEG-7 FASP model or according to the MP7QL FASP model, which has the standard MPEG-7 FASP model as a special case.

The MP7QL query output has the form of MPEG-7 documents where the query results are represented as parts of standard MPEG-7 collections, guaranteeing that the MP7QL language has the closure property (Date, 1995). This allows view definition support and the capability to store the results of the query language expressions as new MPEG-7 descriptions that can be reused by the query language in a recursive manner.

The MP7QL has been expressed using both XML Schema (Fallside, 2001) and OWL (McGuinness and van Harmelen, 2004) syntax. The implementation of an MP7QL query processor is in progress, on top of an XML native database accessed by XQuery. In the rest of this section we present the input and the output format of the MP7QL as well as the MP7QL compliant FASP model.

The Input Format of the MP7QL Query Language

The input format of the MP7QL allows expressing query conditions on every aspect of an MPEG-7 multimedia content description.

The fundamental MP7QL element is the MP7QL query. MP7QL allows the explicit specification of boolean operators and preference values, so that the users can express accurately how the retrieval criteria should be combined and which is the relevant importance of the different criteria. Three MP7QL query types have been defined:

- *Queries with explicit preference values*. The preference values are integers in the range [-100, 100], with default value 10. The type, the range and the default value of the preference values are compatible with the preference values used in the MPEG-7 FASP;
- *Queries with explicit boolean operators* (AND/OR/NOT);
- *Queries with explicit preference values and boolean operators*.

An MP7QL query has a SELECT-FROM-WHERE syntax and is formally described using the regular expression syntax of (1).

Q=[Select][From][Where][OrderBy][GroupBy] (1)

The *Select* element of an MP7QL query allows the specification of the elements and/or attributes of the MPEG-7 descriptions that will be returned in the query results. The *Select* element of an MP7QL query is formally described using the regular expression syntax of (2).

Select=Item [format][transformationRules] [maxItems][numOfPageItems] [page][timeLimit]* (2)

The *Item* elements of *Select* represent, in the form of XPath expressions, the elements and/or the attributes of the MPEG-7 descriptions that should be returned for each of the query results. The *format* attribute represents the URI of the file, where the structure of the output display format (that is, the format in which the query results will be displayed in the user's terminal device) is specified and has as default value the URI of the default query output format. The *transformationRules* attribute represents the URI of the XSL stylesheet (Kay, 2005) that should be applied in the standard MP7QL output in order to be presented according to a different format. The *maxItems* attribute represents the maximum number of the query results that will be returned to the user and has "unbounded" as default value. The *numOfPageItems* attribute represents the number of the query results that will be displayed in each result page and has 10 as default value. The *timeLimit* attribute represents the time limit in seconds until which the query must be replied and has 300 as default value. The *page* attribute specifies which result page should be returned to the user and has 1 as default value.

The *From* element of an MP7QL query allows the specification of the type of the MPEG-7 descriptions on which the query will be posed and is formally described using the regular expression syntax of (3).

*From =FromItem** (3)

The *FromItem* elements of *From* may take predefined string values that specify the type (i.e. ImageType, VideoType, SemanticEntityDefinition, Ontology etc.) of the MPEG-7 descriptions on which the query will be posed. Notice that the MP7QL allows, in addition to the queries on MPEG-7 descriptions, queries on the semantic entities that satisfy specific criteria (for example, "give me the players of the soccer team Barcelona") as well as queries on the constructs of domain ontologies expressed using MPEG-7 syntax (for example, "give me the subclasses of *SoccerPlayer*").

The *OrderBy* element of an MP7QL query allows the specification of the criteria for ordering the result set and is formally described using the regular expression syntax of (4).

*OrderBy=Criterion** (4)

The *Criterion* elements of *OrderBy* represent ordering criteria. A *Criterion* element is formally described using the regular expression syntax of (5).

Criterion=Item [priority][order] (5)

The *Item* element of *Criterion* represents, as an XPath expression, an element or an attribute of the MPEG-7 descriptions, on which the ordering will be based. The *priority* attribute represents the priority of the element/attribute in ordering and has 0 as default value. The *order* attribute represents the type (ascending or descending) of the ordering based on the current element/attribute and has "ascending" as default value.

The *GroupBy* element of an MP7QL query specifies, in the form of an XPath expression, the attribute or element that will be used for grouping the query results.

The *Where* element of an MP7QL query allows the expression of the query conditions set by the user. The structure of the *Where* element is different for the different types of the MP7QL queries. In particular:

1. The *Where* element of an MP7QL query with explicit preference values (WWhere) is formally described using the regular expression syntax of (6).

   *WWhere=(WQS pv)** (6)

   pv is an explicit preference value and *WQS* is a query specification with explicit preference values, which represents the query conditions set by the user. The query conditions may refer both

to the multimedia content descriptions and to the domain knowledge utilized in them.

2. The *Where* element of an MP7QL query with explicit boolean operators (BWhere) is formally described using the regular expression syntax of (7).

$$BWhere=BQS[NOT]\ ((AND|OR)\ BQS\ [NOT])^* \quad (7)$$

BQS is a query specification with explicit boolean operators.

3. The *Where* element of an MP7QL query with explicit preference values and boolean operators (BWWhere) is formally described using the regular expression syntax of (8).

$$BWWhere=BWQS\ pv\ ((AND|OR)\ BWQS\ pv)^* \quad (8)$$

BWQS is a query specification with explicitly specified preference values and boolean operators.

The query specifications have been designed to allow expressing conditions on every aspect of a multimedia object that has been described using MPEG-7, so that the MP7QL may be used for querying any MPEG-7 multimedia object description. Thus, every element of an MPEG-7 multimedia object description has a corresponding query specification element in the MP7QL query specifications. The corresponding query specification element is used to specify the conditions that should hold on the values of the MPEG-7 elements of the segments retrieved.

The string comparison operators (contains, notContains, equals, startsWith, endsWith and keywords) and the number comparison operators (equals, greaterThan, greaterThanOrEqual, lessThan, lessThanOrEqual and differentFrom) may be explicitly specified on the elements of the MP7QL query specifications.

The MP7QL provides *Variables*, in order to support joins on the conditions about the features of the MPEG-7 descriptions. From a syntactic point of view, a variable is an identifier that begins with the "$" character.

The expressive power of the MP7QL query language has been evaluated both against the general-purpose ISO MPEG-7 Query Format Requirements and in a domain-specific (soccer) complete application (Tsinaraki and Christodoulakis, 2007). The MP7QL has been found to cover the general-purpose requirements and to allow the expression of all the domain-specific semantic queries of the soccer application.

The Output Format of the MP7QL Query Language

The MP7QL query results are structured as MPEG-7 descriptions, guaranteeing the closure property of the MP7QL language. If the user wishes to view the query results structured in another way, he should specify the display format and the XSL stylesheet that should perform the transformation in his display device in the *Select* element of the MP7QL queries.

The MP7QL query output format organizes the query results in MPEG-7 descriptions where the query result sets are represented by MPEG-7 collections. The result items returned by an MP7QL query form an MPEG-7 *Mixed Collection*, ordered according to the ordering criteria provided by the user in the *OrderBy* element. If the user has specified a grouping criterion in the *GroupBy* element of the MP7QL query, every group of result items is represented by a mixed collection element that contains the group items ordered according to the ordering criteria. If no results are returned, an empty MPEG-7 collection is returned. Every result item is represented in the collection that contains the query results by a *MixedCollection* element comprised of: (a) *Concept* elements that represent the rank and the relevance of the current result item; (b) A URI reference to the MPEG-7 description of the current result item, which is represented by a *ContentRef* element if the query is about multimedia content descriptions and by a *ConceptRef* element if the query is about reusable semantic entities or ontologies expressed in MPEG-7 syntax; and (c) The element that contains the MPEG-7 description elements of the current result item that were returned according to the user selections in the *Select* part of the query. It is a *Content* element if the query is about multimedia content descriptions and a *Concept* element if the query is about reusable semantic entities or ontologies expressed in MPEG-7 syntax.

The MP7QL Compliant FASP Model

The MP7QL Filtering and Search Preferences (FASP) allow the users to specify their preferences regarding multimedia content consumption. We decided

to develop a new FASP model, because the existing MPEG-7 FASP model does not allow to fully exploit the MPEG-7 multimedia content description capabilities during multimedia content filtering and context-based retrieval. The major limitations of the MPEG-7 FASP model are the lack of boolean and comparison operators and the incapability of expressing conditions on several MPEG-7 description elements, including the semantic ones. This way, semantic services cannot be successfully provided.

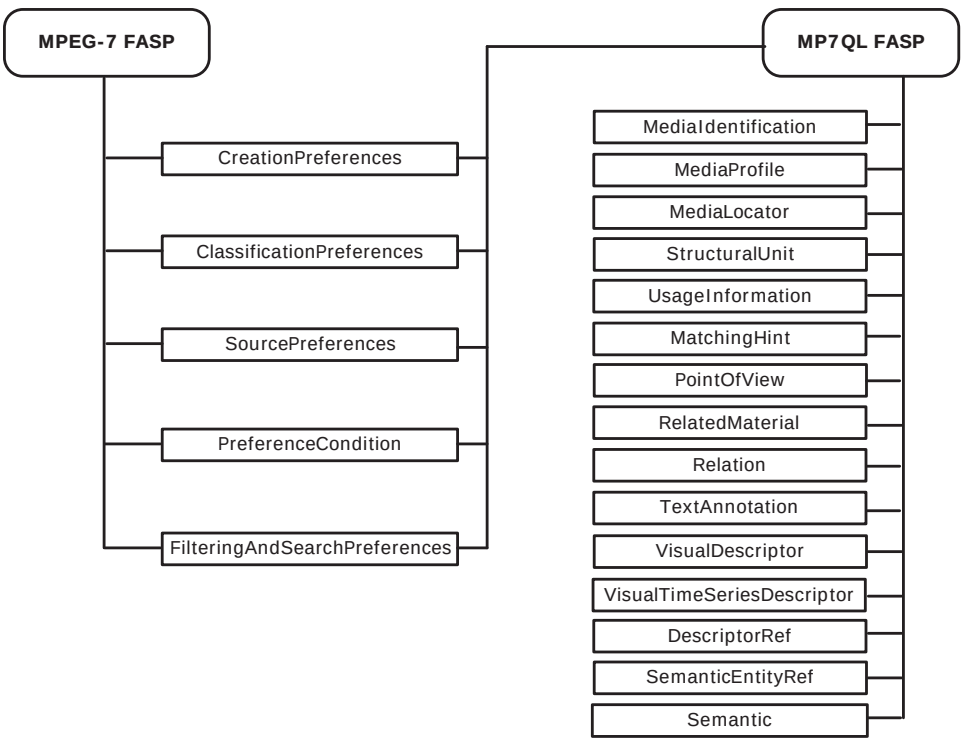
The MP7QL compliant FASP descriptions essentially are MP7QL query specifications. Thus, an MP7QL FASP may have all the elements of an MP7QL query specification. The MP7QL FASP are distinguished into FASP with explicit preference values (in the range [-100, 100]), FASP with explicit boolean operators and FASP with explicit boolean operators and explicit preference values. Notice that the NOT operator and the negative preference values allow the users to express their negative preferences (dislikes) in the FASP.

The MPEG-7 FASP model is a special case of the MP7QL FASP model. In particular, an MPEG-7 FASP is also an MP7QL FASP with explicit preference values, which has only the *CreationPreferences*, *ClassificationPreferences*, *SourcePreferences* , *FilteringAndSearchPreferences*, and *PreferenceCondition* elements (see Figure 1).

FUTURE TRENDS

The future trends in semantic multimedia retrieval and filtering include: (a) The standardization of the MPEG-7 query format. This will allow the standardization of multimedia query expression, in the same way that the MPEG-7 has allowed the standardization of multimedia content description; (b) The development of a retrieval and filtering model on top of the standard MPEG-7 query format, which will form the theoretical basis for satisfying the multimedia content retrieval and filtering requests; (c) The development of optimization techniques, which will allow the efficient MPEG-7 based multimedia retrieval and filtering; and (d) The specification of the MPEG-7 query server

Figure 1. The elements of the MPEG-7 FASP model and the MP7QL FASP model



capabilities description, using a profiling mechanism similar to the one that is available for MPEG-7 (ISO/IEC, 2003b). This way, the query servers provided by different vendors will be allowed to provide different, well-defined subsets of the standardized MPEG-7 query format functionality.

CONCLUSION

We have presented in this chapter the state of the art in semantic multimedia content retrieval and filtering and pointed out the limitations of the existing systems. Then, we introduced the MPEG-7 Query Language (MP7QL), a powerful query language that we have developed for querying MPEG-7 descriptions and its compatible FASP model. Finally, we presented the future trends in semantic multimedia retrieval and filtering.

KEY TERMS

Interoperability: The capability of different systems and services, possibly developed in different platforms and/or offered by different vendors to correctly work together, interact and make use of each other in an open environment.

MPEG-7: The MPEG-7, formally known as the Multimedia Content Description Interface, is the dominant standard in multimedia content description that allows the description of (segments of) multimedia objects from several points of view, including media information, creation information, structure, usage information, textual annotations, media semantics, and low-level visual and audio features.

MPEG-7 Filtering and Search Preferences (FASP): The part of the MPEG-7 user preferences that allows the users to specify their preferences regarding multimedia content retrieval and filtering

Ontology: A logical theory accounting for the intended meaning of a formal vocabulary, i.e. its ontological commitment to a particular conceptualization of the world.

Semantic Multimedia Filtering: Multimedia content filtering based on the user preferences on the semantics of the multimedia content.

Semantic Multimedia Retrieval: Multimedia content retrieval based on the semantics of the multimedia content.

User Preferences: Description of the preferences of the user regarding the consumption of multimedia content and the adaptation of the services accessed. The user preferences may be explicitly set by the user or computed based on his/her background and/or usage history.

Semi-Structured Document Classification

Ludovic Denoyer
University of Paris VI, France

Patrick Gallinari
University of Paris VI, France

INTRODUCTION

Document classification developed over the last ten years, using techniques originating from the pattern recognition and machine learning communities. All these methods do operate on flat text representations where word occurrences are considered independents. The recent paper (Sebastiani, 2002) gives a very good survey on textual document classification. With the development of structured textual and multimedia documents, and with the increasing importance of structured document formats like XML, the document nature is changing. Structured documents usually have a much richer representation than flat ones. They have a logical structure. They are often composed of heterogeneous information sources (e.g. text, image, video, metadata, etc). Another major change with structured documents is the possibility to access document elements or fragments. The development of classifiers for structured content is a new challenge for the machine learning and IR communities. A classifier for structured documents should be able to make use of the different content information sources present in an XML document and to classify both full documents and document parts. It should easily adapt to a variety of different sources (e.g. to different Document Type Definitions). It should be able to scale with large document collections.

BACKGROUND

Handling structured documents for different IR tasks is a new domain which has recently attracted an increasing attention. Most of the work in this new area has concentrated on ad hoc retrieval. Recent Sigir workshops (2000, 2002 and 2004) and journal issues (Baeza-Yates et al., 2002; Campos et. al., 2004) where dedicated to this subject. Most teams involved in this research gather around the recent initiative for the development and the evaluation of XML IR systems (INEX) which has been launched in 2002. Besides this mainstream of research, some work is also developing around other generic IR problems like clustering and classification for structured documents. Clustering has mainly been dealt with in the database community, focusing on structure clustering and ignoring the document content (Termier et al., 2002; Zaki and Aggarwal, 2003). Structured document classification the focus of this paper is discussed in greater length below.

Most papers dealing with structured documents classification propose to combine flat text classifiers operating on distinct document elements in order to classify the whole document. This has mainly been developed for the categorization of HTML pages. (Yang et al., 2002) combine three classifiers operating respectively on the textual information of a page, on titles and hyperlinks. (Cline, 1999) maps a structured document onto a fixed-size vector where each structural entity (title, links, text etc...) is encoded into a specific part of the vector. (Dumais and Chen, 2000) make use of the HTML tags information to select the most relevant part of each document. (Chakrabarti et al., 1998) use the information contained in neighboring documents of an HTML pages. All these methods explicitly rely on the HTML tag semantic, i.e.. they need to "know" whether tags correspond to a title, a link, a reference, etc. They cannot adapt to more general structured categorization tasks. Most models rely on a vectorial description of the document and do not offer a natural way for dealing with document fragments. Our model is not dependent of the semantic of the tags and is able to learn which parts of a document are relevant for the classification task.

A second family of models uses more principled approaches for structured documents. (Yi and Sundaresan, 2000) develop a probabilistic model for tree

like document classification. This model makes use of local word frequencies specific of each node so that it faces a very severe estimation problem for these local probabilities. (Diligenti et al., 2001) propose the Hidden Tree Markov Model (HTMM) which is an extension of HMMs to tree like structures. They performed tests on the WebKB collection showing a slight improvement over Naive Bayes (1%). Outside the field of Information Retrieval, some related models have also been proposed. The hierarchical HMM (Fine et al., 1998) (HHMM) is a generalization of HMMs where hidden nodes emit sequences instead of symbols for classical HMMs. The HHMM is aimed at discovering sub-structures in sequences instead of processing structured data.

Generative models have been used for flat document classification and clustering for a long time. Naive Bayes (Lewis, 1998) is one of the most used text classifier and different extensions have been proposed, e.g. (Koller and Sahami, 1997). Probabilistic models with latent variables have been used recently for text clustering, classification or mapping by different authors. (Vinokourov and Girolami, 2001; Cai and Hofmann, 2003). (Blei and Jordan, 2003) describe similar models for learning the correspondence between images or image regions and image captions. All these models do not handle structured representations.

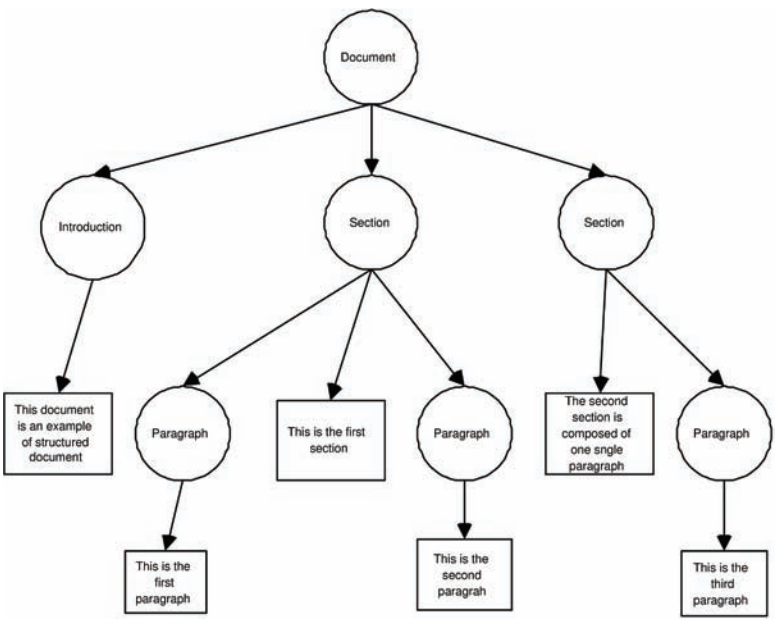
Finally, Bayesian networks have been used for the task of ad-hoc retrieval both for flat documents (Callan et al., 1992) and for structured documents (Myaeng et al., 1998; Piwowarski et al., 2002). This is different from classification since the information need is not specified in advance. The models and problems are therefore different from those discussed here.

MAIN THRUST

We describe a generative model for the classification of structured documents. Each document will be modeled by a Bayesian network. Classification will then amount to perform inference in this network. The model is able to take into account the structure of the document and different types of content information. It also allows one to perform inference either on whole documents or on document parts taken in their context, which goes beyond the capabilities of classical classifier schemes. The elements we consider are defined by the logical structure of the document. They typically correspond to the different components of an XML document.

In this chapter, we introduce structured documents and the core Bayesian network model. We then briefly summarize some experimental results and describe possible extensions of the model.

Figure 1. A tree representation for a structured document composed of an introduction and two sections. Circle and Square nodes are respectively structural and content nodes.



Structured Document

We will consider that a document is a tree where each node represents a structural entity. This corresponds to the usual representation of XML document. A node will contain two types of information:

- A label information which represents the type of the structural entity. A label could be for example *paragraph, section, introduction, title...* Labels depend on the documents corpora, for XML documents, they are usually defined in the DTD.
- A content information: for a multimedia document this could be text, image or signal. For a textual document node with label *paragraph*, the node content will be the paragraph text.

We will refer to structural and content nodes for these two types of information. Figure 1 gives an example for a simple textual document.

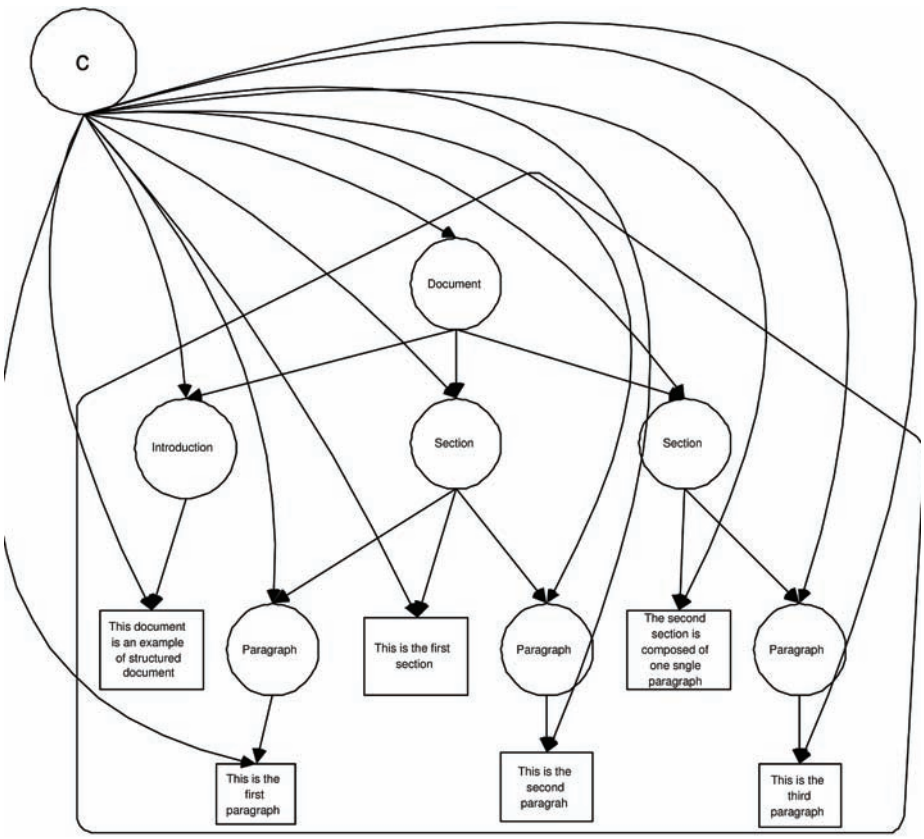
We will consider only textual documents here. Extensions for multimedia document are considered in (Denoyer et al., 2004a).

Modelling Documents with Bayesian Networks

Let us first introduce some notations:

- Let C be a discrete random variable which represents a class from the set of classes C.
- Let Λ be the set of all the possible labels for a structural node.
- Let V be the set of all possible words. denotes the set of all possible word sequences, including the empty one.
- Let d be a structured document consisting of a set of features where is the label of the i-th structural node of d (), is the textual content of this i-th node () and $|d|$ is the number of structural

Figure 2. A final bayesian network encoding «is a descendant of» relation



nodes. *d* is a realization of a random vector *D*. In the following, all nodes are supposed to have a unique identifier, indicated as superscript i.

Bayesian networks offer a suitable framework for modelling the dependencies and relations between the different elements in a structured document. We will associate a network model to each document. Since we focus here on the logical document structure, each network will be defined according to the corresponding document structure. For our classification task, the network parameters will be learned on all the documents from the same class in the training set. Documents from the same class will then share their parameters and there is one set of such parameters for each class.

Different networks could be used for modelling a document, depending on which type of relation we want to take into account. We consider here the explicit document structure and we will not try to uncover any hidden structure between the document elements. Some of the natural relations which could then be modelled are: "is a descendant of" in the document tree, "is a sibling of", "is a successor of" -given a preorder visit of the document tree-, and combinations of these different possibilities. Tests we performed using different types of relations and models of different complexity did not show a clear superiority of one model over the others with respect to classification performances. For simplifying the description, we will then consider tree like Bayesian networks. The network structure is built from the document tree, but need not be identical to this tree. Note that this is not limitative and all the derivations in the paper can be easily extended to BNs with no cycles. Figures 2 show a simple BN which encodes the "is a descendant of" relation and whose structure is similar to the document tree structure.

A Tree-Like model for Structured Document Classification

For this model, we make the following assumptions:

- There are two types of variables corresponding to structure and content nodes.
- Each structure node may have zero or many structure sub-nodes and zero or one content node.
- Each feature of the document depends on the class *c* we are interested in.
- Each structural variable depends on its parent in the document network.
- Each content variable depends only on its structural variable.

The generative process for the model corresponds to a recursive application of the following process: at each structural node *s*, one chooses a number of structural sub-nodes, which could be zero, and the length of the textual part if any. Sub-nodes labels and words are then sampled from their respective distribution which depends on *s* and the document class. The document depth could be another parameter of the model. Document length and depth distributions are omitted in our model since the corresponding terms fall out for the classification problems considered here.

Using such a network, we can write the joint content and structure probability:

$$P(d,c) = P(c)\underbrace{\left(\prod_{i=1}^{|d|} P(s_d^i \mid pa(s_d^i),c)\right)}_{(a)}\underbrace{\left(\prod_{i=1}^{|d|} P(t_d^i \mid s_d^i,c)\right)}_{(b)} \quad (1)$$

where (a) and (b) respectively correspond to **structural** and **textual probabilities.**

Structural probabilities can be directly estimated from data using some smooth estimator.

Since is defined on the infinite set , we shall make additional hypothesis for estimating the textual probabilities . In the following, we use a Naive Bayes model for text fragments. This is not a major option and other models could do as well. Let us define as the sequence of words where k and is the number of word occurrences i.e. the length of . Using Naive Bayes for the textual probability, the joint probability for this model is then:

$$P(d,c) = P(c)\left(\prod_{i=1}^{|d|} P(s_d^i \,|\, pa(s_d^i),c)\right)\left(\prod_{i=1}^{|d|}\prod_{k=1}^{|t_d^i|} P(w_{d,k}^i \,|\, s_d^i,c)\right) \quad (2)$$

Figure 3. The final document sub-net. In the full Bayesian network, all nodes also have node c for parent.

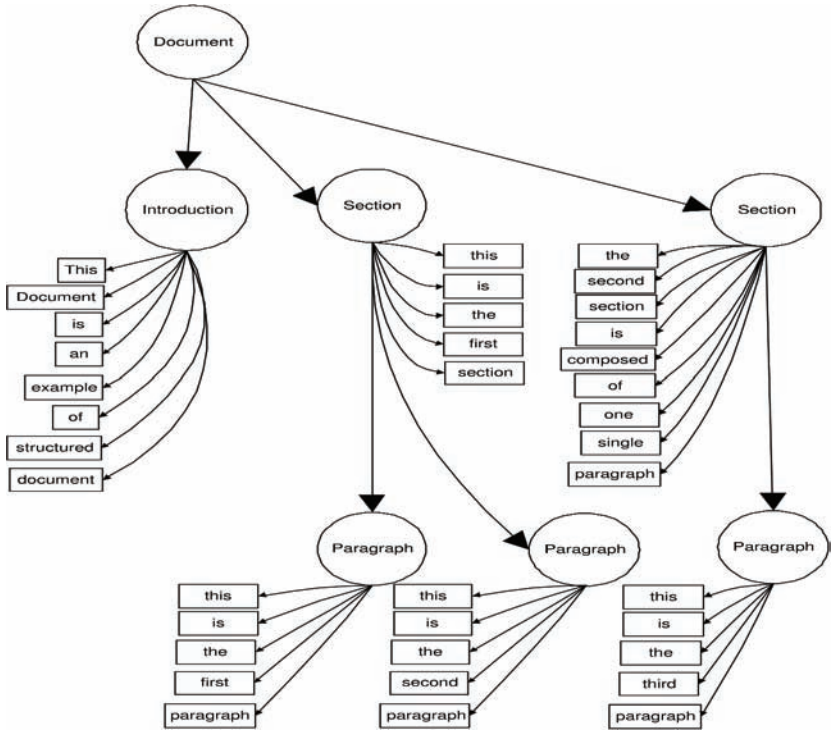


Figure 3 shows the final belief network obtained for the document in Figure 1. For clarity, the class variable is omitted.

Classifying Document Parts

Suppose now that *d* is a large heterogeneous document and that fragments of *d* correspond to different predefined classes. We could be interested into classifying any sub-part *d*' of *d* into one of these classes. If *d*' corresponds to a subtree of *d* and if we consider *d*' out of any context, we simply use Equation (2), replacing *d* with *d*'. We could also be interested into classifying *d*' within the context of document *d*. For this, we need to compute $P(d', c \mid d_{d'})$, where $d_{d'}$ represents *d* with *d*' removed. Let *s*' the structural node which is the father of *d*' root node. We get $P(d', c \mid d_{d'}) = P(d', c \mid s')$, which can be estimated via:

$$P(d', c \mid s') = P(c)\left(\prod_{i=k'}^{|d'|+k'} P(s_d^i \mid pa(s_d^i), c)\right)\left(\prod_{i=k'}^{|d'|+k'} \prod_{k=1}^{|t_d^i|} P(w_{d,k}^i \mid s_d^i, c)\right) \quad (3)$$

where *k*' is the index for the root of *d*' and structure nodes are supposed ordered according to a pre-order traversal of the tree. The interesting thing here is that by computing *P*(*d*,*c*), one automatically gets $P(d', c \mid d_{d'})$ since both quantities make use of the same probabilities and probability estimates. If *d*' does correspond to a partial sub-tree of *d* instead of a full sub-tree or to different subtrees in *d* one gets a similar expression by limiting the structure and content terms in the products in Equation (3) to those in *d*'. Classifying *d*' fragments is then easily performed with this generative classifier. This compositionality property (carrying out global computations by combining local ones) is achieved in this model via the probabilistic conditional independence assumptions. Compositionality is an important property for structured document classification. It is usually not shared by discriminant classifiers. Training discriminant classifiers both on document fragments might be prohibitive when the number of fragment is large e.g. the INEX corpus has about 16 K documents and 8 M fragments.

Learning

In order to estimate the joint probability of each document and each class, the parameters must be learned from a training set of documents. Let us define the θ parameters as:

$$\theta = \bigcup \left(\bigcup_{n\in\Lambda, m\in\Lambda} \theta_{n,m}^{c,s} \bigcup_{n\in V, m\in\Lambda} \theta_{n,m}^{c,w} \right) \quad (4)$$

where $_{s;n,m}$ is the estimation for and $_{w;n,m}$ is the estimation for . *s* in $_{s;.,.}$ indicates a structural parameter and *w* in $_{w;.,.}$ a textual parameter. There is one such set of parameter for each class.

For learning the θ*s* using the set of training documents *TRAIN*, we will maximize the log-likelihood *L* for *TRAIN* :

$$L = \sum_{d\in D_{TRAIN}} \log P(c) + \left(\sum_{i=1}^{|d|} \log \theta_{s_d^i, pa(s_d^i)}^{c,s} \right) + \left(\sum_{i=1}^{|d|} \sum_{k=1}^{t_d^i} \log \theta_{w_{d,k}, s_d^i}^{c,w} \right) \quad (5)$$

The learning algorithm solves for each parameter $_{.;n,m}$ (“.” corresponds to *s* or *w*) the following equation:

$_{.;n,m}$ under constraints :

$$\forall m \in \Lambda, \sum_{n\in\Lambda} \theta_{n,m}^{c,s} = 1$$
$$\forall m \in \Lambda, \sum_{n\in V} \theta_{n,m}^{c,w} = 1 \quad (6)$$

This equation has an analytical solution (Denoyer and Gallinari, 2004a).

In summary, this generative classifier can cope with both content and structure information. It allows one to perform inference on the different nodes and subtrees of the network. Document parts can then be classified in the context of the whole document. More generally decisions can be made by taking into account only a subpart of the document or when information is missing in the document.

(Denoyer and Gallinari, 2004a) describe how this model can take into account multimedia documents (text and image) and show how to extend it into a dicriminant classifier using the formalism of Fisher Kernels.

EXPERIMENTS

(Denoyer and Gallinari, 2004 a) describe experiments on three medium size corpus: INEX (about 15,000 scientic articles in XML,18 classes which correspond to journals), webKB (4520 HTML pages, 6 classes), NetProtect (19652 HTMLS pages with text and image, 2 classes). The BN model scales well on these corpus and outperforms Naïve Bayes with improvements ranging from 2% up to 6% (macro-average and micro-average recall) for whole document classification. These experiments validate experimentally the model and show the importance of taking into account both content and structure for classifying structured documents, even for the basic whole document classification tasks. The model also performs well for document fragment classification.

FUTURE TRENDS

We have presented a generative model for structured document. It is based on Bayesian networks and allows one to model the structure and the content of documents. Tests show that the model behaves well on a variety of situations. Further investigations are needed for analyzing its behavior on document fragments classification. The model could also be modified for learning implicit relations between document elements besides using the explicit structure so that the BN structure itself is learned. An interesting aspect of the generative model is that it could be used for other tasks relevant to IR. It could serve as a basis for clustering structured documents. The natural solution is to consider a mixture of Bayesian networks models where parameters do depend on the mixture component instead of the class as it is the case here. Two other important problems are Schema-mapping and automatic document structuring. These new tasks are currently being investigated in the database and IR communities. The potential of the model for performing inference on document parts when information is missing in the document will be helpful for this type of application. Preliminaries experiments about automatic structuration of documents are described in (Denoyer et al., 2004b).

KEY TERMS

XML (**Extensible Markup Language**): A W3C recommendation for creating special-purpose markup languages. It is a simplified subset of SGML, capable of describing many different kinds of data. Its primary

purpose is to facilitate the sharing of structured text and information across the Internet.

A Bayesian Network: A directed acyclic graph of nodes representing variables and arcs representing dependence relations among the variables.

Machine Learning: An area of artificial intelligence involving developing techniques to allow computers to "learn". More specifically, machine learning is a method for creating computer programs by the analysis of data sets, rather than the intuition of engineers.

Information Retrieval (IR): The art and science of searching for information in documents, searching for documents themselves, searching for metadata which describes documents, or searching within databases, whether relational stand alone databases or hypertext networked databases such as the Internet or intranets, for text, sound, images or data.

Multimedia: Data combining several different media, such as text, images, sound and video.

Probabilistic Model: A classic model of document retrieval based on a probabilistic interpretation of document relevance (to a given user query).

Semi-Structured Data: Data whose structure may not match, or only partially match, the structure prescribed by the data schema

Semi-Supervised Learning

Tobias Scheffer
Humboldt-Universität zu Berlin, Germany

INTRODUCTION

For many classification problems, unlabeled training data are inexpensive and readily available, whereas labeling training data imposes costs. Semi-supervised classification algorithms aim at utilizing information contained in unlabeled data in addition to the (few) labeled data.

Semi-supervised (for an example, see Seeger, 2001) has a long tradition in statistics (Cooper & Freeman, 1970); much early work has focused on Bayesian discrimination of Gaussians. The Expectation Maximization (EM) algorithm (Dempster, Laird, & Rubin, 1977) is the most popular method for learning generative models from labeled and unlabeled data. Model-based, generative learning algorithms find model parameters (e.g., the parameters of a Gaussian mixture model) that best explain the available labeled and unlabeled data, and they derive the discriminating classification hypothesis from this model.

In discriminative learning, unlabeled data is typically incorporated via the integration of some model assumption into the discriminative framework (Miller & Uyar, 1997; Titterington, Smith, & Makov, 1985). The Transductive Support Vector Machine (Vapnik, 1998; Joachims, 1999) uses unlabeled data to identify a hyperplane that has a large distance not only from the labeled data but also from all unlabeled data. This identification results in a bias toward placing the hyperplane in regions of low density $p(x)$. Recently, studies have covered graph-based approaches that rely on the assumption that neighboring instances are more likely to belong to the same class than remote instances (Blum & Chawla, 2001).

A distinct approach to utilizing unlabeled data has been proposed by de Sa (1994), Yarowsky (1995) and Blum and Mitchell (1998). When the available attributes can be split into *independent* and *compatible* subsets, then *multi-view learning* algorithms can be employed. Multi-view algorithms, such as co-training (Blum & Mitchell, 1998) and co-EM (Nigam & Ghani, 2000), learn two independent hypotheses, which bootstrap by providing each other with labels for the unlabeled data.

An analysis of why training two independent hypotheses that provide each other with conjectured class labels for unlabeled data might be better than EM-like self-training has been provided by Dasgupta, Littman, and McAllester (2001) and has been simplified by Abney (2002). The disagreement rate of two independent hypotheses is an upper bound on the error rate of either hypothesis. Multi-view algorithms minimize the disagreement rate between the peer hypotheses (a situation that is most apparent for the algorithm of Collins & Singer, 1999) and thereby the error rate.

Semi-supervised learning is related to active learning. *Active learning* algorithms are able to actively query the class labels of unlabeled data. By contrast, semi-supervised algorithms are bound to learn from the given data.

BACKGROUND

Semi-supervised classification algorithms receive both labeled data $D_l = (x_1, y_1),..., (x_{m_l}, y_{m_l})$ and unlabeled data $D_u = x^u_1,..., x^u_{m_u}$ and return a classifier $f : x \rightarrow y$; the unlabeled data is generally assumed to be governed by an underlying distribution $p(x)$, and the labeled data by $p(x,y) = p(y \mid x)\ p(x)$. Typically, the goal is to find a classifierthat minimizes the error rate with respect to $p(x)$.

In the following sections, we distinguish between *model-based* approaches, mixtures of *model-based and discriminative* techniques, and *multi-view learning*. Model-based approaches can directly utilize unlabeled data to estimate $p(x, y)$ more accurately. Discriminative classification techniques need to be augmented with some model-based component to make effective use of unlabeled data. Multi-view learning can be applied

when the attributes can be split into two independent and compatible subsets.

Model-Based Semi-Supervised Classification

Model-based classification algorithms assume that the data be generated by a parametric mixture model $p(x, y \mid \Theta)$and that each mixture component contains only data belonging to a single class. Under this assumption, in principle, only one labeled example per mixture component is required (in addition to unlabeled data) to learn an accurate classifier. Estimating the parameter vector Θ from the data leads to a *generative* model; that is, the model $p(x, y \mid \Theta)$ can be used to draw new labeled data.

In the context of classification, the main purpose of the model is *discrimination.* Given the model parameter, the corresponding classifier is $f_\Theta(x) = \arg\max_y p(x, y \mid \Theta)$. For instance, when $p(x, y \mid \Theta)$ is a mixture of Gaussians with equal covariance matrices, then the discriminator $f_\Theta(x)$ is a linear function; in the general Gaussian case, $f_\Theta(x)$ is a second-order polynomial. The Expectation Maximization (EM) algorithm (Dempster et al., 1977) provides a general framework for semi-supervised model-based learning — that is, for finding model parameters Θ. Semi-supervised learning with EM is sketched in Table 1; after initializing the model by learning from the labeled data, it iterates two steps. In the E-step, the algorithm calculates the class probabilities for the unlabeled data based on the current model. In the M-step, the algorithm estimates a new set of model parameters from the labeled and the originally unlabeled data for which probabilistic labels have been estimated in the E-step.

The EM algorithm, which is a greedy method for maximizing the likelihood $p(D_l, D_u \mid \Theta) = p(D_l \mid \Theta)\, p(D_u \mid \Theta)$ of the data, has three caveats. The first is that no obvious connection exists between the *maximum likelihood* model parameters Θ and the Bayesian discriminator that minimizes the conditional risk given a new instance x. Practical semi-supervised learning algorithms apply some form of regularization to approximate the *maximum a posteriori* rather than the *maximum likelihood* parameters. The second caveat is that the resulting parameters are a *local* but not necessarily the *global* maximum. The third caveat of semi-supervised learning with EM is more subtle: When the assumed parametric model is *correct* — that is, the data has, in fact, been generated by $p(x, y \mid \Theta)$for some Θ— then the idea is arguable that unlabeled data will improve the accuracy of the resulting classifier $f_\Theta(x)$ under fairly reasonable assumptions (Zhang & Oles, 2000; Cozman, Cohen, & Cirelo, 2003). However, as Cozman et al. have pointed out, the situation is different when the model assumption is *incorrect* — that is, no Θ exists such that $p(x, y \mid \Theta)$ equals the true probability $p(x, y)$, which governs the data. In this case, the best approximation to the labeled data — $\Theta_l = \arg\max_\Theta p(D_l, \mid \Theta)$ — can be a much better classifier f_{Θ_l}than $f_\Theta(x)$ with $\Theta = \arg\max_\Theta p(D_l, D_u \mid \Theta)$, which approximates the labeled and unlabeled data. In other words, when the model assumption is incorrect, then semi-supervised learning with EM can generally result in poorer classifiers than supervised learning from only the labeled data.

Semi-supervised learning with EM has been employed with many underlying models and for many applications, including mixtures of Gaussians and naïve Bayesian text classification (Nigam, McCallum, Thrun, & Mitchell, 2000).

Table 1. Semi-supervised classification with EM.

Input: labeled data $D_l = (x_1, y_1), \ldots, (x_{m_l}, y_{m_l})$; unlabeled $D_u = x^u_1, \ldots, x^u_{m_u}$.
Initialize model parameters Θ by learning from the labeled data.
Repeat until a local optimum of the likelihood $p(x, y \mid \Theta)$ is reached.
E-step: For all unlabeled data x^u_i and class labels y, calculate
$E(f(x^u_1) = y \mid \Theta)$, the expected probability that y is the class of x^u_1 given Θ; that is, use $p(y \mid x, \Theta)$ to probabilistically label the x^u_i.
M-step: Calculate the maximum likelihood parameters
Θ = arg max $p(D_l, D_u$ estimated class probabilities for $Du)$; that is, learn from the labeled and probabilistically labeled unlabeled data.
Return classifier $p(y \mid x, \Theta)$.

Mixtures of Discriminative and Model-Based Learning

The answer to the question of how to utilize unlabeled data in the context of discriminative learning is not obvious. Discriminative learners, such as decision trees, logistic regression, or the Support Vector Machine, directly learn a classifier $y = f(x)$ without taking the detour via a generative model $p(x, y \mid \Theta)$. This classifier contains some information about the posterior $p(y \mid x)$ but does not contain a model of $p(x)$ that could be refined by unlabeled data. Some approaches that mix generative and discriminative models have been studied and use the unlabeled data to tweak their models of the class-conditional likelihood or the mixing probabilities (Miller & Uyar, 1997).

A special model assumption on the class-conditional likelihood $p(x \mid y)$underlies graph-based algorithms. It is often reasonable to assume that similar instances are more likely to have identical class labels than remote instances; clearly, the concept of similarity is very domain specific. In this situation, instances and similarities can be encoded in a graph, and mincuts of that graph correspond to optimal labelings of the unlabeled data (Blum & Chawla, 2001; Zhu, Gharamani, & Lafferty, 2003; Joachims, 2003).

The Transductive Support Vector Machine (Vapnik, 1998; Joachims, 1999) uses unlabeled data to identify a hyperplane that has a large distance not only from the labeled data but also from all unlabeled data. This identification is achieved by a greedy procedure that conjectures class labels for the unlabeled data and then iteratively flips the pair of conjectured class labels that yields the greatest improvement of the optimization criterion. After each flip of class labels, the hyperplane has to be retrained. This procedure results in a bias toward placing the hyperplane in regions of low density $p(x)$, where few instances result in small sums of the slack x_1 terms .

Multi-View Learning

Multi-view learning is a semi-supervised learning paradigm that is fundamentally different from model-based semi-supervised learning. Multi-view algorithms require the available attributes to be split into two independent subsets, or views, and either view has to be sufficient for learning the target concept. I discuss multi-view learning in the following section. The multi-view approach has also been applied to *active* learning (Muslea, Kloblock, & Minton, 2002).

MAIN THRUST

In this section, I discuss the multi-view framework of semi-supervised learning. In particular, I show that multi-view learning can, in a fundamentally different way, improve classification results over supervised learning, and I review some multi-view algorithms.

Multi-view learning applies when the available attributes can be decomposed into two views V_1 and V_2. For instance, V_1 can be the bag-of-words representation of a Web page, whereas V_2 might consist of the inbound hyperlinks referring to the page. Multi-view algorithms require that either view be *sufficient* for learning — that is, there exist functions f_1 and f_2 such that for all x, $f_1(x_1) = f_2(x_2) = f(x)$, where f is the true target function. This rule is also called the *compatibility* assumption. In addition, the views have to be conditionally independent given the class label — that is, $P(x_1, x_2 \mid y) = P(x_1 \mid y)\, P(x_2 \mid y)$.

In these independent views, independent classifiers f_1 and f_2 can be trained. Now Abney (2002) has observed the following: For an unlabeled instance x, you cannot decide whether $f_1(x)$ and $f_2(x)$ are correct or incorrect, but you can decide whether they agree or disagree. You can reasonably assume that either hypothesis has an error probability of no more than ½. For any given instance x with true class y, the probability of a disagreement is then an upper bound on the probability that either hypothesis misclassifies x. This can be shown by the following equations, which first utilize the independence, followed by the assumption that the error is at most ½, and finally the independence again.

This observation motivates the strategy that multi-view algorithms follow: minimize the error on the labeled data, and minimize the disagreement of the two

$$
\begin{aligned}
&P(f_1(x) \neq f_2(x)) \\
&= P(f_1(x) = y, f_2(x) = \overline{y}) + P(f_1(x) = \overline{y}, f_2(x) = y) \\
&\geq \max_i P(f_i(x) = y, f_i(x) = \overline{y}) + P(f_i(x) = \overline{y}, f_i(x) = y) \\
&= \max_i P(f_i(x) \neq y)
\end{aligned}
$$

independent hypotheses on the unlabeled data. Even though the error itself cannot be minimized on unlabeled data due to the absence of labels, by minimizing the disagreement on the unlabeled data, multi-view algorithms minimize an upper bound on the error. The most prominent learning algorithms that utilize this principle are co-training and co-EM, displayed in Table 2. Co-training can be wrapped around any learning algorithm with the ability to provide a confidence score for the classification of an instance. Here, two hypotheses bootstrap by providing each other with labels for the unlabeled examples that they are most confident about.

Co-EM, the multi-view counterpart of semi-supervised learning with EM, requires the base learner to be able to infer class label probabilities for the unlabeled data. In addition, a model has to be learned from conjectured class probabilities for the originally unlabeled data in addition to the labeled data. Because of these requirements, co-EM has frequently been applied with naïve Bayes as an underlying learner (for an example, see Nigam & Ghani, 1999). Recently, Brefeld and Scheffer (2004) studied a co-EM version of the Support Vector Machine; it transforms the uncalibrated decision function values into normalized probabilities and maps these probabilities to example-specific costs, which are used as weights for the error terms x_i in the optimization criterion. Co-EM is more effective than co-training, provided that the independence of the views is not violated (Muslea et al., 2002; Brefeld & Scheffer, 2004).

Multi-view algorithms require the views to be independent; this assumption will often be violated in practice. Muslea et al. (2002) has observed that co-EM, especially, is detrimental to the performance when dependence between attributes is introduced. Brefeld & Scheffer (2004) have observed co-training to be more robust against violations of the independence assumptions than co-EM; Krogel & Scheffer (2004) found even co-training to deteriorate the performance of SVMs for the prediction of gene functions and localizations. This discovery raises the questions of how dependence between views can be quantified and measured and which degree of dependence is tolerable for multi-view algorithms.

It is not possible to measure whether two large sets of continuous attributes are independent. The proof of Abney (2002) is based on the assumption that the two classifiers err independently; you can measure the violation of this assumption as follows Let E_1 and E_2 be two random variables that indicate whether f_1 and

Table 2. Semi-supervised classification with co-training and co-EM

Input: labeled data $D_l = (x_1, y_1),..., (x_{m_l}, y_{m_l})$; unlabeled data $D_u = x^u_1,..., x^u_{m_u}$, attributes are split into two views V_1 and V_2.
Algorithm Co-Training:
For $v = 1..2$: Learn initial classifier f_v from labeled data D_l in view v.
Repeat until D_u is empty.
  For $v = 1..2$: find the examples that f_v most confidently rates positive and negative, remove them from D_u and add them to D_l, labeled positive and negative, respectively.
For $v = 1..2$: learn new classifier f_v from labeled data D_l in view v .

Algorithm Co-EM:
Learn parameters Θ_2 of initial classifier $f_{(\Theta,2)}$ from labeled data D_l in view 2.
Repeat for T iterations.
  For $v = 1..2$:
    M-Step: Estimate class probabilities $p_v(y \mid x, \Theta_{\bar{v}})$ of unlabeled data using the model $\Theta_{\bar{v}}$ in the complementary view v.
    E-Step: Learn parameters Θ_v in current view from labeled data D_l and unlabeled data D_u with class probabilities $p_v(y \mid x, \Theta_{\bar{v}})$.

Both algorithms return confidence weighted hypothesis $\frac{1}{2}(f_{(\Theta,1)} + f_{(\Theta,2)})$.

f_2 make an error for a given instance. The *correlation coefficient* of these random variables is defined as

$$\Phi^2 = \frac{\sum_{i=0}^{1}\sum_{j=0}^{1}(P(E_1=i,E_2=j)-P(E_1=i)P(E_2=j))^2}{P(E_1=i)P(E_2=j)}$$

which quantifies whether these events occur independently — in this case, $\Phi^2 = 0$ — or are dependent. In the most extreme case, when the two hypotheses always err at the same time, then $\Phi^2 = 1$. In experiments with gene function prediction and text classification problems, Krogel & Scheffer (2004) have found a clearly negative relationship between the benefit of co-training for a given problem and the error correlation coefficient Φ^2 of the initial classifiers. When the initial classifiers are correlated, for example,with $\Phi^2 \geq 0.3$, then co-training will often deteriorate the classification result instead of improving it.

FUTURE TRENDS

In knowledge discovery and machine learning, one is often interested in discriminative learning. Generative models allow you to easily incorporate unlabeled data into the learning process via the EM algorithm, but model-based learners optimize the wrong utility criterion when the goal is really discriminative learning (for example, see Cozman et al., 2003). Graph-based approaches (Blum & Chawla, 2001) allow the utilization of unlabeled data for discriminative learning, under the mild model assumption that instances with identical classes are more likely to be neighbors than instances with distinct classes. This idea is currently being investigated for a range of applications (Joachims, 2003; Zhu et al., 2003; Blum, Lafferty, Reddy, & Rwebangira, 2004).

The principle of minimizing the disagreement of independent hypothesis is a simple yet powerful mechanism that allows minimization of an upper bound on the error by using only unlabeled data. Exploiting this principle for additional learning tasks such as clustering (Bickel & Scheffer, 2004; Kailing, Kriegel, Pryakhin, & Schubert, 2004), and by more effective algorithms, is a principal challenge that will lead to more powerful and broadly applicable semi-supervised learning algorithms. Algorithms that automatically analyze attribute interactions (Jakulin & Bratko, 2004) will possibly extend the scope of multi-view learning applicable to learning problems for which independent attribute sets are not available a priori.

CONCLUSION

The Expectation Maximization algorithm provides a framework for incorporating unlabeled data into model-based learning. However, the model that maximizes the joint likelihood of labeled and unlabeled data can, in principle, be a worse discriminator than a model that was trained only on labeled data. Mincut algorithms allow the utilization of unlabeled data in discriminative learning; similar to the transductive SVM, only mild assumptions on $p(x \mid y)$ are made.

The multi-view framework provides a simple yet powerful mechanism for utilizing unlabeled data: The disagreement of two independent hypotheses upper bounds the error — it can be minimized with only unlabeled data. A prerequisite of multi-view learning is two independent views; the dependence of views can be quantified and measured by the error correlation coefficient. A small correlation coefficient corresponds to a great expected benefit of multi-view learning. The co-EM algorithm is the most effective multi-view algorithm when the views are independent; co-training is more robust against violations of this independence. Only when dependencies are strong is multi-view learning detrimental.

KEY TERMS

Compatibility: Views V_1 and V_2 are compatible if there exist functions f_1 and f_2 such that for a11 x, $f_1(x_1) = f_2(x_2) = f(x)$ where f is the true target function.

Independence: Views V_1 and V_2 are conditionally independent given the class if for all $x = (x_1,x_2)$, $P(x_1,x_2 | y) = P(x_1 | y)\, P(x_2 | y)$.

Labeled Data: A sequence of training instances with corresponding class labels, where the class label is the value to be predicted by the hypothesis.

Multi-View Learning: A family of semi-supervised or unsupervised learning algorithms that can be applied when instances are represented by two sets of features, provided that these sets are conditionally independent given the class and that either set suffices to learn the target concept. By minimizing the disagreement between two independent classifiers, multi-view algorithms minimize an upper bound on the error rate that can be determined without reference to labeled data.

Semi-Supervised Classification: The task of learning a mapping from instances to one of finitely many class labels, coming from labeled data consisting of a sequence of instance-class pairs and unlabeled data consisting of just a sequence of instances.

Supervised Learning: The task of learning a mapping from instances to function values (possibly class labels) from a sequence of pairs of instances and function values.

Unlabeled Data: A sequence of training instances without corresponding class labels.

Unsupervised Learning: The task of learning a model that describes a given data set where the attribute of interest is not available in the data. Often, the model is a mixture model, and the mixture component, from which each instance has been drawn, is not visible in the data.

View: In multi-view learning, the available attributes are partitioned into two disjoint subsets, or views, which are required to be *independent* and *compatible.*

Sentiment Analysis of Product Reviews

Cane W. K. Leung
The Hong Kong Polytechnic University, Hong Kong SAR

Stephen C. F. Chan
The Hong Kong Polytechnic University, Hong Kong SAR

INTRODUCTION

Sentiment analysis is a kind of text classification that classifies texts based on the *sentimental orientation* (SO) of opinions they contain. Sentiment analysis of product reviews has recently become very popular in text mining and computational linguistics research. The following example provides an overall idea of the challenge. The sentences below are extracted from a movie review on the Internet Movie Database:

"It is quite boring..... the acting is brilliant, especially Massimo Troisi."

In the example, the author stated that "it" (the movie) is quite boring but the acting is brilliant. Understanding such sentiments involves several tasks. Firstly, evaluative terms expressing opinions must be extracted from the review. Secondly, the SO, or the polarity, of the opinions must be determined. For instance, "boring" and "brilliant" respectively carry a negative and a positive opinion. Thirdly, the opinion strength, or the intensity, of an opinion should also be determined. For instance, both "brilliant" and "good" indicate positive opinions, but "brilliant" obviously implies a stronger preference. Finally, the review is classified with respect to sentiment classes, such as *Positive* and *Negative*, based on the SO of the opinions it contains.

BACKGROUND

Sentiment analysis is also known as opinion mining, opinion extraction and affects analysis in the literature. Further, the terms *sentiment analysis* and *sentiment classification* have sometimes been used interchangeably. It is useful, however, to distinguish between two subtly different concepts. In this article, hence, sentiment analysis is defined as a complete process of extracting and understanding the sentiments being expressed in text documents, whereas sentiment classification is the task of assigning class labels to the documents, or segments of the documents, to indicate their SO.

Sentiment analysis can be conducted at various levels. Word level analysis determines the SO of an opinion word or a phrase (Kamps et al., 2004; Kim and Hovy, 2004; Takamura and Inui, 2007). Sentence level and document level analyses determine the dominant or overall SO of a sentence and a document respectively (Hu and Liu, 2004a; Leung et al., 2008). The main essence of such analyses is that a sentence or a document may contain a mixture of positive and negative opinions. Some existing work involves analysis at different levels. Specifically, the SO of opinion words or phrases can be aggregated to determine the overall SO of a sentence (Hu and Liu, 2004a) or that of a review (Turney, 2002; Dave et al., 2003; Leung et al., 2008).

Most existing sentiment analysis algorithms were designed for binary classification, meaning that they assign opinions or reviews to bipolar classes such as *Positive* or *Negative* (Turney, 2002; Pang et al., 2002; Dave et al., 2003). Some recently proposed algorithms extend binary sentiment classification to classify reviews with respect to multi-point rating scales, a problem known as *rating inference* (Pang and Lee, 2005; Goldberg and Zhu, 2006; Leung et al., 2008). Rating inference can be viewed as a multi-category classification problem, in which the class labels are scalar ratings such as 1 to 5 "stars".

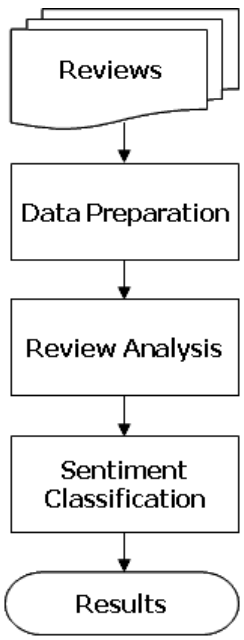
Some sentiment analysis algorithms aim at summarizing the opinions expressed in reviews towards a given product or its features (Hu and Liu, 2004a; Gamon et al., 2005). Note that such *sentiment summarization* also involves the classification of opinions according to their SO as a subtask, and that it is different from classical document summarization, which is about identifying the key sentences in a document to summarize its major ideas.

Sentiment analysis is closely related to *subjectivity analysis* (Wiebe et al., 2001; Esuli and Sebastiani, 2005). Subjectivity analysis determines whether a given text is subjective or objective in nature. It has been addressed using two methods in sentiment analysis algorithms. The first method considers subjectivity analysis a binary classification problem, for example, using *Subjective* and *Objective* as class labels. Pang and Lee (2005) adopted this method to identify subjective sentences in movie reviews. The second method makes use of part-of-speech (POS) information about words to identify opinions (Turney, 2002; Hu and Liu, 2004a; Leung et al., 2008) as previous work on subjectivity analysis suggests that adjectives usually have strong and significant correlation with subjectivity (Bruce and Wiebe, 1999; Wiebe et al., 2001).

MAIN FOCUS

Figure 1 depicts a typical sentiment analysis model. The model takes a collection of reviews as input and processes them using three core steps, *Data Preparation*, *Review Analysis* and *Sentiment Classification*. The results produced by such a model are the classifications of the reviews, the evaluative sentences, or opinions expressed in the reviews.

Figure 1. A typical sentiment analysis model



Data Preparation

The data preparation step performs necessary data preprocessing and cleaning on the dataset for the subsequent analysis. Some commonly used preprocessing steps include removing non-textual contents, markup tags (for HTML pages) and other information that is not required for sentiment analysis, such as review dates and reviewers' names.

Data preparation may also involve the sampling of reviews for building a classifier. Positive reviews often predominate in review datasets as reported in several studies (e.g. Turney, 2002; Dave et al., 2003; Gamon et al., 2005). Some researchers therefore used review datasets with balanced class distributions when training classifiers to help demonstrate the performance of their algorithms (Pang et al., 2002; Leung et al., 2008).

Review Analysis

The review analysis step analyzes the linguistic features of reviews so that interesting information, including opinions and/or product features, can be identified. This step often applies various computational linguistics tasks to reviews first, and then extracts opinions and product features from the processed reviews. Two commonly adopted tasks for review analysis are POS tagging and negation tagging. POS tagging helps identifying interesting words or phrases having particular POS tags or patterns from reviews (Turney, 2002; Hu and Liu, 2004a; Leung et al., 2008), while negation tagging is used to address the contextual effect of negation words, such as "not", in a sentence (Pang et al., 2002; Dave et al., 2003; Leung et al., 2008). For example, "good" and "not good" obviously indicate opposite SO. Given the term "not good", negation tagging recognizes the existence of the word "not" and adds a special negation tag to the word "good" based on some heuristics.

The review analysis step then proceeds to extract opinions and/or product features from the processed reviews. The opinions or features extracted may be *n*-grams, which are *n* adjacent or nearby words in a sentence (e.g. Turney, 2002). Pang et al. (2002) make use of corpus statistics and human introspection to decide

terms that may appear in reviews. Various algorithms adopt a more common method that extracts words or phrases having particular POS tags or patterns as opinions and product features as noted (Turney, 2002; Dave et al., 2003; Takamura and Inui, 2007, Leung et al., 2008).

While Hu and Liu (2004b) also make use of POS tags, they adapted the idea of frequent itemsets discovery in association rule mining to product feature extraction. In the context of their work, an itemset is a set of words that occurs together, and a "transaction" contains nouns or noun phrases extracted from a sentence of a review. They used the CBA association rule miner (Liu et al., 1998) to mine frequent itemsets, and considered each resulting itemset to be a product feature. They then processed a review sentence by sentence. If a sentence contains a frequent feature, they extracted its nearby adjective as an opinion. They also proposed methods for pruning redundant features and for identifying infrequent features.

Sentiment Classification

There are two major approaches to sentiment classification, known as the *SO approach* and the *machine learning approach*. The following subsections describe the overall idea and representative techniques of each of the approaches.

SO Approach

The SO approach involves two subtasks. The first subtask is to determine the SO of the opinions extracted from reviews in the Review Analysis step, while the second subtask is to determine the overall SO of a sentence or a review based on the SO of the opinions it contains.

Turney (2002) proposed an unsupervised SO determination method that computes the SO of an opinion phrase as the Pointwise Mutual Information (PMI) between the phrase and two *seed adjectives*, "excellent" and "poor". Such information is collected using a generic search engine. Specifically, the phrase is likely to represent a positive (resp. negative) sentiment if it co-occurs frequently with the word "excellent" (resp. "poor"). The average of the SO of all opinion phrases in a review is computed, and the review is classified as *Positive* if the average is positive; and *Negative* otherwise.

Hu and Liu (2004a) presented a word-similarity-based algorithm that utilizes the semantical relationship between words to predict SO. Their bootstrapping algorithm depends on a small set of seed adjectives having known SO, such as "great" for *Positive* and "bad" for *Negative*, and automatically expands the set using the synonym and antonym sets in WordNet (Miller et al., 1990), assuming that *semantical similarity implies sentimental similarity*. Specifically, the SO of synonyms is assumed to be the same, whereas that of antonyms is opposite to each other. After predicting the SO of opinions, their algorithm classifies a sentence based on the dominant SO of the opinions in the sentence. Kamps et al. (2004) and Kim and Hovy (2004) also described word-similarity-based methods for determining SO, but their studies deal with word-level classification.

Leung et al. (2006b) suggest that semantical similarity may not imply sentimental similarity in sentiment analysis, based on statistical observations from a movie review corpus. They therefore proposed a relative-frequency-based method for determining the SO of an opinion. Their method estimates the SO and opinion strength of a word with respect to a sentiment class as its relative frequency of appearance in that class. For example, if the word "best" appeared 8 times in positive reviews and 2 times in negative reviews, its opinion strength with respect to *Positive* SO is then 8/(8+2) = 0.8. Leung et al. (2008) deals with the rating inference problem, which classifies reviews with respect to rating scales. They hypothesized that some product features may be more important for determining the rating of a review, and therefore assign weights to opinions according to the estimated importance of their associated product features. They compute the weighted average SO of opinions in a review, and then rate the review by mapping the weighted average onto an *n*-point rating scale.

Machine Learning Approach

The machine learning approach is similar to topic classification, with the topics being sentiment classes such as *Positive* and *Negative* (Pang et al., 2002). It works by breaking down a review into words or phrases, representing the review as a document vector (bag-of-words model), and then classifying the reviews based on the document vectors.

Pang et al. (2002) investigated whether binary sentiment classification can be addressed using standard topic classification techniques. They applied three classifiers, including Naïve Bayes, Support Vector Machines (SVM) and Maximum Entropy, to a movie review corpus. They also attempted to incorporate various features of the reviews into the standard bag-of-words model, such as the positions of words in the reviews, but the performance of the three classifiers was found inferior to those reported for topic classification. Pang and Lee concluded that sentiment classification is more difficult than topic classification, and that discourse analysis of reviews is necessary for more accurate sentiment analysis.

Pang and Lee (2005) formulated rating inference as a metric-labeling problem. They first applied two *n*-ary classifiers, including one-vs-all (OVA) SVM and SVM regression, to classify reviews with respect to multi-point rating scales. They then used a metric-labeling algorithm to explicitly alter the results of the *n*-ary classifiers to ensure that similar items receive similar labels, determined using a similarity function. While term overlapping is a commonly-used similarity function in topic classification, it does not seem effective in identifying reviews having similar ratings (Pang and Lee, 2005). They therefore proposed the Positive-Sentence Percentage (PSP) similarity function, computed as the number of positive sentences divided by the number of subjective sentences in a review. Experimental results in general show that using metric-labeling with PSP improves the performance of the *n*-ary classifiers. Goldberg and Zhu (2006) later extended Pang and Lee's work using transductive semi-supervised learning. They demonstrated that unlabeled reviews (those without user-specified ratings) can help improve classification accuracy.

Zhu and Goldberg (2007) proposed a kernel regression algorithm utilizing *order preferences* of unlabeled data, and successfully applied the algorithm to sentiment classification. The order preference of a pair of unlabeled data, x_i and x_j, indicates that x_i is preferred to x_j to some degree, even though the exact preferences for x_i and x_j are unknown. In the context of sentiment analysis, for example, given two reviews, one may be able to determine which review is more positive than the other without knowing the exact ratings associated with the reviews. Zhu and Goldberg applied their algorithm to the rating inference problem, and empirically showed that order preferences improved rating inference performance over standard regression.

FUTURE TRENDS

Most existing algorithms adopt generic opinion and product feature extraction methods, such as methods based on POS tags, without considering the properties of the domain items concerned. While such generic methods allow easy adaptation of a sentiment analysis algorithm to various domains, the performance achieved by the same algorithm was often found to vary significantly when being applied to datasets from different domains (e.g. Turney, 2002; Aue and Gamon, 2005). This, currently being addressed as a domain adaptation issue (Blitzer et al., 2007), reveals a need for more intelligent sentiment analysis models that utilize domain knowledge when extracting opinions and product features from reviews.

An emerging trend regarding sentiment classification is the paradigm shift from binary classification (e.g. *Positive* vs. *Negative*) to multi-point rating inference (e.g. 1-5 "stars"). Recent studies suggest that rating inference shall not be tackled as a classical multi-category classification problem because the ordering of class labels in rating inference is essential (Okanohara and Tsujii, 2005; Pang and Lee, 2005; Zhu and Goldberg, 2007). This opens up an interesting direction in ordered multi-category classification for future research.

Another interesting research direction is related to the utilization of the sentiments learnt from product reviews. Sentiment analysis has been used to support business and customer decision making by assisting users to explore customer opinions on products that they are interested in (Yamanishi and Li, 2002; Hu and Liu, 2004a). Leung et al. (2008) recently discussed the potential use of sentiment analysis to augment ratings for collaborative filtering (CF), which is also a popular research topic in and application of data mining.

CF provides personalized recommendations to a user based on his/her preferences and the preferences of other users having similar tastes (Leung et al., 2006a). A CF-based system operates on a database of user preferences collected either explicitly by asking users to give scalar ratings on items that they have examined, or implicitly by capturing users' interactions with the system (e.g. purchase histories). Using sentiment analysis to augment ratings for CF on the one hand allows

CF to use product reviews as an additional source of user preferences. On the other hand, it enables existing review hubs to utilize the user preferences learnt from reviews for personalization purpose. In view of these advantages, integrating sentiment analysis and CF is expected to be of high interests to data and text mining practitioners.

CONCLUSION

Sentiment analysis deals with the classification of texts based on the sentiments they contain. This article focuses on a typical sentiment analysis model consisting of three core steps, namely data preparation, review analysis and sentiment classification, and describes representative techniques involved in those steps.

Sentiment analysis is an emerging research area in text mining and computational linguistics, and has attracted considerable research attention in the past few years. Future research shall explore sophisticated methods for opinion and product feature extraction, as well as new classification models that can address the ordered labels property in rating inference. Applications that utilize results from both sentiment analysis and CF are also expected to emerge in the near future.

KEY TERMS

Collaborative Filtering: A recommendation technique that provides personalized recommendations to a user based on his/her expressed interests and the interests of other users having similar preferences.

Opinion Strength: Indicates how strong the opinion is given its sentimental orientation. It is also known as the intensity of an opinion.

Rating Inference: Refers to sentiment classification with respect to multi-point rating scales. It can be viewed as an *n*-ary classification problem in which the class labels are scalar ratings.

Sentiment Analysis: The process of analyzing the sentiments expressed in texts, and then classifying and/or summarizing the sentiments based on their polarity.

Sentiment Classification: A core step in sentiment analysis that classifies a text with respect to sentiment classes, such as *Positive* and *Negative*. An *n*-ary sentiment classification problem is also known as rating inference.

Sentiment Summarization: Summarizes the opinions expressed in a document or in a set of documents towards a product.

Sentimental Orientation: Indicates the polarity, such as *Positive* or *Negative*, of a text known to be subjective.

Subjectivity Analysis: Determines whether a text is subjective or objective (factual) in nature.

Sequential Pattern Mining

INTRODUCTION

Sequential pattern mining deals with data represented as sequences (a sequence contains sorted sets of items). Compared to the association rule problem, a study of such data provides "inter-transaction" analysis (Agrawal & Srikant, 1995). Applications for sequential pattern extraction are numerous and the problem definition has been slightly modified in different ways. Associated to elegant solutions, these problems can match with real-life timestamped data (when association rules fail) and provide useful results.

BACKGROUND

In (Agrawal & Srikant, 1995) the authors assume that we are given a database of customer's transactions, each of which having the following characteristics: sequence-id or customer-id, transaction-time and the item involved in the transaction. Such a database is called a base of data sequences. More precisely, each transaction is a set of items (itemset) and each sequence is a list of transactions ordered by transaction time. For efficiently aiding decision-making, the aim is to obtain typical behaviors according to the user's viewpoint. Performing such a task requires providing data sequences in the database with a support value giving its number of actual occurrences in the database. A frequent sequential pattern is a sequence whose statistical significance in the database is above user-specified threshold. Finding all the frequent patterns from huge data sets is a very time-consuming task. In the general case, the examination of all possible combination is intractable and new algorithms are required to focus on those sequences that are considered important to an organization.

Sequential pattern mining is applicable in a wide range of applications since many types of data are in a time-related format. For example, from a customer purchase database a sequential pattern can be used to develop marketing and product strategies. By way of a Web Log analysis, data patterns are very useful to better structure a company's website for providing easier access to the most popular links (Kosala & Blockeel, 2000). We also can notice telecommunication network alarm databases, intrusion detection (Hu & Panda, 2004), DNA sequences (Zaki, 2003), etc.

MAIN THRUST

Definitions related to the sequential pattern extraction will first be given. They will help understanding the various problems and methods presented hereafter.

Definitions

The item is the basic value for numerous data mining problems. It can be considered as the object bought by a customer, or the page requested by the user of a website, etc. An itemset is the set of items that are grouped by timestamp (e.g. all the pages requested by the user on June 04, 2004). A data sequence is a sequence of itemsets associated to a customer. In table 1, the data sequence of C2 is the following: "(Camcorder, MiniDV) (DVD Rec, DVD-R) (Video Soft)" which means that the customer bought a *camcorder* and *miniDV* the same day, followed by a *DVD recorder* and *DVD-R* the day after, and finally a *video software* a few days later.

A sequential pattern is included in a data sequence (for instance "(MiniDV) (Video Soft)" is included in the data sequence of C2, whereas "(DVD Rec) (Camcorder)" is not included according to the order of the

Table 1. Data sequences of four customers over four days

Cust	June 04, 2004	June 05, 2004	June 06, 2004	June 07, 2004
C1	Camcorder, MiniDV	Digital Camera	MemCard	USB Key
C2	Camcorder, MiniDV	DVD Rec, DVD-R		Video Soft
C3	DVD Rec, DVD-R	MemCard	Video Soft	USB Key
C4		Camcorder, MiniDV	Laptop	DVD Rec, DVD-R

timestamps). The minimum support is specified by the user and stands for the minimum number of occurrences of a sequential pattern to be considered as frequent. A maximal frequent sequential pattern is included in at least "minimum support" data sequences and is not included in any other frequent sequential pattern. Table 1 gives a simple example of 4 customers and their activity over 4 days in a shop. With a minimum support of "50%" a sequential pattern can be considered as frequent if it occurs at least in the data sequences of 2 customers (2/4). In this case a maximal sequential pattern mining process will find three patterns:

- **S1:** "(Camcorder, MiniDV) (DVD Rec, DVD-R)"
- **S2:** "(DVD Rec, DVD-R) (Video Soft)"
- **S3:** "(Memory Card) (USB Key)"

One can observe that S1 is included in the data sequences of C2 and C4, S2 is included in those of C2 and C3, and S3 in those of C1 and C2. Furthermore the sequences do not have the same length (S1 has length 4, S2 has length 3 and S3 has length 2).

Methods for Mining Sequential Patterns

The problem of mining sequential patterns is stated in (Agrawal & Srikant, 1995) and improved, both for the problem and the method, in (Srikant & Agrawal, 1996). In the latter, the GSP algorithm is based on a breadth-first principle since it is an extension of the A-priori model to the sequential aspect of the data. GSP uses the "Generating-Pruning" method defined in (Agrawal, Imielinski, & Swami, 1993) and performs in the following way. A candidate sequence of length (k+1) is generated from two frequent sequences, s_1 and s_2, having length k, if the subsequence obtained by pruning the first item of s_1 is the same as the subsequence obtained by pruning the last item of s_2. With the example in Table 1, and k=2, let s_1 be "(DVD Rec, DVD-R)" and s_2 be "(DVD-R) (Video Soft)", then the candidate sequence will be "(DVD Rec, DVD-R) (Video Soft)" since the subsequence described above (common to s_1 and s_2) is "(DVD-R)". Another method based on the Generating-Pruning principle is PSP (Massegli, Cathala, & Poncelet, 1998). The main difference to GSP is that the candidates as well as the frequent sequences are managed in a more efficient structure. The methods presented so far are designed to depend as little as possible on main memory. The methods presented thereafter need to load the database (or a rewriting of the database) in main memory. This results in efficient methods when the database can fit into the memory.

In (Zaki, 2001), the authors proposed the SPADE algorithm. The main idea in this method is a clustering of the frequent sequences based on their common prefixes and the enumeration of the candidate sequences, thanks to a rewriting of the database (loaded in main memory). SPADE needs only three database scans in order to extract the sequential patterns. The first scan aims at finding the frequent items, the second at finding the frequent sequences of length 2 and the last one associate to frequent sequences of length 2, a table of the corresponding sequences id and itemsets id in the database (e.g. data sequences containing the frequent sequence and the corresponding timestamp). Based on this representation in main memory, the support of the candidate sequences of length k is the result of join operations on the tables related to the frequent sequences of length (k-1) able to generate this candidate (so, every operation after the discovery of frequent sequences having length 2 is done in memory). SPAM (Ayres, Flannick, Gehrke, & Yiu, 2002) is another method which needs to represent the database in the main memory. The authors proposed a vertical bitmap representation of the database for both candidate representation and support counting.

An original approach for mining sequential patterns aims at recursively projecting the data sequences into smaller databases. Proposed in (Han, et al., 2000), FreeSpan is the first algorithm considering the pattern-projection method for mining sequential patterns. This work has been continued with PrefixSpan, (Pei, et al., 2001), based on a study about the number of candidates proposed by a Generating-Pruning method. Starting from the frequent items of the database, PrefixSpan generates projected databases with the remaining data-sequences. The projected databases thus contain suffixes of the data-sequences from the original database, grouped by prefixes. The process is recursively repeated until no frequent item is found in the projected database. At this level the frequent sequential pattern is the path of frequent items driving to this projected database.

Closed Sequential Patterns

A closed sequential pattern is a sequential pattern included in no other sequential pattern having exactly the same support. Let us consider the database illustrated in Table 1. The frequent sequential pattern "(DVD Rec) (Video Soft)" is not closed because it is included in the sequential pattern S2 which has the same support (50%). On the other hand, the sequential pattern "(Camcorder, MiniDV)" (with a support of 75%) is closed because it is included in other sequential patterns but with a different support (for instance, S1, which has a support of 50%). The first algorithm designed to extract closed sequential patterns is CloSpan (Yan, Han, & Afshar, 2003) with a detection of non-closed sequential patterns avoiding a large number of recursive calls. CloSpan is based on the detection of frequent sequences of length 2 such that "*A* always occurs before/after *B*". Let us consider the database given in Table 1. We know that "(DVD Rec) (Video Soft)" is a frequent pattern. The authors of CloSpan proposed relevant techniques to show that "(DVD-R)" always occurs before "(Video Soft)". Based on this observation CloSpan is able to find that "(DVD Rec, DVD-R) (Video Soft)" is frequent without anymore scans over the database. BIDE (Wang & Han, 2004) extends the previous algorithm in the following way. First, it adopts a novel sequence extension, called BI-Directional Extension, which is used both to grow the prefix pattern and to check the closure property. Second, in order to prune the search space more deeply than previous approaches, it proposes a BackScan pruning method. The main idea of this method is to avoid extending a sequence by detecting in advance that the extension is already included in a sequence.

Incremental Mining of Sequential Patterns

As databases evolve, the problem of maintaining sequential patterns over a significantly long period of time becomes essential since a large number of new records may be added to a database. To reflect the current state of the database, in which previous sequential patterns would become irrelevant and new sequential patterns might appear, new efficient approaches were proposed. (Masseglia, Poncelet, & Teisseire, 2003) proposes an efficient algorithm, called ISE, for computing the frequent sequences in the updated database. ISE minimizes computational costs by re-using the minimal information from the old frequent sequences, i.e. the support of frequent sequences. The main new feature of ISE is that the set of candidate sequences to be tested is substantially reduced. The SPADE algorithm was extended into the ISM algorithm (Parthasarathy, Zaki, Ogihara, & Dwarkadas., 1999). In order to update the supports and enumerate frequent sequences, ISM maintains "maximally frequent sequences" and "minimally infrequent sequences" (also known as negative border). KISP (Lin and Lee, 2003) also proposes to take advantage of the knowledge previously computed and generates a knowledge base for further queries about sequential patterns of various support values.

Extended Problems Based on the Sequential Pattern Extraction

Motivated by the potential applications for the sequential patterns, numerous extensions of the initial definition have been proposed which may be related to the addition of constraints or to the form of the patterns themselves. In (Pei, Han, & Wang, 2002) the authors enumerate some of the most useful constraints for extracting sequential patterns. These constraints can be considered as filters applied to the extracted patterns, but most methods generally take them into account during the mining process. These filters may concern the items ("extract patterns containing the item *Camcorder* only") or the length of the pattern, regular expressions describing the pattern, and so on.

The definition of the sequential patterns has also been adapted by some research work. For instance (Kum, Pei, Wang, & Duncan, 2003) proposed ApproxMap to mine approximate sequential patterns. ApproxMap first proposes to cluster the data sequences depending on their items. Then for each cluster ApproxMap allows extraction of the approximate sequential patterns related to this cluster. Let us consider the database in Table 1 as a cluster. The first step of the extraction process is to provide the data sequences of the cluster with an alignment similar to those of bioinformatics. Table 2 illustrates such an alignment.

The last sequence in Table 2 represents the weighted sequence obtained by ApproxMap on the sequences of Table 1. With a support of 50%, the weighted sequence gives the following approximate pattern: "(Camcorder: 3, MiniDV: 3) (DVD Rec: 3, DVD-R: 3) (MemCard: 2) (Video Soft: 2) (USB Key: 2)". It is interesting to observe that this sequential pattern does not correspond to any of the recorded behavior, whereas it represents a trend for this kind of customer.

FUTURE TRENDS

Today several methods are available for efficiently discovering sequential patterns according to the initial definition. Such patterns are widely applicable for a large number of applications. Specific methods, widely inspired from previous algorithms, exist in a wide range of domains. Nevertheless, existing methods have to be reconsidered since handled data is much more complex. For example, existing algorithms consider that data is binary and static. Today, according to the huge volume of data available, stream data mining represents an emerging class of data-intensive applications where data flows in and out dynamically. Such applications also need very fast or even real-time responses (Giannella, Han, Pei, Yan, & Yu, 2003; Cai et al., 2004). In order to increase the immediate usefulness of sequential rules, it is very important to consider much more information. Hence, by associating sequential patterns with a customer category or multi-dimensional information, the main objective of multi-dimensional sequential pattern mining is to provide the end-user with more useful classified patterns (Pinto et al., 2001). With such patterns, an auto-dealer would find, for example, an enriched sequential rule stating that "*Customers who bought an SUV on monthly payment installments 2 years ago are likely to respond favorably to a trade-in now*".

CONCLUSION

Since they have been defined in 1995, sequential patterns have received a great deal of attention. First work on this topic focused on improving the efficiency of the algorithms either with new structures, new representations or by managing the database in the main memory. More recently extensions were proposed by taking into account constraints associated with real life applications. In fact, the increasing contributions on sequential pattern mining are mainly due to their adaptability to such applications. The management of timestamp within the recorded data is a difficulty for designing algorithms; on the other hand this is the reason why sequential pattern mining is one of the most promising technologies for the next generation of knowledge discovery problems.

KEY TERMS

Apriori: The method of generating candidates before testing them during a scan over the database, insuring that if a candidate may be frequent then it will be generated. See also *Generating-Pruning*.

Breadth-First: The method of growing the intermediate result by adding items both at the beginning and the end of the sequences. See also *Generating-Pruning*

Closed Sequential Pattern: A frequent sequential pattern that is not included in another frequent sequential pattern having exactly the same support.

Data Sequence: The sequence of itemsets representing the behavior of a client over a specific period. The database involved in a sequential pattern mining process is a (usually large) set of data sequences.

Depth-First: The method of generating candidates by adding specific items at the end of the sequences. See also *Generating-Pruning*.

Generating-Pruning: The method of finding frequent sequential patterns by *generating* candidates sequences (from size 2 to the maximal size) step by step. At each step a new generation of candidates having the same length is generated and tested over the databases. Only frequent sequences are kept (*pruning*) and used in the next step to create a new generation of (longer) candidate sequences.

Itemset: Set of items that occur together.

Maximal Frequent Sequential Pattern: A sequential pattern included in at least *n* data sequences (with *n* the minimum support specified by the user). A sequential pattern is maximal when it is not included in another frequent sequential pattern. A frequent sequential pattern may represent, for instance, a frequent behavior of a set of customers, or a frequent navigation of the users of a Web site.

Negative Border: The collection of all sequences that are not frequent but both of whose generating sub sequences are frequent.

Sequential Pattern: A sequence included in a data sequence such that each item in the sequential pattern appears in this data sequence with respect to the order between the itemsets in both sequences.

INTRODUCTION

Efficient tools and algorithms for knowledge discovery in large data sets have been devised during the recent years. These methods exploit the capability of computers to search huge amounts of data in a fast and effective manner. However, the data to be analyzed is imprecise and afflicted with uncertainty. In the case of heterogeneous data sources such as text, audio and video, the data might moreover be ambiguous and partly conflicting. Besides, patterns and relationships of interest are usually vague and approximate. Thus, in order to make the information mining process more robust or say, human-like methods for searching and learning it requires tolerance towards imprecision, uncertainty and exceptions. Thus, they have approximate reasoning capabilities and are capable of handling partial truth. Properties of the aforementioned kind are typical soft computing. *Soft computing* techniques like *Genetic Algorithms* (GA), Artificial Neural Networks, Fuzzy Logic, Rough Sets and *Support Vector Machines* (SVM) when used in combination was found to be effective. Therefore, *soft computing* algorithms are used to accomplish data mining across different applications (Mitra S, Pal S K & Mitra P, 2002; Alex A Freitas, 2002).

Extensible Markup Language (XML) is emerging as a de facto standard for information exchange among various applications of World Wide Web due to XML's inherent data self-describing capacity and flexibility of organizing data. In XML representation, the semantics are associated with the contents of the document by making use of self describing tags which can be defined by the users. Hence XML can be used as a medium for interoperability over the Internet. With these advantages, the amount of data that is being published on the Web in the form of XML is growing enormously and many naïve users find the need to search over large XML document collections (Gang Gou & Rada Chirkova, 2007; Luk R et al., 2000).

BACKGROUND

The SVM is an efficient and principled method used for classification and regression purposes. The SVM is capable of classifying linearly separable and non-linearly separable data. GA is an effective technique for searching enormous, possibly unstructured solution spaces. The human search strategy which is efficient for small documents is not viable when performing search over enormous amounts of data. Hence, making search engines cognizant of the search strategy using GA can help in fast and accurate search over large document collections.

The topic categorization of XML documents poses several new challenges. The tags in XML represent the semantics of the contents of the document and thus are more significant than the contents during the process of classification. Therefore, a general framework which assigns equal priority to both, the tags and the contents of an XML document will not be able to exhibit any significant performance improvement. Thus, a *topic categorization* framework with prominence to tags will be highly efficient. The possibility of topic categorization of XML documents using SVM is explored in (Srinivasa K G et al., 2005).

A *Selective Dissemination* of Information (SDI) system helps users to cope with the large amount of information by automatically disseminating the knowledge to the users in need of it. Therefore, the selective dissemination is the task of dispatching the documents

to the users based on their interests. Such systems maintain user profiles to judge the interests of the users and their information needs. The new documents are filtered against the user profiles, and the relevant information is delivered to the corresponding users. In XML documents, the utilization of user defined tags is of great importance to improve the effectiveness of the dissemination task. The possibility of *selective dissemination* of XML documents based on a user model using Adaptive GAs is addressed in (Srinivasa K G et al., 2007:IOS Press).

The keyword search over XML documents poses many new challenges. First, the result of a search over XML documents is not the document in its entirety, but only relevant document fragments and thus, granularity of the search terms must be refined when searching over XML document corpus. Second, the result of a keyword search over XML documents must be semantically interconnected document fragments. Finally, XML documents include large amounts of textual information and part of this is rarely searched. Building a single index for the whole document will make the index bulky and difficult to manage. The possibility of retrieval and ranking of XML fragments based on keyword queries using Adaptive GA for learning tag information is explored in (Srinivasa K G et al., 2005:ICP).

MAIN FOCUS

The application of soft computing paradigms like Genetic Algorithms and Support Vector Machines are used effectively to solve the optimization problems. The XML topic categorization is efficiently carried out using SVMs. Once the XML documents are categorized, the related and relevant information has to be disseminated to the user by a genetically learned user model in combination with SVMs. Once a large number of such XML tags exist, an efficient search over such XML repository is carried out using Adaptive GAs.

Topic Categorization Using SVM

The need for categorization of XML documents into specific user interest categories is in great demand because of huge XML repositories. A machine learning approach is applied to *topic categorization* which makes use of a multi class SVM for exploiting the semantic content of XML documents. The SVM is supplemented by a feature selection technique which is used to extract the useful features. For the application of SVM to the given XML data a feature vector must be constructed. The choice of the feature set determines the overall accuracy of the categorization task. Therefore, all the distinct tags from the training set XML documents are collected. This represents the initial tag pool. The tag pool can have rarely used tags and tags spread over all the categories apart from the more frequently used tags. Such tags can deteriorate the performance of SVM. The purpose of feature selection is to select the optimal feature subset that can achieve highest accuracy. Then, the XML document is parsed and all the tags present in the document are extracted. Only binary values are assigned as dimensions of the feature vector and supplied as the input to the multi class SVM. Later, this classifier is used for categorizing a new XML document based on the topic of relevance.

Selective Dissemination of XML Fragments

As the number of documents published in the form of XML is increasing, there is a need for selective dissemination of XML documents based on user interests. A combination of Adaptive Genetic Algorithms (Srinivasa K G et al., 2007:Elsevier) and a multi class SVM is used to learn a user model. Based on the feedback from the users, the system automatically adapts to the user's preference and interests. The user model and a similarity metric are used for selective dissemination of a continuous stream of XML documents. Using GAs to learn user profiles has two advantages. First, the tag combinations which are interesting to a user can be extracted using relevance feedback mechanism. Second, the context of the search terms given by the users can be adjudged and a profile can be constructed accordingly. From the collection of user profiles, random profiles are sampled and a decision on the category to which they belong is made.

A feature extractor and an SVM are used for the user model construction. The Feature extraction is performed using the measure of expected entropy loss to rank the features that are discriminators among the categories. An extended SVM to support multiclass classification is used to build the user model. A voting vector with a dimension for each class is also used for classifica-

tion. There are as many votes as the number of SVMs and the class having the maximum number of votes yields the corresponding support vectors. Here, SVM first classifies the various profiles into user interest category and then the same model is used to assign a user interest category to an incoming XML document from among the various pre-specified categories. After the user model has assigned a user interest category to the incoming XML document the next step is to find the users to whom the document is to be dispatched. A similarity metric between the incoming document and the user profile can judge the users to whom the document will be of most interest and hence the selective dissemination.

A Semantic Search Using Adaptive Genetic Algorithms

The XML document can be considered as a directed, node-labeled *data graph* $G = (X, E)$. Each node in X corresponds to an XML element in the document and is characterized by a unique *object identifier,* a *label* that captures the semantics of the element and leaf nodes are associated with a sequence of *keywords*. E is the set of edges which define the relationships between nodes in X. The edge $(l, k) \in E$, if there exists a directed edge from node l to node k in G. The edge $(l, k) \in E$ also denotes that node l is the *parent* of node k in G. Node l is also the ancestor of node k if a sequence of directed edges from node l leads to node k. Let the XML document tree be called τ. Let x be an interior node in this tree. We say that x directly satisfies a search term k if x has a leaf child that contains the keyword k and x indirectly satisfies a keyword k if some descendent of x directly satisfies the search term k. A search query $q = \{k_1, k_2, \ldots k_m\}$ is satisfied by a node x *iff* x satisfies each of $k_1, k_2, \ldots k_m$ either directly or indirectly. First a representative training set is chosen to assist the genetic learning of tags. The keyword queries and the relevant search results are collected from the user.

An adaptive genetic algorithm retrieves the tag combination which can answer a maximum number of training queries. Separate indices are built for the frequently used and occasionally used tag combinations. A search over the XML documents in the decreasing order of importance of tags is performed. Finally, the search produces only semantically related results. Making use of adaptive GAs to learn the tag information has two advantages. First, when the same keyword appears more than once in the XML document with different semantics (different tags), the knowledge learnt from the GA is used to rank the search results. Hence, the results that are more relevant to the user queries are better ranked than the other results. Second, separate indices can be built for both the frequently and less frequently searched tags. Thus the indices are smaller in size and hence manageable. The notations for relationship strength and semantic relationship help in efficient retrieval of semantically interconnected results as well as ranking the search results based on the proximity of the keywords.

FUTURE TRENDS

The future of the WWW is the semantic web. Since XML is the integral part of web semantics, mining such XML repository is very essential for knowledge dissemination. There are several possible avenues for future extensions. The algorithms can be refined such that they are able to cluster the users with similar interests together. A system which allows users to explicitly specify their preferences apart from automatically learning their interests will be very efficient.

CONCLUSION

A framework for topic categorization of XML documents that makes use of SVM for the purpose of classification is discussed. Feature selection schemes that can improve the accuracy of the SVM is also addressed. The All-Vs-One Multiclass SVM is used to assign a topic category to the input XML document from among the various pre-specified categories. A system for Selective dissemination of XML documents that makes use of genetic algorithms to learn user interests is discussed. A model which assigns user interest categories to the user profiles as well as the streaming XML documents is also discussed. Another framework for information retrieval from XML documents that uses tag information to improve the retrieval performance is explored. Adaptive GAs, which are efficient for search in large problem spaces, are used to learn the significance of the tags.

KEY TERMS

Genetic Algorithms: Genetic algorithms (GAs) are search procedures that use the mechanics of natural selection and natural genetics.

Selective Dissemination of Information: SDI distributes automatically and electronically to end users the tables of contents from Web in which they are interested. **Semantic Web:** The Semantic Web is an extension of the current Web that will allow you to *find*, *share*, and *combine* information more easily.

Support Vector Machines: Algorithm used to identify patterns in datasets.

Topic Categorization: The use of computer software to categorise web pages based on a particular topic. Taxonomies for categorisation can also be created automatically.

User Modeling: Construction of (typically computer-based) models of users' mental activities and behaviors often used to make predictions about a system's usability or as a basis for interactive help systems.

Soft Subspace Clustering for High-Dimensional Data

Liping Jing

Joshua Zhexue Huang
The University of Hong Kong, Hong Kong

INTRODUCTION

High dimensional data is a phenomenon in real-world data mining applications. Text data is a typical example. In text mining, a text document is viewed as a vector of terms whose dimension is equal to the total number of unique terms in a data set, which is usually in thousands. High dimensional data occurs in business as well. In retails, for example, to effectively manage supplier relationship, suppliers are often categorized according to their business behaviors (Zhang, Huang, Qian, Xu, & Jing, 2006). The supplier's behavior data is high dimensional, which contains thousands of attributes to describe the supplier's behaviors, including product items, ordered amounts, order frequencies, product quality and so forth. One more example is DNA microarray data.

Clustering high-dimensional data requires special treatment (Swanson, 1990; Jain, Murty, & Flynn, 1999; Cai, He, & Han, 2005; Kontaki, Papadopoulos & Manolopoulos., 2007), although various methods for clustering are available (Jain & Dubes, 1988). One type of clustering methods for high dimensional data is referred to as subspace clustering, aiming at finding clusters from subspaces instead of the entire data space. In a subspace clustering, each cluster is a set of objects identified by a subset of dimensions and different clusters are represented in different subsets of dimensions.

Soft subspace clustering considers that different dimensions make different contributions to the identification of objects in a cluster. It represents the importance of a dimension as a weight that can be treated as the degree of the dimension in contribution to the cluster. Soft subspace clustering can find the cluster memberships of objects and identify the subspace of each cluster in the same clustering process.

BACKGROUND

Finding clusters from subspaces of high dimensional data, subspace clustering pursues two tasks, identification of the subspaces where clusters can be found and discovery of the clusters from different subspaces, i.e., different subsets of dimensions. According to the ways with which the subsets of dimensions are identified, subspace clustering methods are divided into the following two categories. *Hard subspace clustering* determines the exact subsets of dimensions where clusters are discovered. Typical examples include PROCLUS, HARP and others. (Chakrabarti & Mehrotra, 2000; Yip, Cheung, & Ng, 2004 ; Parsons, Haque, & Liu, 2004). *Soft subspace clustering* considers that each dimension makes a different level of contribution to the discovery of clusters and the degree of contribution of a dimension to a cluster is represented as the weight of this dimension. The subsets of the dimensions with larger weights in a cluster form the subspace of the cluster. Typical examples include LAC, COSA, SCAD and others (Domeniconi, Papadopoulos, Gunopulos, & Ma, 2004; Frigui and Nasraoui, 2004; Friedman and Meulman, 2004; Chan, Ching, Ng, & Huang, 2004; Law, Figueiredo, & Jain, 2004).

The above subspace clustering methods have more or less three problems. Firstly, they are not scalable to large data (e.g., HARP, COSA). Large high dimensional data can not be well handled with them. Secondly, some use a projection method (e.g., PROCLUS), which makes the clustering results non-understandable.

Recovery of the original dimensions from the projected dimensions turns out to be difficult. Thirdly, some (e.g., SCAD, LAC) can not handle sparse data, which is a well-known phenomenon in real applications (Jing, Huang, & Ng, 2005).

MAIN FOCUS

This chapter is focused on a new soft subspace clustering method. This method determines the subspaces of clusters according to the contributions of the dimensions in discovering the corresponding clusters. The contribution of a dimension is measured by a weight that is assigned to the dimension in the clustering process. Every dimension contributes to the discovery of clusters, but the dimensions with larger weights identify the subspaces of the clusters (Jing, Ng, & Huang, 2007). The new soft subspace clustering algorithm is based on the *k*-means clustering process. Therefore, it can cluster large and high-dimensional sparse data.

The *k*-Means Algorithm

The *k*-means algorithm (MacQueen, 1967) is the mostly used clustering algorithm in data mining. Given a set of numeric objects X and an integer *k*, the *k*-means algorithm searches for a partition of X into *k* clusters that minimizes the sum of the within groups squared errors. This process is often formulated as the following minimization problem.

$$F(U,Z)=\sum_{l=1}^{k}\sum_{i=1}^{n}\sum_{j=1}^{m}u_{i,l}(x_{i,j}-z_{l,j})^2 \quad (1)$$

subject to

$$\sum_{l=1}^{k}u_{i,l}=1,\ 1\le i\le n,\ 1\le l\le k,\quad u_{i,l}\in\{0,1\}$$

where $U=[u_{i,l}]$ is an $n\times k$ partition matrix and $u_{i,l}$ = 1 indicates that the ith object is allocated to the lth cluster. $Z=[z_{l,j}]$ is a set of k vectors representing the centers of the k clusters.

Problem P can be solved by iteratively solving two sub minimization problems. One is to minimize $F(U,\hat{Z})$ with a given $\hat{Z}$ as constant by

$$u_{i,l}=1 \text{ , if } \sum_{i=1}^{m}(x_{i,j}-z_{l,j})^2\le\sum_{i=1}^{m}(x_{i,j}-z_{r,j})^2 \text{ for } 1\le r\le k, \quad (2)$$

$u_{i,l}$ = 0, otherwise.

The other is to minimize $F(\hat{U},Z)$ with a given partition matrix $\hat{U}$ by

$$z_{l,j}=\frac{\sum_{i=1}^{n}u_{i,l}x_{i,j}}{\sum_{i=1}^{n}u_{i,l}} \text{ for } 1\le l\le k, \quad \text{and} \quad 1\le j\le m. \quad (3)$$

The convergence of this k-means minimization process is proved in (Selim & Ismail, 1984).

One of the drawbacks of the *k*-means algorithm is that it treats all features equally in deciding the cluster memberships of objects. This is not desirable when dealing with high dimensional data with a large number of diverse features (dimensions). In such data, a cluster structure is often confined to a subset of features rather than the whole feature set. Inclusion of other features can only obscure discovery of the cluster structure in the clustering process. This drawback can be removed with a feature weighting technique that can identify the feature importance and help the *k*-means algorithm to find clusters in subset of features.

Feature Weights

Feature weighting for clustering is an important research topic in statistics and data mining (Modha & Spangler, 2003; Huang, Ng, Rong, & Li, 2005). The main purpose is to select important features in which a weight is assigned to a dimension for the entire data set. A weight can also be assigned to a feature in each cluster according to the feature importance in forming the corresponding cluster (Jing, Huang, & Ng, 2005; Jing, Ng, & Huang, 2007). In other words, a *k x m* weight matrix $V = [v_{l,j}]$ (l is the cluster index and j the feature index) is built in the clustering process. In this matrix, different clusters have different feature weight values. The weight value for a feature in a cluster is inversely proportional to the dispersion of the feature values from the center of the cluster. Therefore, the high weight value indicates a small dispersion of the feature values in the

cluster, which means that the feature is more important in forming the cluster. A cluster can be identified from the subspace with important features (large weights), and at the same time these important features can be used to describe the meaning of the cluster.

Objective Function

The new objective function is based on the objective function of the standard *k*-means by introducing the feature weights. A term of the entropy of the feature weights is also added. This entropy term represents the certainty of features in the identification of a cluster. Therefore, the clustering process simultaneously minimizes the within cluster dispersion and maximizes the negative weight entropy to stimulate more features to contribute to the identification of clusters. In this way, the problem of identifying clusters by few features in sparse data can be avoided.

The new objective function is given as

$$F(U,Z,V)=\sum_{l=1}^{k}\left[\sum_{i=1}^{n}\sum_{j=1}^{m}u_{i,l}v_{l,j}^{\beta}(x_{i,j}-z_{l,j})^2+\gamma\sum_{i=1}^{m}v_{l,j}\log v_{l,j}\right] \quad (4)$$

subject to

$$\sum_{l=1}^{k}u_{i,l}=1,\ 1\le i\le n,\ 1\le l\le k,\ u_{i,l}\in\{0,1\}$$

$$\sum_{i=1}^{m}v_{l,j}=1,\ 1\le j\le m,\ 1\le l\le k,\ 0\le v_{l,j}\le 1.$$

Here, $V=[v_{l,j}]$ is the $k\times m$ weight matrix, $\beta(>1)$ and γ are two given factors.

The new objective function contains two terms. The first term is the sum of the within cluster dispersions and the second term is the negative weight entropy. The parameter γ controls the strength of the incentive for clustering on more features.

Algorithm

The usual method toward optimization of the objective function (4) with the constraints is to use the partial optimization for one set of variables with other sets of variables treated as constants. The iterative minimization process is formed in three steps.

Step 1: Given $\hat{Z}$ and $\hat{V}$, update the partition matrix *U* by

$$u_{i,l}=1,\ \text{if}\ \sum_{j=1}^{m}v_{l,j}(x_{i,j}-z_{l,j})^2\le\sum_{i=1}^{m}v_{r,j}(x_{i,j}-z_{r,j})^2\ \text{for}\ 1\le r\le k, \quad (5)$$

$ui,l = 0$, otherwise

Step 2: Given $\hat{U}$ and $\hat{V}$, update the cluster centers Z with (3).

Step 3: Given $\hat{U}$ and $\hat{Z}$, calculate the feature weight matrix V as

$$v_{l,j}=\frac{\exp(-D_{l,j}/\gamma)}{\sum_{t=1}^{m}\exp(-D_{l,t}/\gamma)} \quad (6)$$

where

$$D_{l,t}=\sum_{i=1}^{n}u_{i,l}(x_{i,t}-z_{l,t})^2.$$

The soft subspace clustering algorithm is summarized as shown in Algorithm 1.

Algorithm 1 indicates that the new soft subspace clustering method only adds one new step to the *k*-means clustering process to calculate the feature weights of each cluster. Therefore, it is scalable to the number of features, the number of objects and the number of clusters.

FUTURE TRENDS

Similar to the drawbacks of the standard *k*-means, the soft subspace clustering algorithm is also sensitive to the initial settings, e.g., the number of clusters and the initial cluster centers. An effective subspace cluster validation method is needed to evaluate the clustering results. Some cluster validity index (Xie and Beni, 1991; Sun, Wang, & Jiang, 2004) may be modified to validate clusters in subspaces.

The current study of this algorithm has been focused on numeric data. However, a lot of data are categorical in many application domains. How to apply the soft

Algorithm 1:
Input: The number of clusters k and parameter ;
Randomly choose k cluster centers and set all initial weights to 1/m;

Repeat
  Update the partition matrix U by (6);
Update the cluster centers Z by (3);
Update the feature weights V by (5);
Until the objective function (4) obtains its local minimum value.

subspace clustering algorithm to high dimensional data is an interesting research problem that needs to be solved.

Furthermore, outlier detection should be considered in subspace clustering. The preferable way to deal with outliers in partitioning the data is to keep one extra set of outliers, so as not to pollute factual clusters. For instance, the algorithm CLIQUE (Agrawal, Gehrke, Gunopulos, & Raghavan, 1998) handles outliers by eliminating the subspaces with low coverage.

In addition, missing value is an actual challenging issue confronted by subspace clustering, also by data mining. Existing methods dealing with missing values can be roughly treated as a procedure that replaces the missing values in a dataset by some plausible values. The plausible values are generally generated from the dataset using a deterministic or random method. More efficient approach for clustering high dimensional data with missing values should be investigated. This is essentially a sparse data clustering problem.

CONCLUSION

The demand for clustering methods to handle high dimensional data will increase as more and more structured or unstructured data sources are available (e.g., text, image, audio, etc.). The soft subspace clustering algorithm based on the efficient k-means clustering process provides a useful technique for solving large high dimensional data clustering problems. Further study is needed to test this algorithm in different applications. One interesting research topic is validation of clusters discovered from subspaces. The existing cluster validation indices do not consider this situation.

KEY TERMS

Cluster Validation: Process to evaluate a clustering result to determine whether the "true" clusters inherent in the data are found.

Clustering: A process of grouping data objects into clusters according to some similarity measure.

Feature Weighting: A technique to evaluate a feature with some criterion, e.g., its importance and then assign a value to a feature.

High Dimension Data: The data with hundreds or thousands of dimensions, for example, gene or text data.

k-Means: A partitional clustering technique that partitions data objects into *k* clusters by iteratively minimizing the sum of the within cluster dispersions.

Subspace Clustering: An extension of the traditional clustering method by finding clusters in different subspaces formed by a subset of features.

Soft Subspace Clustering: The soft subspace clustering approach determines the subsets of dimensions according to contributions of the features in discovering the corresponding clusters, and the contribution of a feature dimension is measured by a weight that is assigned to the feature in the clustering process.

Spatio-Temporal Data Mining for Air Pollution Problems

INTRODUCTION

Vast amounts of data are being generated to extract implicit patterns of ambient air pollution. Because air pollution data are generally collected in a wide area of interest over a relatively long period, such analyses should take into account both temporal and spatial characteristics. Furthermore, combinations of observations from multiple monitoring stations, each with a large number of serially correlated values, lead to a situation that poses a great challenge to analytical and computational capabilities. Data mining methods are efficient for analyzing such large and complicated data. Despite the great potential of applying data mining methods to such complicated air pollution data, the appropriate methods remain premature and insufficient. The major aim of this chapter is to present some data mining methods, along with the real data, as a tool for analyzing the complex behavior of ambient air pollutants.

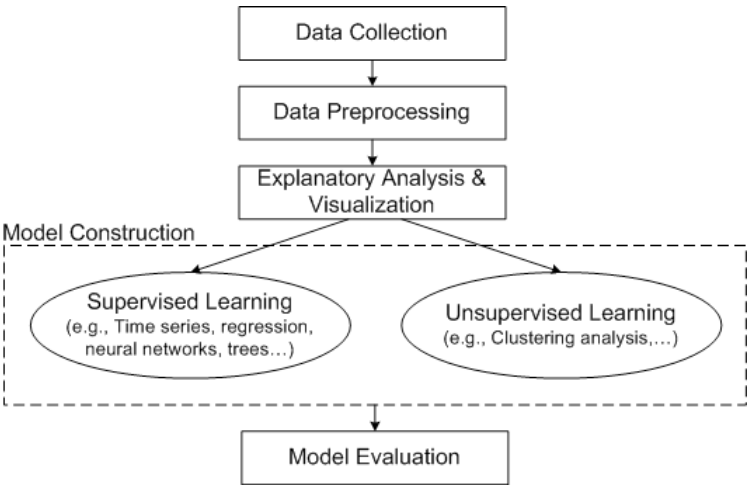
BACKGROUND

In 1990, under the Clean Air Act., the U.S. Environmental Protection Agency (EPA) set the National Ambient Air Quality Standards (NAAQS) for six pollutants, also known as criteria pollutants, which are particulate matter, ozone, sulfur dioxide, nitrogen dioxides, carbon monoxide, and lead (US EPA, 1990). Any exceedance of the NAAQS results in non-attainment of the region for that particular pollutant.

Well-known consequences of air pollution include the green house effect (global warming), stratospheric ozone depletion, tropospheric (ground-level) ozone, and acid rain (Wark, Warner, & Davis, 1998). In this chapter, we present applications on tropospheric ozone and the less publicized air pollution problem of particulate matter. High concentrations of tropospheric ozone affect human health by causing acute respiratory problems, chest pain, coughing, throat irritation, or even asthma (Lippmann, 1989). Ozone also interferes with the ability of plants to produce and store food, damages the leaves of trees, reduces crop yields, and impacts species diversity in ecosystems (Bobbink, 1998; Chameides & Kasibhatla, 1994). Particulate matter is an air contaminant that results from various particle emissions. For example, $PM_{2.5}$ (particulate matter that is 2.5 micrometers or smaller in size) has the potential to cause adverse health effects in humans, including premature mortality, nose and throat irritation, and lung damage (e.g., Pope et al., 2002). Furthermore, $PM_{2.5}$ has been associated with visibility impairment, acid deposition, and regional climate change.

To reduce pollutant concentrations and establish the relevant pollution control program, a clear understanding of the pattern of pollutants in particular regions and time periods is necessary. Data mining techniques can help investigate the behavior of ambient air pollutants and allow us to extract implicit and potentially useful knowledge from complex air quality data. Figure 1 illustrates the five primary stages in the data mining process in air pollution problems: data collection, data preprocessing, explanatory analysis and visualization, model construction, and model evaluation.

Figure 1. Overview of data mining in air pollution problems.



MAIN FOCUS OF CHAPTER

Data Collection

Because air pollution data are generally collected in a wide region of interest over a relatively long time period, the data are composed of both temporal and spatial information. A typical air pollution database consists of pollutant observations $O(S_i, T_j)$, for monitoring site S_i at time T_j for $i=1,2,\ldots,m$, $j=1,2,\ldots,n$, where m and n is the number of monitoring sites and time points, respectively. Since most air pollution data hold these two properties, spatial and temporal variability should be incorporated into the analysis in order to accurately analyze the air pollution characteristics. Table 1 provides a list of publicly accessible databases and their web addresses that contain a variety of air pollution data.

Data Preprocessing

Preprocessing of air pollution data is a crucial task because inadequate preprocessing can result in low-quality data and make it difficult to extract meaningful information from subsequent analyses. The collected air pollution data typically contain a number of potential outliers that are far away from the rest of the observations and missing values possibly due to measurement or instrumental errors. It is necessary to process missing values and outliers in both the time and space domains. Imputing missing values or replacing potential outliers with a sample average is the simplest method because it can be calculated without any pre-specified assumptions or complex mathematical formulas. However, the sample average assumes that each observation is equally important and does not take into account the fact that the data are collected over time and space. A weighted average can be an efficient method to replace the outliers or impute the missing values. One example of using a weighted average is the inverse-distance-squared weighted method (McNair, Harley, & Russell, 1996). This method determines weights based on spatial proximity to the query points. The interpolated value for site S_i at time T_j, $I(S_i, T_j)$ is computed as follows:

$$I(S_i, T_j) = \frac{\sum_{k=1,k\neq i}^{m} O(S_k, T_j) \cdot \omega_k}{\sum_{k=1,k\neq i}^{m} \omega_k}, \quad (1)$$

where m is the number of monitoring sites and ω_s is calculated as follows:

$$\omega_k = \begin{cases} \frac{1}{r_k^2} & if \quad r_k \leq d \\ 0 & if \quad r_k > d \end{cases} \quad (2)$$

Table 1. Example of publicity accessible database for air pollution data

Network	Locations	Parameters	Time Range	Sources
AIRS-Gaseous	United States (U.S.)	O_3, CO, SO_2, NO_2, PM Mass concentrations	1990-present	AIRS/AQS http://www.epa.gov/ttn/airs/airsaqs/
PAMS, AIRS-Gaseous	U.S. Ozone Nonattainment area	O_3, NO_2, NO_X, Nitric Acid	1994-present	Same as AIRS-Gaseous
AIRS-Speciated	U.S.	$PM_{2.5}$ Mass Concentration, Speciated Aerosol	2001-present	Same as AIRS-Gaseous
SEARCH - Continuous	Southeastern U.S.	$PM_{2.5}$ Mass Concentration, Speciated Aerosol, Gaseous, Surface Meteorology	1998-present	http://www.atmospheric-research.com/public/index.html
SEARCH - 24 hour	Southeastern U.S.	$PM_{2.5}$ Mass Concentration, Speciated Aerosol	1998-present	Same as SEARCH-Continuous

r_k is the distance from site S_i to site S_k at time T_j and d can be specified by the users. Thus, $I(S_i, T_j)$ is the weighted average value observed in the surrounding m sites in which the weights are determined by the way that observations in close spatial proximity are given more weight than those that are spatially separated.

Other approaches for processing outliers and missing values include functional or maximum likelihood imputation schemes. Polynomial functions and splines can be used to interpolate regularly-spaced data. Maximum likelihood, which typically requires high computation, uses an iterative approach based on model parameter estimation. Examples of this approach include Expectation-Maximization (Schafer, 1997) and kriging (Stein, 2006).

Explanatory Analysis and Visualization

The main purpose of exploratory analysis and visualization is to provide initial guidelines that enable the subsequent analyses to be more efficient. Principal component analysis (PCA) is a multivariate data analysis technique that helps reduce the dimension of a data set via an orthogonal linear transformation (Jolliffe, 2002). The transformed variables, called principal components (PCs) are uncorrelated, and generally, the first few PCs are sufficient to account for most of variability of the entire data. Thus, plotting the observations with these reduced dimensions facilitates the visualization of high-dimensional data. PCA has been used in a variety of air pollution applications, for example, Tilmes & Zimmermann (1998) and Abdul-Wahab & Al-Alawi (2002). Lengyel et al. (2004) observed the diurnal pattern (day and night) of tropospheric ozone concentrations using reduced dimensions in PCA. Lehman et al. (2004) applied a rotated PCA approach to study the spatial and temporal variability of tropospheric ozone concentrations in the eastern United States.

Correspondence analysis is another useful explanatory technique that analyzes the relationship between two or more categorical variables. Correspondence analysis examines the contingency table containing the frequency data to investigate how it deviates from expectation assuming the columns and rows are independent (Johnson & Wichern, 2002). Similar to PCA, correspondence analysis provides low-dimensional data that facilitate the visualization of the association in multiple levels in contingency tables. Multiple cor-

respondence analysis that extends to the case of more than three categorical variables was used to examine the relationship between nitrogen dioxide exposure levels and related qualitative variables (Piechocki-Minguy et al., 2006).

Model Construction

Data mining tools for constructing models can be divided into two categories, supervised and unsupervised approaches. Supervised approaches require both the explanatory variable and the response variable, while unsupervised approaches rely solely upon the explanatory variables. Time series analysis is one of the classical supervised approaches for analyzing the data, collected over time. Numerous studies have used time-series analysis to investigate and predict the behavior of air pollution (Lehman et al., 2004; Shi & Harrison, 1997). Recently, Chelani and Devotta (2006) proposed a hybrid autoregressive integrated moving average (ARIMA) model that combined the Box and Jenkins ARIMA model with nonlinear dynamical modeling to forecast nitrogen dioxide concentrations.

Regression analyses aim to build the models based on the relationship between the explanatory and response variables. Regression analysis has been applied to identify the representative monitoring locations (Goswami, Larson, Lurnley, & Liu, 2002), and to predict a variety of air pollutant concentrations (Davis & Speckman, 1999; Lengyel et al., 2004). Artificial neural networks have also been widely used for predicting ozone concentrations in different locations around the world (e.g., Abdul-Wahab & Al-Alawi, 2002; Wang, Lu, Wang, & Leung, 2003).

Unsupervised approaches aim to extract the information purely from the explanatory variables. Although visualization techniques elicit the natural groupings of the observations, the interpretation of graphical results is not necessarily straightforward. Clustering analysis is an unsupervised approach that systematically partitions the observations by minimizing within-group variations and maximizing between-group variations, then assigning a cluster label to each observation. Numerous clustering methods have been introduced for grouping air pollution data (Gramsch, Cereceda-Balic, Oyola, & Von Baer, 2006; Oanh, Chutimon, Ekbodin,

Table 2. Performance measurement for model

Performance Measurement	Equation
Mean Biased (mg/m³)	$MB = \frac{1}{m*n}\sum_{j=1}^{n}\sum_{i=1}^{m}\left[O_f(S_i,T_j) - O_a(S_i,T_j)\right]$
Mean Error (mg/m³)	$MB = \frac{1}{m*n}\sum_{j=1}^{n}\sum_{i=1}^{m}\left\|O_f(S_i,T_j) - O_a(S_i,T_j)\right\|$
Root Mean Square Error (mg/m³)	$RMSE = \sqrt{\frac{1}{m*n}\sum_{j=1}^{n}\sum_{i=1}^{m}\left[\left(O_f(S_i,T_j) - O_a(S_i,T_j)\right)^2\right]}$
Mean Normalized Bias (%)	$MNB = \frac{1}{m*n}\sum_{j=1}^{n}\sum_{i=1}^{m}\left[\frac{O_f(S_i,T_j) - O_a(S_i,T_j)}{O_a(S_i,T_j)}\right]$
Mean Normalized Error (%)	$MNE = \frac{1}{m*n}\sum_{j=1}^{n}\sum_{i=1}^{m}\left\|\frac{O_f(S_i,T_j) - O_a(S_i,T_j)}{O_a(S_i,T_j)}\right\|$
Root Mean Square Normalized Error (%)	$RMSNE = \sqrt{\frac{1}{m*n}\sum_{j=1}^{n}\sum_{i=1}^{m}\left[\left(\frac{O_f(S_i,T_j) - O_a(S_i,T_j)}{O_a(S_i,T_j)}\right)^2\right]}$

$O_f(S_i, T_j)$: Fitted value from the model, $O_a(S_i, T_j)$: Actual value, m: Total number of monitoring sites, n: Total number of time points.

& Supat, 2005); however, no consensus exists about the best method to satisfy all conditions. A previous study applied the *k*-means clustering algorithm with Euclidean distance to sulfur dioxide data from 30 sites in the eastern United States. They obtained six clusters in which the sites within a cluster have a similar pattern of meteorological factors and sulfur dioxide levels (Holland, Principe, & Sickles, 1999).

Model Evaluation

The significance of constructed models should be evaluated for predicting the future behavior of air pollution. The basic approach for model evaluation is to separate data into two data sets, a training set and a testing set. The training set is used to construct the models and these models are then evaluated by their prediction ability on the testing set. Prediction errors typically measure the difference between the actual and fitted values. Table 2 lists the frequently used model performance evaluation measures for air pollution modeling.

CASE STUDIES

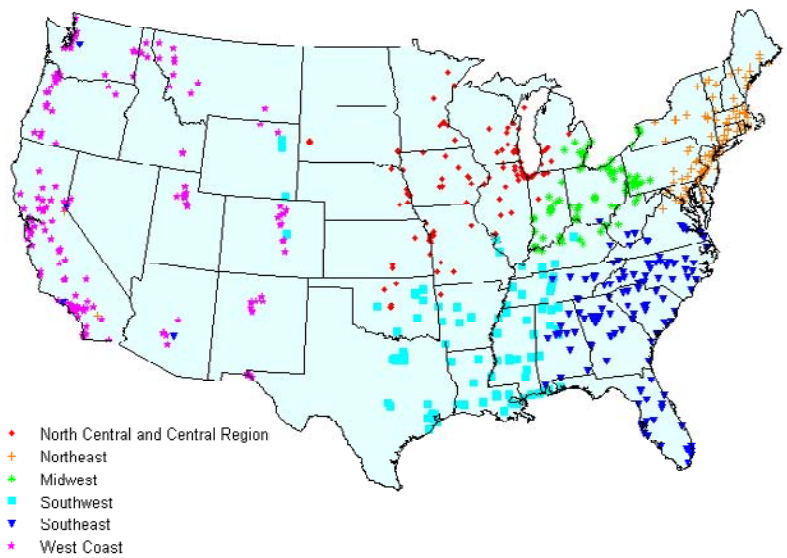
The main purpose of the case studies is to demonstrate how five stages of data mining process described above can be applied in real air pollution problems through the following two small examples.

Clustering Analysis of $PM_{2.5}$ Concentrations over the Continental United States

The purpose of this case study is to characterize spatial variations of $PM_{2.5}$ concentrations at 789 monitoring sites across the continental United States based solely upon their temporal patterns. Monitoring data were obtained from the Environmental Protection Agency's Aerometric Information Retrieval System (EPA-AIRS) database, which contains 24-hour average $PM_{2.5}$ concentrations measured every third day during 2000 (from January 2000 to December 2000) at 789 monitoring sites in the continental United States. Outliers and missing values were imputed in the data preprocessing step using the inverse-distance-squared weighted method (McNair et al., 1996).

A *k*-means clustering method was used to characterize the spatial variations of $PM_{2.5}$ concentrations based upon their temporal patterns. The results of the *k*-means clustering algorithm depend on the distance metrics and the number of clusters (*k*). For the distance metric, we used the correlation distance that allows us to measure the similarity in shape between the two temporal profiles

Figure 2. k-means clustering results (k=6) for the continental United States



from each monitoring site. We denote $Z(S_i, T_j)$ by the $PM_{2.5}$ concentration for monitoring site S_i at time T_j. Then, for the monitoring sites *x* and *y*, the correlation distance of two temporal profiles that consist of a series of *J* time points can be computed as follows:

$$D_{[Z(S_x,T_j),Z(S_y,T_j)]} = \frac{1}{J}\sum_{i=1}^{J}\left(\frac{Z(S_x,T_j)-\overline{Z}_{s_x}}{\sigma_{Z_{s_x}}}\right)\left(\frac{Z(S_y,T_j)-\overline{Z}_{s_y}}{\sigma_{Z_{s_y}}}\right), \quad (3)$$

where

$$\overline{Z}_{s_x} = \frac{1}{J}\sum_{j=1}^{J} Z(S_x,T_j) \text{ and } \sigma_{Z_{Sx}} = \left(\frac{1}{J}\sum_{j=1}^{J}\left(Z(S_x,T_j)-\overline{Z}_{s_x}\right)^2\right)^{1/2}. \quad (4)$$

To determine *k*, we used a heuristic approach that minimizes the variability within the same group and found the optimal number for *k* was six. The results of six-means clustering analysis are displayed on the U.S. map (Figure 2). It is seen that the monitoring sites in close spatial proximity are grouped together, demonstrating the identification of spatially homogeneous regions based on the temporal patterns of $PM_{2.5}$ concentrations.

The clustered sites can be grouped according to the following ad-hoc categories chosen by geographical locations, with the number of monitoring sites in each cluster indicated in parentheses: (1) North Central & Central Region (145); (2) Northeast (137); (3) Midwest (106); (4) Southwest (101); (5) Southeast (139); and (6) West (161).

Prediction of Ozone Concentration in the Dallas-Fort Worth Area

This case study attempts to investigate the behavior of daily maximum 8-hour ozone concentrations measured at 15 monitoring sites in the Dallas-Fort Worth (DFW) area from June 1, 2002 to May 31, 2006. Regression trees were developed to study how meteorological variables impact ozone concentrations. Monitoring data were obtained from the database maintained by the Texas Commission on Environmental Quality (TCEQ; http://www.tceq.state.tx.us), which contains daily maximum 8-hour ozone concentrations and meteorological variables from June 1, 2002 to May 31, 2006 at 15 monitoring sites in the DFW area. Missing values were imputed using inverse-distance-squared weighted method. The explanatory variables in a tree model include maximum wind gust, outdoor temperature, resultant wind direction, resultant wind speed, solar radiation, standard deviation of horizontal direction, wind speed, resultant wind speed from south to north, resultant wind speed from west to east, standard deviation of wind from south to north, and standard deviation of wind from west to east.

Regression tree analyses were conducted using the Classification and Regression Tree (CART) software (http://www.salfordsystems.com/). The actual derived tree is not shown here due to its size (the number of terminal nodes = 15). As an example, we obtained the following rule from one of the terminal nodes in the derived regression tree: "If the solar radiation was higher than 0.23 langleys per minute, ozone concentration lag 1 greater than 44.23 ppb, and speed less than 5.13 mph, the average ozone concentration is 64.292ppb (with standard deviations 10.244)." CART software provides "variable importance scores." The variable that receives a 100 score indicates the most influential variable for prediction, followed by other variables based on their relative importance to the most important one. The result shows that the ozone with single time lag, which addresses the serial correlation in ozone, is most important, followed by the solar radiation variables. It is interesting to note that for the solar radiation and temperature variables, both the single time lag and no time lag are important. This indicates a time-lagged effect of these variables affects the current ozone concentration. In other words, ozone concentration in the current day is impacted by the solar radiation and temperature in the previous day.

FUTURE TRENDS

Statistical analyses for time series or spatial data have been widely used to investigate the behavior of ambient air pollutants. Because air pollution data are generally collected over time at monitoring stations of interest, the analysis should simultaneously consider both spatial and temporal information. Despite numerous analytical tools available to analyze spatial or time series data separately, the appropriate procedures for analysis of spatio-temporal data are still lacking (Gryparis, Coull, Schwartz, & Suh, 2007; Schabenberger &

Gotway, 2005). Various data mining techniques can play an important role to identify inherent patterns in spatio-temporal data and help establish reliable models to understand the behavior of ambient air pollution. Further, the optimization of control strategies to reduce air pollution will rely on efficient and accurate models relating how the relevant variables change over time and space; thus, the role of data mining has significant potential for improving air quality in the future (Yang, Chen, Chang, Murphy, & Tsai, 2007).

CONCLUSION

Data mining techniques provide efficient approaches for investigating the behavior of ambient air pollution problems. This chapter provides an overview of the data mining process in air pollution modeling. This data mining process could also be applied to other application areas with spatial and temporal monitoring data, such as process control on semiconductor, water quality, meteorological studies, and airborne bioterrorism. Data mining applications along with two real case studies were discussed. Further analysis tools that consider spatial and temporal properties simultaneously are still needed.

Clustering Analysis: Clustering analysis systematically partitions the observations by minimizing within-group variations and maximizing between-group variations, then assigning a cluster label to each observation.

Principal Component Analysis (PCA): PCA is a multivariate data analysis technique primarily for dimensional reduction and visualization. PCA creates new variables based on orthogonal transformations of the original variables.

Regression Tree: Regression trees partition the input variable space into disjoint hyper-rectangular regions and fit a model that predicts the response variable with a constant value.

Spatial Analysis: The systematic approach to understand the nature of geographic data.

Supervised Learning Approach: The process of establishing models based on both the input and output variables.

Time-Series Analysis: The statistical analysis to understand a sequence of data points collected over time and predicts future events.

Unsupervised Learning Approach: A modeling process that depends only on input variables but does not take into account the information from the response variable.

Spectral Methods for Data Clustering

Wenyuan Li
Nanyang Technological University, Singapore

Wee Keong Ng
Nanyang Technological University, Singapore

INTRODUCTION

With the rapid growth of the World Wide Web and the capacity of digital data storage, tremendous amount of data are generated daily from business and engineering to the Internet and science. The Internet, financial real-time data, hyperspectral imagery, and DNA microarrays are just a few of the common sources that feed torrential streams of data into scientific and business databases worldwide. Compared to statistical data sets with small size and low dimensionality, traditional clustering techniques are challenged by such unprecedented high volume, high dimensionality complex data. To meet these challenges, many new clustering algorithms have been proposed in the area of data mining (Han & Kambr, 2001).

Spectral techniques have proven useful and effective in a variety of data mining and information retrieval applications where massive amount of real-life data is available (Deerwester et al., 1990; Kleinberg, 1998; Lawrence et al., 1999; Azar et al., 2001). In recent years, a class of promising and increasingly popular approaches — spectral methods — has been proposed in the context of clustering task (Shi & Malik, 2000; Kannan et al., 2000; Meila & Shi, 2001; Ng et al., 2001). Spectral methods have the following reasons to be an attractive approach to clustering problem:

- Spectral approaches to the clustering problem offer the potential for dramatic improvements in efficiency and accuracy relative to traditional iterative or greedy algorithms. They do not intrinsically suffer from the problem of local optima.
- Numerical methods for spectral computations are extremely mature and well understood, allowing clustering algorithms to benefit from a long history of implementation efficiencies in other fields (Golub & Loan, 1996).
- Components in spectral methods have the naturally close relationship with graphs (Chung, 1997). This characteristic provides an intuitive and semantic understanding of elements in spectral methods. It is important when the data is graph-based, such as links of WWW, or can be converted to graphs.

In this paper, we systematically discuss applications of spectral methods to data clustering.

BACKGROUND

To begin with the introduction of spectral methods, we first present the basic foundations that are necessary to understand spectral methods.

Mathematical Foundations

Data is typically represented as a set of vectors in a high-dimensional space. It is often referred as the matrix representation of the data. Two widely used spectral operations are defined on the matrix.

- EIG(A) operation: Given a real symmetric matrix $A_{n\times n}$, if there is a vector $x \in R^n \neq 0$ such that $Ax=\lambda x$ for some scalar λ, then λ is called the eigenvalue of A with corresponding (right) eigenvector x. EIG(A) is an operation to compute all eigenvalues and corresponding eigenvectors of A. All eigenvalues and eigenvectors are real, that is, guaranteed by Theorem of real schur decomposition (Golub & Loan, 1996).
- SVD(A) operation: Given a real matrix $A_{m\times n}$, similarly, there always exists two orthogonal matrices $U \in R^{m\times m}$ and $V \in R^{n\times n}$ ($U^TU= I$ and $V^TV=I$) to decompose A to the form $A=USV^T$, where $S = \text{diag}(\sigma_1, ..., \sigma_r) \in R^{r\times r}$, r=rank(A) and $\sigma_1 \geq \sigma_2 ... \geq \sigma_r = ... = \sigma_n = 0$. Here, the σ_i are the singular values of A and the first r columns of U and V are the left and right (respectively) singular vectors of A. SVD(A) is called Singular Value Decomposition of A (Golub & Loan, 1996).

Typically, the set of eigenvalues (or singular values) is called the spectrum of A. Besides, eigenvectors (or

singular vectors) are the other important components of spectral methods. These two spectral components have been widely used in various disciplines and adopted to analyze the key encoding information of a complex system. Therefore, they are also the principle objects in spectral methods for data clustering.

Transformations

As observed by researchers, two key components of spectral methods — eigenvalues and eigenvectors — scale with different matrices. Therefore, before the analysis and application of them, some transformations, or more exactly, normalizations of two spectral components are needed. Although this might look a little complicated at first, this way to use them is more consistent with spectral geometry and stochastic processes. Moreover, another advantage of normalized components is due to its better relationship with graph invariants while the raw components may fail to do. There are three typical transformations often used in spectral methods.

- Laplacian: Given a symmetric matrix $A=(a_{ij})_{n\times n}$ with $a_{ij}\geq 0$, we define Laplacian $L_A=(l_{ij})_{n\times n}$ of A as

$$l_{ij}=\begin{cases}1-\dfrac{a_{ij}}{d_i}. & \text{if } i=j\\ -\dfrac{a_{ij}}{\sqrt{d_i d_j}}. & \text{if } a_{ij}\neq 0\\ 0. & \text{otherwise}\end{cases}$$

  The spectral graph theory takes this transformation (Chung, 1997).
- Variant of Laplacian: Given a symmetric matrix $A=(a_{ij})_{n\times n}$ with $a_{ij}\geq 0$, we define the variant of Laplacian $T_A=(t_{ij})_{n\times n}$ of A to be $T_A=D^{-1/2}(S-I)D^{-1/2}$. It can be easily proved that $L_A+T_A=2I$. This transformation of the matrix is often used (Li et al., 2004; Ng et al., 2001).
- Transition (or Stochastic) Matrix: Given a symmetric matrix $A=(a_{ij})_{n\times n}$ with $a_{ij}\geq 0$, we define the transition matrix $P_A=(p_{ij})_{n\times n}$ of A satisfying $p_{ij}=a_{ij}/d_i$ so that the sum of each row is 1. Apparently, P is a stochastic matrix, in the sense that it describes the transition probabilities of a Markov chain in the natural way.

In the definitions of these three matrices, $d_i=\sum_j a_{ij}$ is the sum of the i-th row vector and $D=\mathrm{diag}(d_1, \ldots, d_n)$. These three matrices have real eigenvalues and eigenvectors. Moreover, the eigenvalues of Laplacian and the transition matrix lie in [0, 2] and [-1, 1], respectively. We can easily deduce from the relationship between L_A and T_A to obtain $\mathrm{SPECTRUM}(T_A)=\{1-\lambda \mid \lambda\in \mathrm{SPECTRUM}(L_A)\}$, where SPECTRUM(•) represents the set of eigenvalues of a matrix. Hence, the eigenvalues of T_A lie in [-1, 1] and all the conclusions and properties of L_A are also applicable to T_A. Moreover, L_A and T_A have the same eigenvectors.

Relations to Graph

As a graph is represented by its adjacency matrix, there is a close relationship between the graph and the spectral components of its adjacency matrix. It is a long history to explore the fundamental properties of a graph from the view of the spectral components of this graph's adjacency matrix in the area of mathematics. Especially, eigenvalues are closely related to almost all major invariants of graphs and thus, play a central role in the fundamental understanding of graphs. Based on this perspective, spectral graph theory has emerged and rapidly grown in recent years (Chung, 1997). Hence, many characteristics of spectral components of a matrix can be intuitively explained in terms of graphs and meanwhile graphs also can be analyzed from its spectral components. A notable case is the authority and hub vertices of the Web graph that is important to Web search as shown in HITS algorithm (Kleinberg, 1998). Another example is that the spectrum of the adjacency matrix of a graph can be analyzed to deduce its principal properties and structure, including the optimization information about cutting a graph. This view has been applied to discover and predict the clustering behavior of a similarity matrix before the actual clustering is performed (Li et al., 2004).

MAIN THRUST

Spectral Analysis for Preprocessing of Data Clustering

In clustering, one common preprocessing step is to capture or predict the characteristic of target data set before the clustering algorithm is performed. Here, the spectral analysis of a data set is introduced to predict the clustering behavior before the actual data clustering. Investigating the clustering process as shown in Jain et al. (1999), an assumption is concluded that the *feature set*, and *similarity measure* embody intrinsic knowledge of the clustering domain. Data clustering algorithms are greatly dependent on the similarity matrix. Therefore, the similarity matrix can be the principal object to be considered for decoding clustering information of the data set.

Given the similarity matrix $S=(s_{ij})_{n\times n}$, we define $G(S)=<V, E, S>$ as its associated graph where V is the set of n vertices and E is the set of weighted edges. In this graph, each vertex v_i corresponds to the i-th column (or row) and the weight of each edge (v_i,v_j) corresponds to the non-diagonal entry s_{ij}. In G(S), a large weight value between two vertices represents high connectivity between them, and vice versa. In order to analyze the clustering behaviors of G(S), we employ the variant of the Laplacian T_S as the transformation of S. T_S has n eigenvalues with decreasing order $\lambda_1 \geq \lambda_2 \ldots \geq \lambda_n$, which are also called the G(S) spectrum. Two observations of the G(S) spectrum for the clustering behavior of S were found (Li et al., 2004). They indicate the relationships between the clustering behavior of S and the principal properties and structure of G(S).

1. If λ_2 is higher, there exists a better bipartition for S.
2. For the sequence

   $$\alpha_i = \frac{\lambda_i}{\lambda_2} (i \geq 2),$$

   $\exists k \geq 2$, it has $\alpha_i \rightarrow 1$ and $\alpha_i - \alpha_{i+1} > \delta$ $(1 < \delta < 1)$, then k indicates the cluster number of the data set.

They can be accounted for by spectral graph theory. The partition and connectivity of G(S) correspond in a natural way to the clustering behavior of S. Thus, through the analysis of the G(S) spectrum, we can infer details about the partition and connectivity of the graph G(S), and then obtain the clustering behavior of S. Next, we introduce the Cheeger constant, which is important in the understanding of properties and structure of G(S) (Chung, 1997). It is a typical value to measure the goodness of the optimal bipartition for a graph. Therefore, h(G) is an appropriate measure to indicate the clustering quality of the bipartition in G(S): The lower h(G) is, the better the clustering quality of the bipartition in G(S). Given the relationship between the bipartition and Cheeger constant, we have the so-called Cheeger inequality (Chung, 1997):

$$\frac{1-\lambda_2}{2} \leq h(G) \leq \sqrt{2(1-\lambda_2)}$$

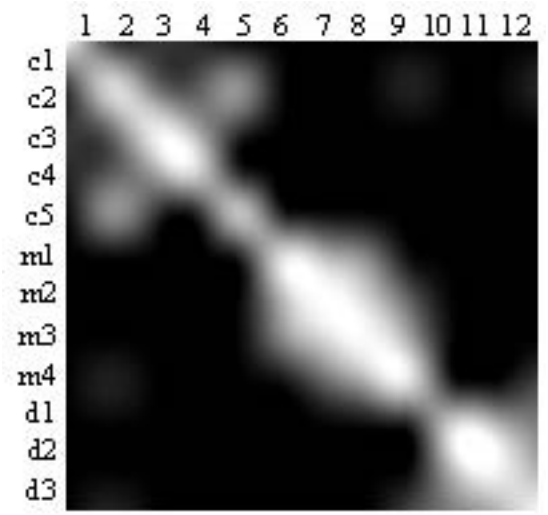
The inequality gives the bounds of h(G) by λ_2. It shows that if λ_2 is high enough to approach 1, h(G) will be very low; this indicates that there exists a good bipartition in G(S). Then we obtain Observation (1). Generally speaking, the above conclusion for G(S) is also applicable to its induced subgraphs G(S_i). Similarly, λ_2 of G(S_i) shows the clustering quality of the bipartition in G(S_i). Then we obtain Observation (2). Li et al. provided details of the theoretical and empirical results of these observations (2004).

Spectral Clustering Algorithms

Information within the spectral components is very indicative of the clustering results in the process of clustering algorithms. The intuition behind the spectral methods can be shown in the following simple example.

This example is from the example of text data when Landauer (1998) introduced LSA (p. 10). Here, we add three more passages. It uses as text passages the titles of twelve technical memoranda: five about human computer interaction (HCI), four about mathematical graph theory, and three about clustering techniques. Their topics are conceptually disjoint. We manually selected the italicized terms as the feature set and used the cosine similarity measure to compute the similarity matrix, as shown in gray scale image in *Figure 1*. The shade of each point in the image represents the value of the corresponding entry in similarity matrix. In this figure, we can see that the first, second and third diagonal blocks (white ones) correspond to the topics "HCI," "graph," and "clustering" respectively,

Figure 1. Gray scale image of the similarity matrix



while off-diagonal area shows the disjointed features of these topics.

Based on the theoretical analysis of Observation (1), the second eigenvector of the similarity matrix indicates its clustering behavior. Therefore, unlike the investigation of λ_2, we examine the eigenvector x_2, corresponding to λ_2. Certainly, the similarity needs to be transformed. After transformations, the second eigenvectors of its Laplacian and transition matrix are illustrated in *Figures 2* and *3*, respectively.

In figures, we can clearly see that the second eigenvector assigns large negative weights on the first five coordinates, large positive weights on the following four coordinates and nearly zero weights on the last three coordinates. This result is exactly identical to our class labels in *Table 1*.

This example clearly shows how the information of eigenvectors indicates the clustering behavior of a data set. In general, the eigenvectors corresponding to large eigenvalues tend to capture global clustering characteristics of a data set. Therefore, according to these intuitive observations, clustering algorithms based on spectral components can be classified into two types.

- **Recursive type:** The algorithms divide data points into two partitions based on a single eigenvector (for example, the second eigenvector) and then recursively divide each sub-partitions in the same way to find the optimum partitions.
- **Multiway type:** The algorithms use more information in multiple eigenvectors to do a direct partition of data.

Next, we will review four typical spectral clustering algorithms.

- The Shi & Malik algorithm (Shi & Malik, 2000): This algorithm was proposed as a heuristic algorithm to minimize the *normalized cut* criterion for graph partitioning in the area of image segment. Given a graph G=(V, E), the normalized cut between two sets $A \cup B = V$, $A \cap B = \varnothing$ is defined as

Figure 2. Coordinates of the second eigenvector in Laplacian

$$\mathrm{Ncut}(A,B) = \frac{\mathrm{cut}(A,B)}{\mathrm{vol}(A)} + \frac{\mathrm{cut}(A,B)}{\mathrm{vol}(B)}$$

where the vertex set V is partitioned into two clusters A and B so that Ncut(A,B) over all two way partitions of V is minimized. This problem is proved to be NP-hard. However, Shi & Malik show that the spectral algorithm may find optimum under some special condition. Specifically, it uses the second eigenvector of the transition matrix P_S to do bipartition. This algorithm is a kind of recursive type.

- The Kannan, Vempala, & Vetta algorithm (Kannan et al., 2000): This algorithm is similar to the Shi & Malik algorithm except a key point. It uses Cheeger constant as defined in the above section to be the criterion of bipartition and the second eigenvector of the transition matrix P_S to do bipartition. Therefore, this algorithm is also one of recursive spectral clustering algorithms.
- The Meila & Shi algorithm (Meila & Shi, 2001): This algorithm is of multiway type. It first transforms the similarity matrix S to be the transition matrix P_S. Then it computes $x_1, x_2, \ldots, x_k$, the eigenvectors of P_S corresponding to the first k largest eigenvalues and generates the matrix X=[$x_1, x_2, \ldots, x_k$]. Finally it applies any non-spectral clustering algorithm to cluster rows of X as points in a k-dimensional space.
- The Ng, Jordan, & Weiss algorithm (Ng et al., 2001): This algorithm is also a kind of multiway type. It uses the variant of Laplacian matrix T_S in the transformation step. Then it computes $x_1, x_2, \ldots, x_k$, the eigenvectors of P_S corresponding to the first k largest eigenvalues and generates the matrix X=[$x_1, x_2, \ldots, x_k$]. After obtaining the matrix Y by normalizing each of X's rows to have unit length

  (i.e $y_{ij} = x_{ij} / \sqrt{\sum_j x_{ij}^2}$).

  Finally, treating each row of Y as a point in k dimensions, it clusters them by k-means clustering algorithm.

Although there are various spectral clustering algorithms, they have largely common steps and theoretical proofs: (1). All need the transformation of the similarity matrix S before the actual clustering. And they may use L_S, T_S or P_S. (2). Eigenvectors of the transformed matrix are undoubtedly used as the important data for clustering. The use of eigenvectors is also the reason why they are called spectral clustering algorithms. (3). The underlying theory of these algorithms is based on the optimization problem of graph cut. And the criterions of bipartition of the graph are introduced to prove the possible optimum solution given by eigenvectors.

FUTURE TRENDS

There is a close relationship between spectral components and a notable phenomenon frequently occurring in real-world data – power law. Distributions in much

real-life data from nature and human social behaviors, including city sizes, incomes, earthquake magnitudes, even the Internet topology, WWW and collaboration networks, which are composed of a large number of common events and a small number of rarer events, often manifest a form of regularity in which the relationship of any event to any other in the distribution scales in a simple way (Zipf, 1949; Malamud et al., 1998; Faloutsos et al., 1999; Barabási et al., 2000; Albert, 2001; Kumar et al., 2000). In essence, such distribution can be generalized as the power law, which is often represented by log-linear relations. Considering the ubiquity of power law in the real-world data, there has been a recent surge of interest in graphs whose degrees have the power-law distribution, because these graphs are often derived from real-life data. As we have discussed, spectral methods have close relationships with graphs, an intriguing problem naturally arising is: Does power-law in graphs affect the spectral methods? Actually, the eigenvalues of such graphs also follow power law, but with a little lower exponent than that of degrees (Mihail & Papadimitriou, 2002). Meanwhile, they pointed out that, "The effectiveness of several of the SVD-based algorithms requires that the underlying space has low rank, that is, a relatively small number of significant eigenvalues. Power laws on the statistics of these spaces have been observed and are quoted as evidence that the involved spaces are indeed low rank and hence spectral methods should be efficient" (Mihail & Papadimitriou, 2002, p. 8). However, this is the beginning of research on how is the effectiveness of spectral methods on real-world data. More experiments and theoretical analysis are needed.

CONCLUSION

Spectral techniques based on the analysis of the largest eigenvalues and eigenvectors have proven algorithmically successful in detecting semantics and clusters in graphs and some real-world data. In PageRank and HITS algorithms (Lawrence et al., 1999; Kleinberg, 1998), only the first eigenvector is considered and mined. In spectral clustering algorithms, the second eigenvector is proved to indicate more information about clustering behaviors in the targeted data set. However, it is worth noting that the empirical results of most spectral clustering algorithms discussed above are limited to the small or synthetic data set, not for the large scale and real-life data sets. Spectral methods shall be applied to more areas and compared with other existing methods.

KEY TERMS

Adjacency Matrix: A matrix representing a graph with n vertex. It is an n-by-n array of Boolean values with the entry in row u and column v defined to be 1 if there is an edge connecting vertex u and v in the graph, and to be 0 otherwise.

Graph Invariants: Quantities to characterize the topological structure of a graph. If two graphs are topologically identical, they have identical graph invariants.

HITS Algorithm (Hypertext Induced Topic Selection): A Web search technique for ranking Web pages according to relevance to a particular search term or search phrase. Two concepts, "authority" and "hub," are proposed to characterize the importance of each Web page.

Markov Chain: A finite state machine with probabilities for each transition, that is, a probability that the next state is s_j given that the current state is s_i.

PageRank Algorithm: A Web search technique for ranking Web pages according to relevance to a particular search term or search phrase. Based on the random surfer model and Web graph, the index, PageRank, is proposed to rate the importance of each Web page to users.

Power Law Distribution: A probability distribution function, $P[X=x]\sim cx^{\pm}$, where constants $c>0$ and $\pm>0$, and $f(x)\sim g(x)$ represents that the limit of the ratios goes to 1 as x grows large.

Spectral Graph Theory: A theory on the study of the eigenvalue properties of Laplacian matrix of a graph.

Stages of Knowledge Discovery in E-Commerce Sites

Christophe Giraud-Carrier
Brigham Young University, USA

Matthew Smith
Brigham Young University, USA

INTRODUCTION

With the growth and wide availability of the Internet, most retailers have successfully added the Web to their other, more traditional distribution channels (e.g., stores, mailings). For many companies, the Web channel starts off as little more than an online catalog tied to a secure electronic point of sale. Although valuable in its own right, such use of the Web falls short of some of the unique possibilities it offers for intelligent marketing. Consider the following intrinsic differences between physical, brick-and-mortar stores, and online, Web-based stores. Physical stores are rather static and mostly customer-blind. In particular, 1) the store's layout and content are the same for all customers, 2) changes to layout and/or content are generally costly, and 3) visits are not traceable except for limited sale's data, such as what was bought, when it was bought and by what method of payment. Online stores or commercial Web sites, on the other hand, are naturally dynamic and customer-aware. Indeed, 1) layout and content can be modified easily and cheaply, 2) layout and content can be tailored to individual visitors, and 3) every visit automatically generates a rich trail of information about the customer's experience (e.g., visit duration, pages viewed, items bought if any, etc.), and possibly about the customer's persona (e.g., demographics gathered through an online questionnaire at registration time).

With such flexibility and nearly everything traceable and measurable, the Web is a marketer's dream come true. Although data-independent initiatives, such as offering social interactions (e.g., user forums) or providing virtual versions of physical stores (e.g., displays, lighting, music) (Oberbeck, 2004), can clearly enhance the user experience, the full benefit of the emerging and growing Web channel belongs to those who both gather and adequately leverage the rich information it provides.

BACKGROUND

Web mining emerged in the late 1990's as the branch of data mining concerned with the mining of data and structure on the Web. As pointed out early in the game, the transfer from traditional data mining to mining on the Web is not without significant challenges (Monticino, 1998; Spiliopoulou, 1999). Yet, many business analysts were just as quick to argue that the potential benefits far outweigh the costs (Greening, 2000; Edelstein, 2001), and researchers began developing specialized techniques and tools (Spiliopoulou & Pohle, 2001).

There have traditionally been three sub-areas of Web mining, based upon the type of data being mined: Web usage mining focuses on extracting information from users' interactions with a Web site; Web content mining focuses on extracting knowledge from the textual (and more recently, multimedia) content of Web pages; and Web structure mining focuses on discovering patterns of connection among Web pages (Kosala & Blockeel, 2000). A number of survey papers and texts have been dedicated to descriptions of various Web mining techniques and applications, as well as relevant research issues (Han & Chang, 2002; Kolari & Joshi, 2004; Scime, 2005; Liu, 2007).

In this chapter, we depart a little from this research-oriented approach. Indeed, we do not discuss the different types of data that may be mined on the Web, but rather highlight stages in the analysis of Web data, from simplest to most elaborate, so that business users may appreciate the potential of such analysis and have an implementation roadmap. At each stage, different

types of data (usage, content and structure) may be, and indeed are, used.

MAIN FOCUS

In the context of e-commerce, Web mining lends itself naturally to a staged approach, where moving from one stage to the next requires increasing sophistication, but also produces increasing return-on-investment. The first stage is limited to the analysis of the direct interaction of the user with the site; the second stage introduces behavioral information; and the third stage enables personalization of the user's experience. We examine each in turn.

Stage 1: Clickstream Analysis

The amount of data found in Web server logs is enormous and clearly evades direct human interpretation. Yet, it is rich in potential, making Web server logs the readiest source of data to analyze on a Web site (Srivastava et al., 2000; Fu et al., 2000; Moe & Fader, 2004). Web log analysis tools, such as AWStats, The Webalizer, SiteCatalyst, ClickTracks, Google Analytics, and NetTracker have been designed specifically to summarize and interpret Web server log data, allowing marketers to gain basic knowledge about e-commerce customers' activities, including unique number of visitors and hits, visit duration, visitors' paths through the site (i.e., clickstream), visitors' host and domain, search engine referrals, robot or crawler visits, visitors' browser and operating system, and search keywords used. These clickstream analysis reports may provide insight into business questions such as:

- Where do most visitors come from?
- What proportion of visitors come from a direct link or bookmark, a search engine, or a partner Web site (if any)?
- Which search engines (e.g., Google, Yahoo, MSN, etc.) and search terms are most frequently used?
- How long do visitors stay on the Web site?
- How many pages do visitors see on average?
- Which pages are most popular?
- How does Web site activity evolve throughout the day, week or month?
- From which pages do visitors commonly exit the Web site?

This information in turn helps e-retailers better understand the dynamics of customers' interactions with online offerings, and aids in such decisions as: which referrer to invest in, which pages to remove or replace, which pages to improve, etc. For instance, if clickstream analysis shows that a substantial number of visitors are accessing content several clicks deep into the Web site, then it might be valuable to make that content more accessible to visitors (e.g., maintaining and linking to "Top Sellers," "Most Wished for Items," or "Most Popular Items" pages on the home page).

Stage 2: Behavior Analysis

In general, transactional data and order information are not stored directly in standard Web server logs. Yet, both are essential in discovering patterns of buying and non-buying customers. The next stage of knowledge discovery requires linking clickstream data to order information. With adequate design, a host of new business-relevant questions may be answered when the front-end clickstream data is linked to, and mined together with, the back-end transactional data, allowing marketers to take further control of their e-commerce activity (Mobasher et al., 1996; Gomory et al., 1999; Rusmevichientong et al., 2004). The following are a few classical examples.

- What is the conversion rate (i.e., how many Web site visitors become buying customers)?
- How many would-be customers begin shopping (i.e., partially filling up their shopping cart) but drop out before proceeding to or completing check-out?
- How well did special offer *X* do (i.e., how much revenue vs. interest did it generate)?
- Who buys product *P*?
- Who are the most profitable customers?
- What is being bought by whom?

Answers to these questions help e-retailers better understand their customers' buying behavior as well as the value of their offerings. This information, in turn, leads to considerations such as what products to focus on, how to turn browsers into customers, how

to recognize customer types so as to respond to their needs/interests on-the-fly, etc.

It is important to recognize that behavior analysis cannot be an after-thought. Indeed, it must be carefully planned and reflected in the e-commerce site's design. For example, assume an e-retailer wishes to run a special offer and measure its impact. Then, a mechanism capable of capturing the supporting data must be set in place. In the online world, this may be accomplished simply and cost-effectively by adding a special ad somewhere on the Web site and tracking the visitors who click on it. Tracking is easily done using a distinguisher in the URL, yet this must be reflected in the implementation prior to launching the special offer. Once the mechanism is in place, one can easily measure the offer's success rate by computing the ratio of those who click and convert (i.e., buy the special offer) to those who only click.

Stage 3: Personalization

Every marketer's dream is to know enough about customers so as to tailor offers to each individually, in terms of both products and prices. Even when the needed knowledge is available, this is nearly impossible in a traditional store. Internet technology, on the other hand, makes it possible to adapt layout, contents and services offered "to the needs of a particular user or a set of users, taking advantage of the knowledge gained from the users' navigational behavior and individual interests, in combination with the content and the structure of the Web site" (Eirinaki & Vazirgiannis, 2003). This kind of personalization is the final stage of knowledge discovery in e-commerce (Perkowitz & Etzioni, 1999; Mobasher et al., 2000; Allen et al., 2001; Eirinaki & Vazirgiannis, 2003; Linden et al., 2003). It can lead to finely-honed marketing actions, such as:

- Show product *P* to customer *C*.
- Offer a discounted price on bundle *B* to customer *C*.
- Suggest services and products that customer *C* is likely to be interested in.
- Provide timely chat or co-browsing to most valuable customers (Beagle Research Group, 2004).

Interestingly, with dynamic Web design, one may use both information previously obtained and data provided in real-time (i.e., as the visitor interacts with the site) to tailor the exchange between the parties. Some of the largest e-businesses have had enormous success personalizing Web content. For instance, Google presents relevant advertisements based on keywords in which a visitor is interested; Amazon.com uses collaborative filtering, based on clusters of users with similar buying behavior, to recommend products to users on-the-fly; and Yahoo!'s LAUNCHcast makes recommendation to listeners by clustering music ratings elicited explicitly from visitors.

Ideally, personalization benefits both the customer and the e-retailer. Successful recommendations benefit customers by readily providing them with items most likely to be of interest, sometimes even introducing items that they were previously unaware of. In fact, not only are the most relevant products delivered but the transaction itself requires less time, thus improving overall customer satisfaction. In turn, more visitors will convert (i.e., buy what is suggested to them) and existing customers will return (i.e., build loyalty), so that the e-retailer sees increased revenue and profit at a relatively small cost.

FUTURE TRENDS

From the content mining perspective, multi-lingual and multimedia Web sites offer a number of interesting challenges to the Web mining research community. Advanced text mining, including the use of semantics (e.g., Web 2.0) as well as image processing techniques may serve as useful tools to enhance Web mining.

From the structure mining perspective, interesting opportunities exist within the idea of social networks. As people interact with one another, either explicitly or only implicitly, through one or more Web sites, analysts may begin to build social networks (Wasserman & Faust, 1994). Leveraging customer social networks presents additional opportunities for strategic personalized marketing. Identifying the group(s) to which a customer belongs is an effective method for personalizing content. Furthermore, since it appears that some customers have a disproportionate ability to shape public opinion (Dye, 2000), social networks

can be utilized to identify such individuals as well as the customers they influence. After identifying these groups and the influential people within them, ads and products can be strategically targeted to effectively create "buzz" (Rosen, 2000).

CONCLUSION

E-commerce activities have much richer data footprints than their physical counterparts, thus providing much greater opportunities for intelligent e-business. In order to be successful, knowledge discovery has to be planned for in the design phase of e-commerce applications. It can then be leveraged through a series of incremental stages, intended to bring increasing return-on-investment at each stage and to help e-retailers get closer to an optimal use of the Web channel. Indeed, the unique nature of the online world makes achievable the double objective of maximizing the customer's experience and maximizing revenues.

Great success has already been achieved, both technically and commercially, with Web mining. A thorough analysis of lessons learned and typical challenges faced, based on a number of implementations for a variety of customers, was published recently (Kohavi et al., 2004). Much can still be done, but thanks to the Internet's flexibility, e-commerce is probably the closest one can hope for to get back to Mr. Miller's corner shop's successful one-to-one marketing (Cabena et al., 1997).

KEY TERMS

Clickstream Analysis: Analysis of the "footprint" left by visitors to a Web site. This footprint, generally referred to as a clickstream, is stored in the Web server log file.

Data Mining: Application of visualization, statistics and machine learning to the discovery of knowledge in databases. There is general consensus that the knowledge found through data mining should in some way be novel and actionable.

E-Commerce: Set of commercial activities (e.g., marketing, sales) conducted over the Internet.

Web Mining: Application of Data Mining techniques to Web data, generally consisting of usage data, content and structure. Web usage mining attempts to discover patterns of behavior (e.g., navigation) from user interactions with a Web site. Web content mining focuses on extracting knowledge from the actual content (e.g., text) of Web sites. Web structure mining considers links across Web sites to identify interesting graph patterns (e.g., hubs, authorities).

Web Server Log File: A file maintained by the Web server that stores information about visitors' interaction with the Web site. It consists of such data as basic identifying information (e.g., originating IP address) as well as time-stamped entries for all pages visited, from the time a visitor enters the site to the time he/she leaves it.

Statistical Data Editing

Claudio Conversano
University of Cagliari, Italy

Roberta Siciliano
University of Naples, Federico II, Italy

INTRODUCTION

Statistical Data Editing (SDE) is the process of checking and correcting data for errors. Winkler (1999) defines it the set of methods used to edit (clean-up) and impute (fill-in) missing or contradictory data. The result of SDE is data that can be used for analytic purposes.

Editing literature goes back to 60's with the contributions of Nordbotten (1965), Pritzker et al. (1965) and Freund and Hartley (1967). A first mathematical formalization of the editing process is in Naus et al. (1972), who introduce a probabilistic criterion for the identification of records (or the part of them) that failed the editing process. A solid methodology for generalized editing and imputation systems is developed in Fellegi and Holt (1976). The great break in rationalizing the process came as a direct consequence of the PC evolution in the 80's: Editing started to be performed on-line on PCs even during the interview and by the respondent in computer assisted self-interviewing (CASI) models of data collection (Bethlehem et al., 1989).

Nowadays, SDE is a research topic in academia and statistical agencies. The European Economic Commission periodically organizes a workshop on the subject concerning both scientific and managerial aspects of SDE (www.unece.org/stats).

BACKGROUND

Before the computers advent, editing was performed by large groups of persons undertaking very simple checks and detecting only a small fraction of errors. The computers evolution allowed survey designers and managers to review all records by consistently applying even sophisticated checks to detect most of the errors in the data that could not be found manually. The focus of both methodologies and applications was on the possibilities of enhancing the checks and of applying automated imputation rules to rationalize the process.

SDE Process

Statistical organizations periodically perform a SDE process. It begins with data collection. An interviewer can quickly examine the respondent answers and highlight gross errors. Whenever data collection is performed using a computer, more complex edits can be stored in it in advance and can be applied to data just before their transmission to a central database. In such cases, the core of editing activity is performed after completing data collection. Nowadays, any modern editing process is based on the a-priori specification of a set of edits, i.e., logical conditions or restrictions on data values. A given set of edits is not necessarily correct: important edits may be omitted and conceptually wrong, too restrictive or logically inconsistent edits may be included. The extent of these problems is reduced by a subject-matter expert edits specification. Problems are not eliminated, however, because many surveys involve large questionnaires and require the complex specification of hundreds of edits. As a check, a proposed set of edits is applied on test data with known errors before application on real data. Missing edits or logically inconsistent ones, however, may not be detected at this stage. Problems in the edits, if discovered during the actual editing or even after it, cause editing to start anew after their correction, leading to delays and incurring larger costs than expected. Any method or procedure which would assist in the most efficient specification of edits would therefore be welcome.

The final result of a SDE process is the production of clean data and the indication of the underlying causes of errors in the data. Usually, an editing software is able to produce reports indicating frequent errors in the data. The analysis of such reports allows to investigate the data error generation causes and to improve the results

of future surveys in terms of data quality. Elimination of sources of errors in a survey allow a data collector agency to save money.

SDE Activities

SDE concerns two aspects of data quality; (1) Data Validation: the correction of logical errors in the data; (2) Data Imputation: the imputation of correct values once errors in data have been localized. Whenever missing values appear in data, missing data treatment is part of the data imputation process to be performed in the SDE framework.

Types of editing

The different 'kinds' of editing activities are:

- **Micro Editing:** The separate examination of each single record for the assessment of the logical consistency of data, using a mathematical formalization in the automation of SDE.
- **Macro Editing:** Examination of the relationships between a given data record and the others, in order to account for the possible presence of errors. A classical example is outlier detection, i.e. the examination of the proximity between a data value and some measures of location of the distribution it belongs to. Outlier detection literature is vast and it is possible to refer to any of the classical text in the subject (for instance Barnett and Lewis, 1994). For compositional data, a common outlier detection approach is provided by the aggregate method, aimed to identify suspicious values (i.e. possible errors) in the total figures and to drill-down to their components to figure out the sources of errors. Other approaches use both data visualization tools (De Waal et al., 2000) and statistical models describing changes of data values over the time or across domains (Revilla and Rey, 2000).
- **Selective Editing:** An hybrid between micro and macro editing: the most influential among the records that need imputation are identified and their correction is made by human operators, whereas remaining records are automatically imputed by the computer. Influential records are often identified looking at the characteristics of the corresponding sample unit (e.g. large companies in an industry survey) or applying the "score variable method" (Hidiroglou and Berthelot, 1986) that accounts for the influence of each subset of observations on the estimates produced for the whole dataset.
- **Significance Editing:** A variant of selective editing introduced by Lawrence and McKenzie (2000). The influence of each record on the others is examined at the moment the record is processed and not after all records have been processed.

MAIN THRUST

Editing literature does not contain relevant suggestions. The Fellegi-Holt method is based on set theory concepts, which helps to perform efficiently several steps of the process. This method represents a milestone, since all recent contributions are aimed to improve it, particularly its computational effectiveness.

The Fellegi-Holt Method Data

Fellegi and Holt (1976) provide a solid mathematical model for SDE in which all edits reside in easily maintained tables. In conventional editing, thousands of lines of if-then-else code need to be maintained and debugged.

In the Fellegi-Holt model, a set of edits is a set of points determined by edit restraints. An edit is failed if a record intersects the set of points. Generally, discrete restraints are defined for discrete data and linear inequality restraints for continuous data. An example for continuous data is:

$$\sum_i a_{ij} x_j \le C_j, \ \forall j = 1, 2, \ldots\ldots, n$$

whereas for discrete data an edit is specified in the form $\{Age \le 15, \ marital\ status = Married\}$. The record *r* falling in the set of edit restraints fails the edit. It is intuitive one field (variable) in a record *r* must be changed for each failing edit. A major difficulty arises if fields (variables) associated with failing edits are changed: then, other edits that did not fail originally will fail.

The mathematical routines code in the Fellegi-Holt model can be easily maintained. It is possible to check

the logical validity of the system prior to the receipt of data. In one pass through the data of an edit-failing record, it is possible to fill in and change values of variables so that the record satisfies all edits.

Checking the logical validity is often referred to as determining the consistency or logical consistency of a set of edits. The Fellegi-Holt goals are:

1. Data in each record should be made able to satisfy all edits by changing the fewest possible variables.
2. Imputation rules should derive automatically from edit rules.
3. When imputation is necessary, it should maintain the joint distribution of variables.

Goal 1 refers to the *error localization*. The Fellegi-Holt method requires the generation of all the implicit and explicit edits for its solution. Explicit edits are generated by subject matter expert according to the nature of the variables, whereas implicit edits are derived from a set of explicit edits. If the implicit edit fails, then necessarily at least one of the explicit edits used in the generation of the implicit ones fail. The Fellegi-Holt method main hint is the demonstration of a theorem about the possibility of finding a set of fields to change in a record that yield a changed record satisfying all edits.

If a complete set of implicit edits can be logically derived prior to editing, then the integer programming routines that determine the minimal number of fields to change in a record are relatively fast. Generally, the derivation of all implicit edits prior to editing is difficult (Garfinkel et al., 1986). When most of the implicit edits are available, Winkler and Chen (2002) describe an efficient way to determine the approximate minimal number of fields to change.

Fellegi and Sunter (1969) show that implicit edits provide information about edits that do not originally fail but may fail as a record is changed.

Improving the Speed of the Implicit Edit Generation

Systems employing the Fellegi-Holt method have been mainly developed for categorical variables. The main problem concerns the implicit edit generation, since the computational time is a steep exponential function of the number of explicit edits. A common but not completely satisfactory solution is to split the set of explicit edits into subsets and generate implicit edits separately for each subset. Editing systems employing the Fellegi-Holt method for categorical variables usually works by splitting the set of explicit edits. These systems are used in Italy (Barcaroli et al., 1997), Spain and Canada. Garfinkel et al. (1986) provide an algorithm (implemented by the U.S. Census Bureau) for reducing the amount of computation required for implicit edit generation by identifying in advance, for each candidate set of contributing edits and generating field, those subsets (prime covers) that have a possibility of producing the maximal number of new edits. Prime covers are groups of edits which do not have any subsets with the same properties. For each set of contributing edits there may exist more than one prime covers. Anyway, these methods often fail producing all implicit edits when dealing with survey questionnaire presenting complicated skip patterns.

Error Localization Using an Incomplete Set of Edits

Some approaches do not generate the complete set of edits but attempt to perform error localization on the basis of an incomplete set of edits.

Winkler and Chen (2002) provide an heuristic to perform iteratively error localization when some implicit edits are missing. In practice, starting from a subset of implicit edits it is possible to detect new ones from the explicit edits failed by a given data record. The error localization process stops as soon as a certain data record does not fail any explicit edit.

As for edits involving numerical variables, great difficulties arises for the generation of implicit edits. Efforts have concentrated only on linear and ratio edits applying the Chernickova (1964) algorithms. Some slight modifications of these algorithms have been implemented by the major statistical agencies (Canada, The Netherlands, USA).

Other approaches are based on statistical tools, in particular tree-based models (Conversano and Cappelli, 2002) and nearest-neighbors methods (Bankier et al., 2000).

Careful Design and Evaluation of the Set of Query Edits

The design of the entire set of edits is particularly important to get an acceptable cost/benefit outcome of editing. Edits have to be coordinated for related items and adapted to the date to be edited. Probable measures for improving current processes are relaxing bounds by replacing subjectively set limits by bounds based on statistics from the data to be edited, and removing edits which produce unnecessary flags. It should be noted there is a substantial dependence between edits and errors for related items. Furthermore, edits have to be targeted on the specific error types of the survey, not on possible errors.

SDE for Exceptionally Large Files

A model-based SDE procedure is proposed in Petrakos et al. (2004) within the Knowledge Discovery from Databases (KDD) and Data Mining framework. It uses recursive partitioning algorithms to perform SDE. This approach results in a fully automated procedure inspired by the *Total Quality Management* (TQM) principles ("*Plan, Do, Check, Act*") of the well-known "Deming Cycle" named *TreeVal*, that can be used for the derivation of edits not requiring, at least initially, the help of subject matter experts. An application on real data provided by the Official Statistical Institute of Portugal documents about its effectiveness.

As for periodic surveys, a *Survey Database* stores data deriving from previous similar surveys. It is made up of "clean data", namely data that were validated in the past. Instead, the *Incoming Data* contains cases that must be validated before being included into the Survey Database.

To simplify the SDE process, the validation procedure is not applied on the whole survey data *tout-court*, but on subsamples of cases/variables of the Survey Database which are selected according to a specific data selection and validation planning (*Plan*). These subsamples concur to define the *Pilot Dataset*, used to derive edits through the FAST recursive partitioning algorithm (*Do*) introduced by Mola and Siciliano (1997). The corresponding subsamples of the Incoming Data are selected (*Validation Sample*) and validated using edits derived in the previous step (*Check*). The clean *Validated Data* are stored in the Survey Database and used to edit subsequent subsamples (*Act*).

Another strictly related SDE field is Data Fusion (DF, Saporta, 2002). It consists in merging information collected from different sample surveys and is based on two samples: the *donor file* is a complete data matrix (X) related to a first survey; the *receptor file* (Y) is similar to X except for a certain number of missing variables. Missingness is due to lack of an entire part of the second survey. The goal is to complete Y beginning from the knowledge acquired from X. Consequently, DF is a particular case of data imputation since a group of instances is missing because it was not originally collected. Thus, two different and independent databases have to be merged. Several approaches to DF exist, some based on factor analysis (Aluja-Banet et al., 1997), others on tree-based methods (D'Ambrosio et al., 2007) .

FUTURE TRENDS

As a matter of fact, editing is a part of the data total quality improvement process, not the whole data quality process. In fact, editing alone cannot detect all errors, and definitively not correct all mistakes committed during the survey design, data collection and processing.

For future application of SDE in Business Intelligence the following editing rules, to be performed in priority order, have to be specified:

1. Identify and collect data on problem areas, and error causes in data collection and processing, producing the basics for the (future) improvement of the survey vehicle.
2. Provide information about the quality of data.
3. Identify and handle concrete important errors and outliers in individual data.

Besides its basic role to eliminate fatal errors in data, SDE should highlight, not conceal, serious problems in the survey vehicle. The focus should be on the cause of an error, not on the particular error *per se*.

CONCLUSION

Since data need to be free of errors before being analyzed in a statistical way, SDE appears essential wherever data are collected. But SDE is not a standalone activity, since it should be integrated within data

collection, processing and estimation. Besides the goals of data correction and imputation, a main task of SDE is to provide a basis for designing measures to prevent errors.

Focusing on the recent uses of SDE, it emerges that the paradigm "the more (and tighter) checks, the better the data quality" is not always valid, since it does not exist an editing method that clearly outperform the others. When performing SDE, the entire set of the query edits should be designed meticulously, be focused on errors influencing the estimates, and be targeted on existing error types recognizable by edits. The effects of edits should be continuously evaluated by the analysis of performance measures and other diagnostics the process can be designed to produce.

KEY TERMS

Data Checking: Verification of the correctness conditions of data, also including the specification of the type of the error or condition not met and the qualification of the data and its division into the "error free" and "erroneous data". Data checking may be aimed at detecting error-free data or at detecting erroneous data.

Data Editing: Detection and correction of errors (logical inconsistencies) in data.

Data Fusion: Combining or merging data coming from different sources, usually different sample surveys.

Data Imputation: Substitution of estimated values for missing or inconsistent data items (fields). Substituted values are intended to create a data record that does not fail edits.

Data Validation: Verification of whether the value of a data item comes from the given (finite or infinite) set of acceptable values.

Editing Procedure: Detection and handling of errors in data, usually in three phases: definition of a consistent system of requirements, their verification on given data, and elimination or substitution of data which is in contradiction with the defined requirements.

Explicit Edit: An edit explicitly written by a subject matter specialist.

Error Localization: (Automatic) identification of the fields to impute in an edit-failing record. Usually, an optimization algorithm determines the minimal set of fields to impute, so that the final (corrected) record will not fail edits.

Implicit Edit: An unstated edit logically derived from explicit edits previously specified by a subject matter specialist.

Logical Consistency: Verification of whether a given logical condition is met. It is usually employed to check qualitative data.

Statistical Metadata Modeling and Transformations

Maria Vardaki
University of Athens, Greece

INTRODUCTION

The term metadata is frequently used in many different sciences. Statistical metadata generally used to denote "*every piece of information required by a data user to properly understand and use statistical data*." Modern statistical information systems (SIS) use metadata in relational or complex object-oriented metadata models, making an extensive and active usage of metadata. Early phases of many software development projects emphasize the design of a conceptual data/metadata model. Such a design can be detailed into a logical data/metadata model. In later stages, this model may be translated into physical data/metadata model.

Organisations aspects, user requirements and constraints created by existing data warehouse architecture lead to a conceptual architecture for metadata management, based on a common, semantically rich, object-oriented data/metadata model, integrating the main steps of data processing and covering all aspects of data warehousing (Pool et al, 2002).

In this paper we examine data/metadata modeling according to the techniques and paradigms used for metadata schemas development. However, only the integration of a model into a SIS is not sufficient for automatic manipulation of related datasets and quality assurance, if not accompanied by certain operators/ transformations. Two types of transformations can be considered: (i) the ones used to alleviate breaks in the time series and (ii) a set of model-integrated operators for automating data/metadata management and minimizing human errors. This latter category is extensively discussed.

Finally, we illustrate the applicability of our scientific framework in the area of Biomedical statistics.

BACKGROUND

Metadata and metainformation are two terms widely used interchangeably in various sciences and contexts. Until recently, metainformation was usually held as table footnotes. This was mainly due to the fact that the data producer and/or consumer had underestimated the importance of this kind of information.

When metadata integration in a pre-arranged format became evident, the use of metadata templates was proposed. This was the first attempt to capture metadata in a structured way. This approach was soon adopted since it reduced chances of ambiguous metadata as each field of the templates was well documented. However, they still had limited semantic power, as they cannot express the semantic links between the various pieces of metainformation.

To further increase the benefits of using metadata, attempts have been made to establish ways of automating the processing of statistical data. The main idea behind this task is to translate the meaning of data in a computer-understandable form. A way of achieving this goal is by using large, semantically rich, statistical data/metadata models like the ones developed in Papageorgiou et al (2001, 2002). However, in order to minimize compatibility problems between dispersed systems, the need that emerges is to build an integrated metadata model to manage data in all stages of information processing. The quantifiable benefits that have been proven through the integration of data mining with current information systems can be greatly increased, if such an integrated model is implemented. This is reinforced by the fact that both relational and OLAP technologies have tremendous capabilities for navigating massive data warehouses; nevertheless, brute force navigation of data is not enough. Such an integrated model was developed in Vardaki & Papageorgiou (2004), and it was demonstrated that an abstract, generally applied model, keeping information about storage and location of information as well as data processing steps, is essential for data mining requirements. Other related existing work focuses either mainly on OLAP databases (Pourabbas and Shoshani, 2006) or on semantically rich data models used mainly for data capturing purposes. In these cases, the authors focus their attentions on data

manipulations and maximization of the performance of data aggregations.

A number of modeling techniques and technologies have been discussed in literature and considered for the implementation of various research projects. Mainly in the case of medical statistics the Entity-Attribute-Value (EAV) (also known as "Object-Attribute-Value Model" and "Open Schema") database modeling technique has been extensively used (Dinu and Nadkarni, 2006). Also, Papageorgiou et al (2001) developed an Object Oriented metadata model for the series of processes followed in a Statistical Institute. Finally, the XML-based solution has been extensively used.

However, although a metadata model is an important step towards automation of data/metadata management and processing, the definition of a set of transformations/ operators is essential for harmonization purposes and for the automatic manipulations of statistical information. Two types of transformations can be considered: (i) the methodological transformations which are used when there are inconsistencies between practices of data collection, compilation and dissemination of statistics and (ii) operators that permit specific manipulations of the underlying data and their related metadata stored in the databases.

Regarding the methodological transformations, these are used to alleviate breaks in time series. When data collected in a specific time period are not fully comparable with the data of the following years we say that we have a break in time series. Breaks frequently occur in time series and involve changes in standards and methods that affect data comparability over time since they make data before and after the change not fully comparable. Information about breaks in time series is a quite important piece of statistical metadata because of the adverse effects they can have to statistical inference based on fragmented data. A number of transformations can be applied to minimize the effect of such incompatibility.

In case of simultaneous manipulation of both data and metadata, this is achieved by introducing a set of tools (transformations) to assist the data producer and user in manipulating both data and metadata simultaneously. Sets of such transformations have been discussed by Papageorgiou et al (2002) and Vardaki and Papageorgiou (2006).

MAIN THRUST

This chapter aims in discussing metadata modeling and related techniques and also introduce a set of underlying transformations. More specifically, topics that are covered include essential considerations in statistical metadata modeling development, modeling techniques and paradigms. Furthermore, a set of transformations is proposed for automation of data/metadata processing in a Statistical Information System.

The applicability of our scientific framework is further discussed in a case study in the area of medical statistics describing how the metadata model and the proposed transformations can allow for simultaneous handling of datasets collected during dispersed similar clinical trials performed by different medical centers.

Statistical Metadata Modeling

The design of a data/metadata model is a crucial task for further processing. If the model is undersized, it will be incapable of holding important metadata, thus, leading to problems due to missing metainformation. On the other hand, if it is oversized, it will keep information that is captured, rarely used and never updated, thus leading to severe waste of resources. Obviously, an oversized model cannot be easily implemented or used by the Institute's personnel. However, it is also difficult to predict the needs of data consumers, since the amount of required metainformation depends on the application under consideration. A step-by-step model development can serve the purpose.

We briefly consider three stages of data/metadata modeling:

- The conceptual metadata model (schema) consisting of entity classes (or objects), attributes and their relationships.
- The semantic data model describing the semantics.
- The operators/transformations abstract schema

Of course the database structure and coding as well as the data/metadata storage selection should be also represented.

Apart from choosing what metainformation is worth capturing, there is an additional difficulty in choosing the most appropriate modeling technique. Discussions

and controversial arguments have been registered in literature over the Entity-Relational (E-R) and the Object-Oriented (O-O) paradigms.

Finally, although not related to statistical modeling, we should refer to the Common Warehouse Metamodel (CWM), a specification for modeling metadata for relational, non-relational, multi-dimensional, and most other objects found in a data warehousing environment. The specification is released and owned by the Object Management Group (OMG, 2007).

Modeling Techniques and Languages

It is recommended that an integrated, semantically rich, platform-independent, statistical metadata model, should be designed to cover the major stages of the statistical information processing (data collection and analysis including harmonization, processing of data and metadata and dissemination/output phases), which can minimize complexity of data warehousing environments and compatibility problems between distributed databases and Information Systems.

Enhanced Entity-Relationship (E-R) models were developed some years ago which, in turn, proved that they lacked inheritance relationships. They can represent the entity-attribute dependency adequately; however, they lack flexibility if we need to add new metadata to reflect an additional process.

Then, the Object-Oriented (O-O) paradigm (Papazoglou et.al, 2000) has started to be used, where the statistical metadata model was described and designed in Uniform Modeling Language (UML) for a better representation of 2-level inter-dependencies (class-attribute). Unified Modeling Language (UML) is an industry standard used in modeling business concepts when building software systems using object-oriented technology. It is developed by Object Management Group (OMG, 2007).

On the other hand, Extensible Markup Language (XML) is designed especially for Web documents. It allows designers to create their own customized tags, enabling the definition, transmission, validation, and interpretation of data between applications and between organizations.

The main benefits of a metadata model designed in UML are the flexibility and that the same conceptual model may be used to generate different XML Schemas and XMI for the data level as well as other representations. Even if a new technological infrastructure is adopted, the initial conceptual UML model remains the same, or can be easily updated.

Transformations

Methodological Transformations

The *methodological transformations* include all the possible transformations that are used to enhance the data homogeneity by correcting errors that were introduced due to methodological inconsistencies and restore their effects in breaks in time series. In order to evaluate fragmentation of data in both time and space, several coefficients of fragmentation in both space and time can be developed (see also Papageorgiou et al, 2002).

Operators for Automatic Manipulation of Data/Metadata

A statistical metadata model should keep information about the series of processes that have been applied on the data of a survey (since the survey is a central characteristic in statistics). This can be achieved with the integration of several operators/ transformations. All the operators have the closure property, meaning that the application of an operator on a Survey/Dataset/Table always produces a new Survey/Dataset/Table.

The importance of operators is that they allow for simultaneous manipulation of both data and metadata. Consequently, they severely reduce the possibility of data and metadata mismatches. In addition, operations are necessary for building SISs that support metadata-guided statistical processing. In this case, the user simply describes the statistical Table of interest and the system automatically finds a series of operators that can be applied onto existing tables in order to produce the requested one.

An indicative set of transformations can be briefly described as follows (see also Vardaki & Papageorgiou, 2008):

- **Selection:** It closely resembles the one from the relational algebra. The result of applying this operator is a new table holding only a subset of the initial data satisfying the selection criterion.
- **Projection:** It also closely resembles the one from the relational algebra. The result of applying this operator is a new table holding only a subset of Variables of the initial data.

- **Reclassification:** The reclassification operator converts the values of a Variable in another classification using a different grouping criterion. However, the results of a reclassification may lead to tables with missing values, or with inaccurate values, especially when the existing values' classification is not fully convertible into the requested one.
- **Join:** The join operator resembles the join operator of the relational algebra. It is applied on two tables having one or more common variables (joined Variables). The result is a new table having all the Variables of both tables (obviously, the common Variables included once.).
- **Algebraic operators:** This is a general operator used to denote simple mathematical operations (e.g. additions, multiplications, etc.) that are frequently applied into a Table. The algebraic operator is the only one, which requires additional documentation and semantic metadata to be specified by the user, during its application. The reason is that there is no automated way for SISs to understand the semantic meaning of such an operator.

Case Study: Applicability in Biomedical Statistics

An area where metadata and metadata modeling is currently thriving is the biomedical field and especially the case of clinical and pre-clinical studies. We can find extensive discussions on the Entity-Attribute-Value (EAV) modeling regarding knowledge representation for complex heterogeneous biomedical databases (Dinu and Nadkarni, 2006).

Towards the approach of the O-O paradigm and UML representation, SCENPRO (http://www.scenpro.com/) has developed a disease-oriented (and specifically cancer-oriented) UML Object Model. The National Cancer Institute (NCI) has proposed the Cancer Biomedical Informatics Grid (caBIG) UML model and CaCORE is a related interoperability infrastructure (Komatsoulis et.al, 2007). In addition, the Clinical Data Interchange Standards Consortium (CDISC) (http://www.cdisc.org) developed a XML-based metadata model defined to guide sponsors in the preparation of data that is to be submitted to the Food and Drug Administration (FDA), thus supporting standard interchange between medical and biopharmaceutical data (Deshpande et al, 2002).

Both NCI and CDISC collaborated with Health Level Seven (HL7) and FDA experts in the promising project, BRIDG (Weng et al, 2007), for developing a UML model aiming to bridge standards and also the gap between clinical research and healthcare.

Our case study aims in demonstrating conceptually how a flexible metadata model, integrated into Clinical Study Data Management Systems (CSDMS) together with a set of proposed transformations, allows for automatic, simultaneous handling of different clinical trials performed by several centers or in various time periods.

Consider two similar medical research studies performed in outlying regions (therefore the participating populations – and the samples taken – are disjoint) and the two resulting datasets, having a number of equivalent variables (resulting from the related similar questions of the questionnaire given to the study subjects). Our conceptual approach allows only for a simplified demonstration of the transformations application on the two studies' datasets as follows:

Initially, we identify the equivalent variables in the two tabulated datasets.

Then, by applying the projection transformation to both tabulated datasets, we remove the non-equivalent variables (represented by columns in a table) from each dataset, leaving only the equivalent sets of variables. In case two equivalent variables are measured with different classifications we apply the reclassification operator to convert the measurement unit of one of them into the measurement unit of its equivalent. For example, in clinical trials performed in the United Kingdom the factor "body weight" of a patient is usually measured in pounds, whereas in Germany they measure it in kgs. If we want to combine similar trials from these two countries using kgs, we will have to apply a reclassification from pound to Kgs using the relation 1 pound = 0.4536 kgs approximately.

After that, we can derive a new survey (table) with data obtained by merging the two sets of data with equivalent variables (columns). The new survey (table) will have the Union of the two studies' study populations and the same columns (same number and description of equivalent set of variables).

We can then perform any other transformations we consider necessary like selection of specific rows (each row representing a study subject) according to

eligibility criteria, addition of variables, or join of the two studies (under certain pre-conditions), etc., or apply any algebraic transformations we want.

FUTURE TRENDS

Future plans include the potential of metadata to improve data quality as a consequence of transformations handling, as well as, on integrating the proposed model with relevant data warehousing and OLAP technologies. Therefore, the automation of statistical processing calls for the derivation of some quality metrics that will subsequently be used during the plan optimization and selection stage.

Other future research can concentrate on how to integrate metadata that can not be extracted from Data Warehousing components but resides in various other sources. Also, the harmonisation of various metadata terminologies as well as semantics integration and mappings is very promising. Similarly, the implementation of an integrated common shared metamodel is essential in order to bridge the gap between syntax and semantics of metadata representation in various software components of a Data Warehousing system.

This will lead to a possible unified adoption of standards used for data/metadata exchange, since nearly each house uses a different metadata model that most of the times is compatible only with software provided by the same software vendor.

Regarding non-classical data analysis methods, like for example the symbolic analysis, the the metadata model metainformation for the classical and the symbolic data, keeping also the processing history of original and symbolic data manipulations and the application of certain statistical methods or/and the visualization of the final results (Papageorgiou and Vardaki, 2008).

Regarding the biomedical sector, a metadata model describing the entire process of a medical research seems very promising. A number of equivalencies and transformations should be integrated for automatic combination of dispersed medical studies' data.

CONCLUSION

Structured metadata are indispensable for the understanding of statistical results. The development of a flexible, platform-independent metadata model, integrated into a SIS, is essential for the improvement of the information system and is widely considered as promising for improving effectiveness and efficiency of managing data warehouse environments. The support of automated, metadata-guided processing is vital for the next generation of statistical web sites as well as for asserting data quality.

We discussed current modeling techniques and paradigms and a number of transformations which, if properly used, can minimize the amount of data exposed to network, thus reducing problems concerning confidentiality and security of data. The reason is that computers will be able to assist the user in manipulating and processing both data and metadata. Thus, human intervention and the possibility of common human errors will be reduced. Therefore, an enhancement of services' quality and a minimum need for highly trained personnel are expected.

In our case study in the area of medical statistics we illustrated that the automatic, simultaneous manipulation of dispersed data is achieved with the use of the introduced transformations.

KEY TERMS

Common Warehouse Metamodel (CWM): A specification for modeling metadata for relational, non-relational, multi-dimensional, and most other objects found in a data warehousing environment. The specification is released and owned by the Object Management Group.

DataInterchange: The process of sending and receiving data in such a way that the information content or meaning assigned to the data is not altered during the transmission.

Data Processing: The operation performed on data in order to derive new information according to a given set of rules.

Metadata Modeling: The analysis, construction and development of the frames, rules, constraints, models and theories applicable and useful for the modeling in a predefined class of problems.

Meta-Object Facility (MOF): An Object Management Group (OMG) standard for Model Driven Engineering. The official reference page may be found at OMG's MetaObject Facility. MOF originated in the need of a Metamodeling architecture to define the UML. MOF is designed as a four-layered architecture. It provides a meta-meta model at the top layer.

Platform- Independent Model: A platform-independent model or PIM is a model of a software or business system that is independent of the specific technological platform used to implement it.

Statistical Information System: It is the information system oriented towards the collection, storage, transformation and distribution of statistical information.

Statistical Metadata: They are data about statistical data. Metadata provide information on data and about processes of producing and using data. Metadata describe statistical data and - to some extent - processes and tools involved in the production and usage of statistical data.

Transformations: A set of operators to assist the user in manipulating both data and metadata simultaneously

XML: Extensible Markup Language (XML) is a general-purpose markup language. It is classified as an extensible language because it allows its users to define their own tags. Its primary purpose is to facilitate the sharing of structured data across different information systems, particularly via the Internet.

Statistical Models for Operational Risk

Concetto Elvio Bonafede
University of Pavia, Italy

INTRODUCTION

A statistical model is a possible representation (not necessarily complex) of a situation of the real world. Models are useful to give a good knowledge of the principal elements of the examined situation and so to make previsions or to control such a situation.

In the banking sector, models, techniques and regulations have been developed for evaluating Market and Credit risks, for linking together risks, capital and profit opportunity. The regulations and vigilance standards on the capital have been developed from the Basel Committee founded at the end of 1974 by the G10.

The standards for the capital's measurement system were defined in 1988 with the "Capital Accord" (BIS, 1988); nowadays, it is supported from over 150 countries around the world. In January 2001 the Basel Committee published the document "The New Basel Capital Accord" (BIS, 2001), which is a consultative document to define the new regulation for the bank capital requirement. Such a document has been revisited many times (see BIS, 2005).

With the new accord there is the necessity of appraising and managing, beyond the financial risks, also the category of the operational risks (OR) already responsible of losses and bankruptcies (Cruz (Ed.), 2004; Alexander (Ed.), 2003; Cruz, 2002).

BACKGROUND

The operational risk (OR), according to the new Basel accord, is due to detrimental events caused by the inadequacy or the failure of internal processes and systems, human errors and external events, for instance natural calamity (BIS, 2005).

The evaluation of a suitable risk profile is important, because banks with the same levels of market and credit risk can have a different OR profile. The operational risk, in fact, is an intrinsic characteristic of the bank, of the performed activities and of the place in which the institution is located (Cruz (Ed.), 2004).

Due to the peculiarity of OR, the difficulties that are peculiar to its modelling are the following:

1. The OR set is heterogeneous and strongly dependent of the context where it is valued.
2. Some events, which are referable to the OR, produce damages that are hardly evaluable.
3. Some OR events are very rare. Probably the single bank has never faced such events, and in this case the institution needs also external data.
4. For some events the past history is not a good indication of the future.
5. Lack of reliable historical data.
6. Associated problems with events' estimate that have high frequency and low impact (HFLI) and vice versa with low frequency and high impact (LFHI).

Besides, the greatest problems arise from the organization of the database (DB) for the construction and validation of the models, (Cruz (Ed.), 2004; Alexander (Ed.), 2003).

The Basel Committee with the new accord recommends the use of three methods for the valuation of the *value at risk* (VaR) characterized by increasing complexity: base (*BIA*), standard (*STA*) and advanced (AMA), (BIS, 2005; Cornalba & Giudici 2004).

Such approaches are subjected to criticisms due to the difficulties to evaluate operational risk and for the way in which they influence the capital (necessary to cover OR) in function of the institution amplitude (Cruz (Ed.), 2004; Alexander (Ed.), 2003).

MAIN FOCUS

The AMA approach is more complex, but it makes the calculation of the *value at risk* (VaR) more sensitive to the risk profile and generally smaller than the approach calculated with *BIA* and *STA*. Every bank can use its advanced internal model if it satisfies the qualitative

and quantitative standards defined by the new accord (BIS, 2005; BIS, 2003).

The AMA methods are bottom-up type and this because the VaR calculation is achieved considering the losses obtained by dividing the bank's activities in eight business lines (BL) and seven event types (ET or risk category). In this manner there will be at least 56 different kind of losses, one for each intersection BL/ET.

The models for the AMA approaches are divided in two principal classes, quantitative and qualitative models. The actuarial and analytical models represent the former; the latter are constituted by Scorecard Approach (SA). Bayesian methods are placed between the two categories, (Fanoni, Giudici & Muratori, 2005; Giudici & Bilotta, 2004; Cornalba & Giudici, 2004; Cruz (Ed.), 2004; Alexander (Ed.), 2003; Cruz, 2002).

To quantify the risk is necessary to know the statistical distribution of the number of risky events (frequency) and the statistical distribution of theirs consequences (severity or impact).

All the models have to be validated with *scenario analysis* and *backtesting*. (BIS, 2005; Fanoni, Giudici & Muratori, 2005; Cruz (Ed.), 2004; Alexander (Ed.), 2003).

Scorecard Approach

The scorecard approach models are based on the expert opinions collected using questionnaires (scorecard). By scorecard, the frequency, the severity and the quality of the controls are appraised and so the effectiveness of the system of risk management is already integrated in the model (Alexander (Ed.), 2003).

Inside the questionnaires the frequency and the severity are (generally) classified in five levels (high, high/middle, middle, middle/low and low) and similarly the quality of the controls with (excellent, good, fair, weak and poor). The questionnaire is periodically compiled (every six months, every year, etc…) and, usually, the expert himself is the one who fill it (self-assessment), (Fanoni, Giudici & Muratori 2005; Alexander (Ed.), 2003; Cruz, 2002).

The Basel Committee requires that the estimates are validated on a quantitative base using internal and external historical data related to the OR losses. The difference between this approach and the qualitative method is that the risk profile can change in function of the results that periodically emerge from the compilation of the scorecards. In such way, the method follows the "trend" recognized by the experts (forward-looking characteristic) and so it has a prevision action, (Cruz (Ed.), 2004; Alexander (Ed.), 2003).

The procedure of assessment is obtained after having mapped the activities of the bank and the possible risks according to the standards defined by Basel.

The assessment operation depends on factors as, for instance, (see Alexander (Ed.), 2003):

- The nature of the analyzed activities.
- The geographical location.
- The greatness and complexity of the main activities and of the necessary operations to perform them.

Besides, the choice of the indicators and the appropriate metrics to define the risk profile (as the *Key Risk Driver*) and to monitor and control the harmful events (as the *Key Risk Indicator*) will depend on the previous phase.

The results obtained are visualized on a graph (risk map) where on axles we report for each risk the frequency and the severity. Therefore the graph shows how the various harmful events are distributed and emphasizes possible LFHI or HFLI situations, (Alexander (Ed.), 2003). Afterwards, the graph can be divided in action zones to define the activities to be implemented to face such risks, as, for instance, to accept, to share, to avoid or to transfer them, etc.

Once defined the risk frequencies and severities, some *scenario analyses* are performed to underline the risks, the control systems and the losses associated at the sceneries (see Alexander (Ed.), 2003).

Actuarial and Analytical Models

In these models we use the database of the historical data to estimate either the loss distribution via simulation or the necessary parameters to calculate the VaR, the expected and unexpected losses. The only use of historical data makes these models backward-looking and, therefore, not very flexible for forecasts.

Actuarial Model

The actuarial model calculates the VaR through a percentile of the annual loss distribution (Loss Distribution Approach).

Once we have defined the operational losses database (see Cruz 2002) used for the construction of the actuarial model we have to calculate for every intersection BL/ET the distributions of the frequency (N) and the severity (X). The first distribution is discrete and the second is continuous (see Cruz, 2002; King, 2001).

The loss distribution is evaluated by the combination of the frequency and severity distributions. Then, from the loss distribution we calculate the VaR and, subsequently, the unexpected loss defined as the difference between the VaR and the expected loss.

After we have found the probability density function (p.d.f) for the frequency and the severity, we will combine them by calculating the aggregate loss L:

$$L = \sum_{i=1}^{N} X_i \quad \text{with N~P (n; } \mathbf{a}\text{) and } X_i \sim f(x_i; \mathbf{b});$$

where P(•) and f(•) are respectively the p.d.f of frequency and severity with vector parameters **a** and **b**.

It is very difficult to determine the distribution of L. So under the following hypotheses:

- The severities X_i are identically and independent distributed.
- The distribution of frequency (N) is independent on that of severity (X_i).

Such distributions can be calculated via Monte-Carlo simulation.

By implementing a simulation method we obtain an L realization from which we calculate the VaR, the expected and the unexpected loss (Colombo & Gigli, 2005; Fanoni, Giudici & Muratori, 2005; Cruz (Ed.), 2004; Alexander (Ed.), 2003).

We calculate the realization of L for each BL/ET intersection. It is important to underline that the value of the total VaR, obtained by considering all intersections, can vary according to the dependences among BL/ET, (see Fanoni, Giudici & Muratori, 2005).

The steps for the construction of the actuarial model are summarized in Fanoni, Giudici & Muratori (2005) and in Alexander (Ed.) (2003). For a deepened quantitative approach see Cruz (2002), Cruz (Ed.) (2004) and King (2001).

Analytical Model

The analytical model can be seen as the limit, in a statistical sense, of the actuarial model, when the number of simulations goes to infinity, (Fanoni, Giudici & Muratori, 2005; Alexander (Ed.), 2003). With this model the unexpected loss is calculated (Operational Risk Requirement or ORR), without explicitly determining the loss distribution. A strong limitation, that we have to accept, is the use of Normal distribution for the severity. For the frequencies distribution we can specify every kind of discrete distributions.

The ORR according to the analytical model is:

$$ORR = \phi \times \sigma_L$$

(σ_L = standard deviation of the loss's distribution) and it is calculated with the following formula:

$$ORR = \phi\, \mu_s \sigma_f \sqrt{1 + \left(\frac{\sigma_s}{\mu_s}\right)^2}$$

- σ_f is the frequency standard deviation.
- μ_s and σ_s are respectively the average and standard deviation of the severity.
- ϕ is the skewness coefficient of the loss distribution.

The asymmetry coefficient ϕ is defined as the ratio between the difference of the VaR and the expected loss and the standard deviation of the loss distribution:

$$\phi = \frac{VaR - (\text{expected loss})}{\sigma_L}$$

Due to the difficulty of calculating the shape of the loss's distribution, the coefficient ϕ is difficult to esteem. In every case we can indicate the extreme of the interval for ϕ.

The lower limit depends on the fact that the severity distribution is a Gaussian, so when it is combined with the frequency distribution, the skewness's value will be 3.1 if the VaR is calculated at 99.9 percentile.

Since the loss distribution is less asymmetrical than the distributions of the frequencies and severity, the upper limit of ϕ is that of the frequency distribution because the severity is a Gaussian.

From the skewness's (ϕ) interval width we can have an idea of the parameter's uncertainty. Such length is reduced with the increase of the number of risky events.

What we have mentioned above must be done for every BL\ET, therefore it should be:

$$ORR_{ij} = \phi_{ij}\sigma_{ij}$$

where σ_{ij} is the standard deviation of the annul loss distributions for every intersection BL/ET (i-*th* business line and j-*th* event type).

As for the actuarial approach in function of the level of correlation among the risks for every BL\ET, the ORRs are combined in opportune way (see Alexander (Ed.), 2003). This model cannot be applied in the case of negative correlation, (Fanoni, Giudici & Muratori 2005; Alexander (Ed.), 2003).

Bayesian Approach

The Bayesian approach allows the integration of objective data (generally quantitative type as internal historical loss) with those subjective (generally qualitative type comes from self-assessment or those of external database). In this manner different sources of information can be composed and the model can also undergo to the AMA standards.

The subjective data are used for estimating the prior p.d.f (which can be certain or uncertain) of the parameter of interest, while the objective data are used for estimating the likelihood for the same parameter.

With the Bayesian technique we can esteem the parameters for the distributions of interest (frequency, severity or directly the loss) using the posterior distribution obtained by the combination of the likelihood and prior distributions. In general, the likelihood and the posterior distributions are calculated by using numerical methods as Monte Carlo Markov Chain, (Alexander (Ed.), 2003; Cruz, 2002).

Besides, schemes of inference can be implemented to decide which is the best action to utilize to decrease the loss. In this way we are able to appraise the different strategies of containment, (Cruz, 2002).

In this type of approach there are the Bayesian Networks (BN) which belong to the class of the Probabilistic Expert Systems (see Cowell, Dawid, Lauritzen & Spiegelhalter, 1999). The BN is used to define the loss distribution and to evaluate the strategies of intervention to mitigate the risks; in such case, they take the name of decisional graph, (Alexander (Ed.), 2003; Giudici, 2003; Jensen, 2001). With the BN is performed a multivariate and an integrate analysis of the different kinds of risks or losses. If we use the AMA classification in BL/ET we will have a BN with 56 nodes. In this case every node represents a loss.

A BN is an acyclic graph formed by nodes (or vertexes) and direct arcs. Every vertex represents a casual variable with discrete or continuous states. The relationships among the variables, given by the arcs, are interpreted in terms of conditioned probability according to the Bayes theorem.

The concept of conditioned independence allows the factorization of the joined probability, through Markov property, in a series of local terms which describe the relationships among the variables:

$$f(x_1, x_2, ..., x_n) = \prod_{i=1}^{n} f(x_i \mid pa(x_i))$$

where the pa (x_i) indicates the parents' state of the variables in the nodes X_i.

The problem of a BN is the necessity of a good database to extract the conditioned probabilities and the structure of the net (learning problem) (Jensen, 2001; Heckerman, 1995).

The Bayesian methods allow us to combine the backward-looking with the forward-looking technique; they are useful to consider the dependences among the BL\ET losses and also to appraise the impact of casual factors (or causal depend on the use) on them, (Cornalba & Giudici 2004; Giudici & Bilotta, 2004).

The most evident criticism to these approaches is that the information on the prior distribution can be subjective. However this could be also a good thing if we wanted to make the method sensitive to the personnel of the institution.

FUTURE TRENDS

The Basel Committee foresees the complete realization of the second accord and also of the operational risk standards, for the end of 2007. For the financial institutions that don't consider the operational risks as possible causes of losses yet, it will be opportune to begin to implement an operational loss database where to apply the models.

Besides, the standards for the operational risk will influence not only the banks, but also the access to the credit of the small and medium enterprises which will be subjected to the operational risk evaluation for a better interest rate.

The operational risk is well specified in the banking sector but it is important to consider also other fields, as for example those of telecommunication or manufacture industry and so on. In the future we will see more operational risk analysis on Information Technology (IT) field, especially in the case of IT intensive business (as for online bank). On this road we will observe the birth of IT Operational Risks which will be defined not only for banks but also for different industry fields.

CONCLUSION

Among the different models there is not yet the tendency to use a model more than another, because it strongly depends on the resources of the institution and on its strategy.

The scorecard methods are completely different from those actuarial and analytical because they analyze the institution from different aspects. The scorecards see the vision of the people (therefore they can be used in absence of an appropriated DB), instead the others that of the data. For both, the construction is not simple since the scorecards need good questionnaires and very efficient personnel due to the subjectivity of the procedure, instead the actuarial and analytical models need good database to identify the parameters of the distributions. All methods, however, have problems due to the modeling of the dependences. For the quantitative models the dependences can be considered with the *copula* functions (Dalla Valle, Fantazzini & Giudici 2005; Alexander (Ed.), 2003) and the Bayesian Network, while for the scorecards there are more difficulties but an approach at such problem can be done with BN (Bonafede & Giudici, 2006).

In conclusion, the Bayesian approaches can integrate different sources of information so they are more sensitive to background changes. Moreover, they allow the evaluation of strategies of intervention even if there are more difficulties to be implemented.

KEY TERMS

Backtesting: Statistical hypothesis tests to verify either the VaR or the ORR.

BIA or Basic Indicator Approach: A top-down methodology, for the calculation of the capital requirement (CR_{OR}) to cover OR, based on the average of the gross income (GI) over the previous three years (t):

$$CR_{OR} = \alpha \times \sum_{t=1}^{3} \frac{GI_t}{3} = 15\% \times \sum_{t=1}^{3} \frac{GI_t}{3}$$

where α is a coefficient esteemed by the Basel Committee in a value of 15%.

Copula: An expression for the multivariate distribution in function of the marginal distributions. Given a random vector $\{X_1,\ldots,X_n\}$, its marginal distributions $F_{Xi}(x)$ and the copula function that describes the dependences among the variables, then the $F_{Xi}(x)$ can be combined by copula function to get the joint distribution with the demanded dependence.

Key Risk Driver or KRD: A measure associated to the company risk profile. Meaningful changes of the KRD could implicate important changes on the general level of the quality or to point out a potential increase to the exposure to operational risks or of other nature. In this manner a KRD gives a predictive action.

Key Risk Indicator or KRI: A category of measure used for monitoring the activities and the controls because the KRI has association with the losses; it will be monitored during the year. Such a variable is identified during the phase of process mapping in which the KRDs are identified and then the KRIs. The expert opinions can be weighed by KRI.

Scenario Analysis: A verification of the model sensitivity with the variation of some parameters as frequency, severity and correlation among the losses.

STA or Standard Indicator Approach: Top-down methodology, for the calculation of the capital requirement (CR_{OR}) to cover OR, based on the average of the gross income (GI) of eight business lines (i) over the previous three years (j):

$$CR_{CR} = \sum_{i=1}^{8} \beta_i \times \left(\frac{\sum_{j=1}^{3} \max\{GI_{ij};0\}}{3} \right);$$

where β_i is a coefficient (for every business lines) esteemed by the Basel Committee.

Value at Risk: The possible maximum loss in the 99.99% of the cases in a year, this is the 99.99 percentile of the loss's distribution. Operationally it is used the 99 percentile.

Statistical Web Object Extraction

INTRODUCTION

The World Wide Web is a vast and rapidly growing repository of information. There are various kinds of objects, such as products, people, conferences, and so on, embedded in both statically and dynamically generated Web pages. Extracting the information about real-world objects is a key technique for Web mining systems. For example, the object-level search engines, such as *Libra* (http://libra.msra.cn) and *Rexa* (http://rexa.info), which help researchers find academic information like papers, conferences and researcher's personal information, completely rely on structured Web object information.

However, how to extract the object information from diverse Web pages is a challenging problem. Traditional methods are mainly template-dependent and thus not scalable to the huge number of Web pages. Furthermore, many methods are based on heuristic rules. So they are not robust enough. Recent developments in statistical machine learning make it possible to develop advanced statistical Web object extraction models. One key difference of Web object extraction from traditional information extraction from natural language text documents is that Web pages have plenty of structure information, such as two-dimensional spatial layouts and hierarchical vision tree representation. Statistical Web object extraction models can effectively leverage this information with properly designed statistical models.

Another challenge of Web object extraction is that many text contents on Web pages are not regular natural language sentences. They have some structures but are lack of natural language grammars. Thus, existing natural language processing (NLP) techniques are not directly applicable. Fortunately, statistical Web object extraction models can easily merge with statistical NLP methods which have been the theme in the field of natural language processing during the last decades. Thus, the structure information on Web pages can be leveraged to help process text contents, and traditional NLP methods can be used to extract more features.

Finally, the Web object extraction from diverse and large-scale Web pages provides a valuable and challenging problem for machine learning researchers. To nicely solve the problem, new learning methodology and new models (Zhu et al., 2007b) have to be developed.

BACKGROUND

Web object extraction is a task of identifying interested object information from Web pages. A lot of methods have been proposed in the literature. The wrapper learning approaches like (Muslea et al., 2001; Kushmerick, 2000) take in some manually labeled Web pages and learn some extraction rules (wrappers). Since the learned wrappers can only be used to extract data from similar pages, maintaining the wrappers as Web sites change will require substantial efforts. Furthermore, in wrapper learning a user must provide explicit information about each template. So it will be expensive to train a system that extracts data from many Web sites. The methods (Zhao et al., 2005; Embley et al., 1999; Buttler et al., 2001; Chang et al., 2001; Crescenzi et al., 2001; Arasu, & Garcia-Molina, 2003) do not need labeled training samples and they automatically produce wrappers from a collection of similar Web pages.

Two general extraction methods are proposed in (Zhai & Liu, 2005; Lerman et al., 2004) and they do not explicitly rely on the templates of Web sites. The method in (Lerman et al., 2004) segments data on list

pages using the information contained in their detail pages, and the method in (Zhai & Liu, 2005) mines data records by string matching and also incorporates some visual features to achieve better performance. However, the data extracted by (Zhai & Liu, 2005; Lerman et al., 2004) have no semantic labels.

One method that treats Web data extraction as a classification problem is proposed in (Fin & Kushmerick, 2004). Specifically, Fin & Kushmerick (Fin & Kushmerick 2004) use a support vector machine to identify the start and end tags for a single attribute. For the task of extracting multiple attributes, this method loses the dependencies between different attributes. Instead, the statistical models, which are the theme of this article, can effectively incorporate the statistical dependencies among multiple related attributes, such as a product's name, image, price and description, and achieve globally consistent extraction results.

MAIN FOCUS

Statistical Web object extraction models focus on exploring structure information to help identify interested object information from Web pages. Zhu et al. (Zhu et al, 2005; Zhu et al, 2006; Zhu et al, 2007a; Zhu et al, 2007b) have developed a complete statistical framework for Web object extraction and text content processing on Web pages. The key issues in statistical Web object extraction are selecting appropriate data representation formats, building good graphical models to capture the statistical dependencies, and exploring the structure information of Web pages to process text contents.

Data Representation Formats

Most existing Web mining methods take the HTML source codes or the HTML tag trees as their data representation format. However, due to the low-level representation these methods often suffer from many problems, such as scalability and robustness, when being applied to large-scale diverse Web pages. Instead, the higher level visual information, such as font, position, and size, is more robust and expressive, which will be the features and data representation formats used in statistical models.

Existing statistical models are built based on two different views and data representation formats of Web pages.

1. **2D spatial layout:** When a Web page is displayed to readers, it is actually a two-dimensional image. The HTML elements have their spatial information, such as position (i.e., coordinates in the 2D plane) and size (i.e., height, width, and area). With this spatial information, the elements are well-laid in the 2D plane for easy reading. Thus, the first representation format of Web data is a two-dimensional grid, each of whose nodes represents an HTML element. The edges between the nodes represent the spatial neighborhoods of the HTML elements.
2. **Hierarchical organization:** 2D spatial layout is a flat representation of a Web page. But if we look at the HTML tag trees, which are natural representations of Web pages, we see that the HTML elements are actually pended on a hierarchy. The hierarchical structure in some sense reveals a specific type of organization of the elements. This hierarchical organization information can be helpful in identifying the boundaries of data records or even in identifying the target attributes.

Statistical Web Object Extraction Models

According to the two different data representation formats—2D spatial layout and hierarchical organization, two types of statistical models have been studied.

1. **2D local model:** The two-dimensional Conditional Random Fields (Zhu et al, 2005) are introduced to model a data record, which consists of a set of HTML elements. The 2D model put the elements on a grid according to their spatial information and neighborhood relationships. Each node on the grid is associated with a random variable, which takes values from a set of class labels, such as name, image, price, and description in product information extraction. The model defines a joint distribution of all the variables and we can do some statistical inference to get the most probably labeling results of all the random variables. From the labeling results, we know which element is

the product's name, which is the image, which is the price, and etc. When building the model, we have to provide a set of labeled training data to learn its parameters.

2. **Hierarchical integrated model:** The previous 2D local model is a de-coupled method, that is, the detection of data records and the labeling of HTML elements are performed separately. This will cause several disadvantages, such as error propagation, lack of semantics in data record detection, lack of mutual interactions in attribute labeling, and failure in incorporating long-distance dependencies. To address these problems, hierarchical integrated models (Zhu et al, 2006) are introduced. These models are based on the hierarchical representation of Web pages. However, in practice, instead of the HTML tag trees, vision trees (Cai et al, 2004) are used as the data representation format. Vision trees have their advantages in representing content structure, while HTML tag trees tend to represent presentation structure. Also, tags trees tend to be diverse in the Web environment.

Statistical Models for Text Content Processing

In both the 2D local model and the hierarchical integrated model, HTML elements are taken as atomic extraction units. However, in many cases an HTML element can contain multiple interested attributes. For example, an element in a paper record can contain the names of several coauthors (Zhu et al, 2007a). If we want to identify each author's name, text content processing like segmentation must be performed.

Traditional NLP methods can address this problem in natural language sentences. However, they are not directly applicable to Web data extraction because on Web pages many text contents are text fragments and they are typically lack of the grammars as required in NLP systems. Fortunately, all the proposed statistical models can be easily merged with statistical NLP methods. One preliminary work is (Zhu et al, 2007a), where the structure information of Web pages is integrated into text content processing. Promising results are achieved in extracting researchers' information, such as name, title, affiliation, contact information, and publication information.

FUTURE TRENDS

Statistical Web object extraction techniques will become key components of any Web data mining systems. It is of great interest for machine learning researchers to develop more powerful and more automatic learning systems to extract the huge information from the Web. In the near future, more theories and machine learning techniques of statistical Web object extraction will be developed. Meanwhile, comprehensive comparisons of these theories and techniques will be carried out. More and more object-level vertical search engines will be available for users.

CONCLUSION

Extracting Web object information from diverse Web pages is important and challenging. Traditional approaches like wrapper learning and single attribute extractors cannot satisfy the increasing demands, especially in developing object-level vertical search engines. Statistical machine learning methods are more robust and scalable. To build a good statistical extraction model, selecting an appropriate data representation and building a good graphical model are key steps. On Web pages plenty of structure information, such as two-dimensional spatial layouts and hierarchical vision-tree representation, can be explored in statistical models to achieve promising results.

KEY TERMS

Conditional Random Fields: One type of graphical models that define a conditional probability of labels given the input features. The advantage of this model is that it does not pay efforts to model the input features and thus no independence assumption is made. In contrast, the generative models like HMMs directly model the input features and define a joint distribution of both labels and inputs. To achieve computational tractability, strong independence assumption must be made in generative models.

Data Records: Another data unit of Web pages. A data record is a block in a Web page and contains the information of a single object. For example, a product record usually contains the product's name, image, price, and some descriptions.

Graphical Models: A modeling language that combines graph theory and probability theory. A graphical model consists of two parts—a graph and a probability distribution of the random variables associated with the graph's vertices. Given a graphical model, various queries can be asked, such as the marginal probability, the posterior probability, and the most likely assignment of some random variables. The inference can be efficiently carried out by exploring the sparseness of the graph structure.

HTML Elements: The atomic data units of Web pages. An HTML element can be a text fragment, an image, a button, or just some decoration items.

Statistical Web Object Extraction: Web object extraction models that learn statistical information from provided data sets. It can effectively incorporate heterogeneous features of Web data.

Structured Extraction Model: One type of extraction models in which multiple attributes are extracted at the same time. For example, for product information extraction all the product attributes (e.g. name, image, price, and description) are identified simultaneously. The advantage of structured extraction models is that they can incorporate the statistical dependencies between multiple attributes, which will be lost in a model that identifies each attribute separately.

Vision Tree: A data representation format of Web pages. Like HTML tag trees, a vision tree is itself a tree. The difference from HTML tag trees is that tag trees tend to reveal presentation structure rather than content structure and are often not accurate enough to discriminate different semantic parts in a Web page. A vision tree is built with a vision-based page segmentation (VIPS) approach (Cai et al., 2004), which makes use of page layout features such as font, color, and size to construct the tree. Each node on a vision tree represents a data block on a Web page. The root block represents the whole page and each inner block is the aggregation of all its child blocks. The leaf blocks are the atomic HTML elements, which form a flat segmentation of the Web page.

Web Object Extraction: An information extraction task that identifies interested object information from Web pages. The difference from traditional information extraction is that traditionally information extraction is typically conducted on natural language documents which are quite different from Web pages. Natural language sentences are composed according to a particular type of grammars, while the HTML elements on Web pages have more structures but are typically lack of grammars.

Storage Systems for Data Warehousing

Alexander Thomasian
New Jersey Institute of Technology - NJIT, USA

José F. Pagán
New Jersey Institute of Technology - NJIT, USA

INTRODUCTION

Data storage requirements have consistently increased over time. According to the latest WinterCorp survey (http://www/WinterCorp.com), "The size of the world's largest databases has tripled every two years since 2001." With database size in excess of 1 terabyte, there is a clear need for storage systems that are both cost effective and highly reliable.

Historically, large databases are implemented on mainframe systems. These systems are large and expensive to purchase and maintain. In recent years, large data warehouse applications are being deployed on Linux and Windows hosts, as replacements for the existing mainframe systems. These systems are significantly less expensive to purchase while requiring less resources to run and maintain.

With large databases it is less feasible, and less cost effective, to use tapes for backup and restore. The time required to copy terabytes of data from a database to a serial medium (streaming tape) is measured in hours, which would significantly degrade performance and decreases availability. Alternatives to serial backup include local replication, mirroring, or geoplexing of data.

The increasing demands of larger databases must be met by less expensive disk storage systems, which are yet highly reliable and less susceptible to data loss.

This article is organized into five sections. The first section provides background information that serves to introduce the concepts of disk arrays. The following three sections detail the concepts used to build complex storage systems. The focus of these sections is to detail: (i) *Redundant Arrays of Independent Disks* (RAID) arrays; (ii) multilevel RAID (MRAID); (iii) concurrency control and storage transactions. The conclusion contains a brief survey of modular storage prototypes.

BACKGROUND

The fifty year old magnetic disk drive [technology] remains a viable storage medium because they can accommodate an excess of 500 Gigabytes (GB), are nonvolatile, inexpensive, have an acceptable random access time (10 milliseconds), and exhibit a *Mean Time to Failure (MTTF)* exceeding 10^6 hours. Concurrent with their benefits, disk failures occur frequently in large data centers.

RAID serves to mitigate disk failures in large installations (Chen et al. 1994). RAID level 5 (RAID5) masks the failure of a single disk by reconstructing requested blocks of a failed disk, on demand. Additionally, it automatically reconstructs the contents of the failed disk on a spare disk.

The RAID paradigm is inadequate for *Very Large Disk Arrays (VLDA's)* used in data warehousing applications, because the non-disk components may be less reliable than the physical disks. *Hierarchical RAID (HRAID)* achieves a high reliability by using multiple levels of RAID controllers (Baek et al. 2001). The higher and lower RAID levels of HRAID are specified as RAIDX(M)/Y(N), where X and Y are the RAID level and *M* and *N* denote the number of virtual disks or *storage nodes (SN's)* at the higher level and physical disks at the lower level. *Multilevel RAID (MRAID)* was proposed as an alternative to HRAID, because of its two key differences: (i) disks are organized into *SN's* (or bricks) at the lower level, this constitutes the *smallest replaceable unit (SRU)*, (ii) the association among SN's is logical and dynamic rather than hardwired (Thomasian 2006).

Each SN consists of an array of disks, an array controller, a partially nonvolatile cache, and the capability to interconnect. SN costs are kept low, in some designs, by using mirroring to protect data on each SN.

The internal structure of a brick in IBM's Intelligent Brick prototype is illustrated in (Wilcke et al. 2006)

Figure 2. Bricks are cube shaped and communicate via capacitive coupling between insulated flat metal plates at each of its six surfaces. Higher capacities are attained by stacking bricks on top of each other. Gigabit Ethernet is used to provide connectivity to external cubes. A fail-in-place or deferred maintenance system is also postulated.

MAIN THRUST

We first review RAID systems, before discussing multilevel RAID. We next describe storage transactions, which are required for the correct operation of the system.

RAID LEVELS

There are seven RAID levels (Chen et al. 1994) which are classified as *k disk failure tolerant (kDFT)* arrays (Thomasian et al. 2007). RAID0 is 0DFT because it has no redundancy. Data is divided into *striping units (SUs)*, which are written to the disks in a round-robin manner. This technique of writing data, in small units, across multiple disks is termed striping. Striping also serves to balance the load across an array of *N* disks.

RAID1 is also referred to as *Basic mirroring (BM)*. The simplest RAID1 configuration requires two disks, where data is written such that both disks are exact copies of each other. RAID1 has *M = N/2* disk pairs, where *N* is the number of physical disks. RAID1 can tolerate up to M disk failures (one disk of a pair), however failure of both disks (in a pair) will lead to data loss. Hence, RAID1 is 1DFT. BM has twice the read transaction rate of a single disk because reads are duplexed between the disk pairs. Similarly, a single disk failure will shift the load to the working disk and essentially double the load on the surviving disk.

In *Interleaved Declustering (ID)* the total number of disks (*N)* are divided into *c* groups, so that there are *M = N / c* disks per group. In this scheme, disks are partitioned into primary and secondary areas. Data is written completely to a primary area of a single disk. Additionally, this data is divided into blocks and written to the secondary areas of the remaining *M – 1* disks in the group. Each group is a 1DFT array and a single disk failure will increase the load on the surviving disks by *M / (M – 1)*.

In *Chained Declustering (CD)* the primary data on each disk is replicated to the secondary area of the next disk modulo *N*, e.g., for $i < N$ $(N+i) \bmod N = i$.

In *Group Rotate Declustering (GRD)*, data is striped across a group of disks (*M = N / 2)* and replicated (in a rotated manner) across the remaining *M* disks. The load on surviving disks in CD and GRD may be balanced with appropriate routing of read requests. The tradeoff between load balancing and reliability in these RAID1 configurations is discussed in (Thomasian and Blaum 2006). The aforementioned paradigms can be applied to bricks and to arrays of multiple bricks, thus facilitating a balanced load on failures.

RAID2 uses Hamming codes which are inefficient and increases the number of check disks in proportion to the logarithm of existing data disks.

RAID3, RAID4, and RAID5 are 1DFTs because they require one disk for parity. RAID3 uses small SUs which are intended for parallel data transfers, thus increasing the transfer rate. RAID3 is most efficient with synchronized disks. RAID4 allocates the parity SU on the Nth disk which is computed from the SUs on the first *N-1* disks. On disk *N*, let D_i, $1 \le i \le N-1$ denote the first *N-1* SUs. The parity of the SUs is: $P_{1:4} = D_1 \oplus D_2 \oplus D_3 \oplus D_4$ where $\oplus$ is the XOR operator, such that $1 \oplus 1 = 0$. If disk 1 fails then block d_1 in SU D_1 can be reconstructed as $d_1 = d_2 \oplus d_3 \oplus d_4 \oplus p_{1:4}$.

When data block d_1 is updated, instead of reading all corresponding blocks, we can update the parity block by computing $d_1^{diff} = d_1^{old} \oplus d_1^{new}$ and using d_1^{diff} to compute $p_{1:4}^{new} = p_{1:4}^{old} \oplus d_1^{diff}$. RAID4 has two disadvantages: (i) the parity disk is not accessed by read requests, (ii) it becomes a hot-spot when write requests dominate. RAID5 uses the left-symmetric distributed parity layout. Here, blocks are arranged in left to right diagonals. Reading a block on a failed disk, in RAID5, will generate reads to corresponding blocks on the surviving *N - 1* disks, thus doubling the load on these disks. A solution to this problem is *clustered RAID – CRAID*, which uses a parity group of size *G < N*, so that load increase to the other disks is $\alpha = (G - 1)/(N - 1)$.

RAID6 is a 2DFT with two parity disks, P and Q parities. Reed-Solomon codes and specialized parity codes: EVENODD, *Row Diagonal Parity - RDP*, X-codes, and RM2 (Thomasian and Blaum 2007) are typically used. X-codes require *N* to be prime, while

RM2 uses more than the minimal capacity of two disks for parities. In a 2DFT array (such as RAID6) incurs a higher processing overhead than a 1DFT (such as RAID5) because writes must update two parities instead of one. The relative performance of RAID6 and RM2 versus RAID5 and RAID0 is investigated in (Thomasian et al. 2007).

Rebuild is a systematic reconstruction of a failed disk on a spare. Successive tracks of the surviving disks are read and XOR-ed to compute missing tracks. Distributed sparing is a better alternative because it efficiently uses the bandwidth of all disks. If the parity SUs in RAID5 are used as spare SUs, then RAID5 reverts to a RAID0. However, If the Q parity of RAID6 is used as a spare SU, then RAID6 reverts to a RAID5.

Internode Replication and Erasure Coding

Replication is preferable to erasure coding because it attains a higher access rate. Additional improvement can be realized by judicious routing and scheduling of requests, e.g., the *distributed shortest processing time first – DSPTF* method (Lumb, Golding, and Ganger 2004).

Read requests can be processed by any SN holding the requested data, however, updates should be applied to all SNs, i.e., read-one, write-all paradigm. The linearizability correctness paradigm requires reads to access the latest version of any data. More generally, appropriate *concurrency control (CC)* algorithms are required for replicated data (Thomasian 1996).

Erasure coding across SNs is discussed in (Thomasian 2006). If the number of SNs in a VLDA is very large, erasure coding may be applied to SN clusters. Consider *M* SNs in a cluster, which is organized as a Multilevel RAID array, that is *l node failure tolerant* (*l NFT)*. Each SN, then, will contain *N* disks and is a *k*DFT array. For simplicity, we will use $k = l = 1$, i.e., nested RAID arrays written as RAID5(M)/5(M).

It would be inefficient to allocate one SN for all of the Q parities. Instead, distributing the Q parities among all SNs would better balance the read load. Similarly, each SN can allocate *1/N* of its capacity to P parities and another *1/N* to Q parities, and the two parities can be placed in parallel diagonals to balance the load. P parities will protect data blocks (and Q parities) in the same stripe, while Q parities serve to protect data blocks across SNs.

Example 1

A disk array composed of four SNs containing four disks each, where $M = N = 4$, is shown in Table 1. Each SU is designated as $x^{m}_{i,j}$, where $1 \le i \le N$ is the stripe or row number, $1 \le j \le N$ is the disk number, and $1 \le m \le M$ is the SN number (*x* may be either *d*, *p*, or *q*). The Q parities are rotated across SNs and disks, to balance the load.

To update $d^{2}_{4,1}$ we:

1. Compute $d^{2diff}_{4,1} = d^{2new}_{4,1} \oplus d^{2old}_{4,1}$ and update its parities in parallel:
$$p^{2new}_{4,3} = p^{2old}_{4,3} \oplus d^{2diff}_{4,1}, q^{1new}_{4,1} = q^{1old}_{4,1} \oplus d^{2diff}_{4,1}.$$
2. Compute $q^{1diff}_{4,1} = q^{1new}_{4,1} \oplus q^{1old}_{4,1}$ to update its *p* parity: $p^{1new}_{4,4} = p^{1old}_{4,4} \oplus q^{1diff}_{4,1}$.

Disk failures can be dealt with either within an SN, or with an erasure coding scheme across SNs. For example, consider a failure of SN_1 where we need to reconstruct its first stripe:

$$d^{1}_{1,1} = d^{2}_{1,1} \oplus q^{4}_{1,1}$$

$$d^{1}_{1,2} = q^{3}_{1,2} \oplus d^{4}_{1,2}$$

$$q^{1}_{1,4} = d^{2}_{1,4} \oplus d^{3}_{1,4}$$

$$p^{1}_{1,3} = d^{1}_{1,1} \oplus d^{1}_{1,2} \oplus q^{1}_{1,4}$$

If disk 1 at SN_2 had failed, it should be reconstructed before SN_1 can be reconstructed:

$$d^{2}_{1,1} = p^{2}_{1,2} \oplus q^{2}_{1,3} \oplus d^{2}_{1,4}$$

For higher efficiency, it is better to overlap the rebuilding of disk 1 at SN_2 with the rebuilding SN_1.

Storage Transactions

A race condition arises when updating $p^{1}_{1,3}$ to reflect changes to both $d^{1}_{1,1}$ and $d^{1}_{1,2}$, at the same time. The

Table 1. Data layout in MRAID5(4)/5(4) - nested RAID5 arrays with M = 4 SNs and N = 4 disks per SN.

Node 1				Node 2				Node 3				Node 4			
$d^1_{1,1}$	$d^1_{1,2}$	$p^1_{1,3}$	$q^1_{1,4}$	$d^2_{1,1}$	$p^2_{1,2}$	$q^2_{1,3}$	$d^2_{1,4}$	$p^3_{1,1}$	$q^3_{1,2}$	$d^3_{1,3}$	$d^3_{1,4}$	$q^4_{1,1}$	$d^4_{1,2}$	$d^4_{1,3}$	$p^4_{1,4}$
$d^1_{2,1}$	$p^1_{2,2}$	$q^1_{2,3}$	$d^1_{2,4}$	$p^2_{2,1}$	$q^2_{2,2}$	$d^2_{2,3}$	$d^2_{2,4}$	$q^3_{2,1}$	$d^3_{2,2}$	$d^3_{2,3}$	$p^3_{2,4}$	$d^4_{2,1}$	$d^4_{2,2}$	$p^4_{2,3}$	$q^4_{2,4}$
$p^1_{3,1}$	$q^1_{3,2}$	$d^1_{3,3}$	$d^1_{3,4}$	$q^2_{3,1}$	$d^2_{3,2}$	$d^2_{3,3}$	$p^2_{3,4}$	$d^3_{3,1}$	$d^3_{3,2}$	$p^3_{3,3}$	$q^3_{3,4}$	$d^4_{3,1}$	$p^4_{3,2}$	$q^4_{3,3}$	$d^4_{3,4}$
$q^1_{4,1}$	$d^1_{4,2}$	$d^1_{4,3}$	$p^1_{4,4}$	$d^2_{4,1}$	$d^2_{4,2}$	$p^2_{4,3}$	$q^2_{4,4}$	$d^3_{4,1}$	$p^3_{4,2}$	$q^3_{4,3}$	$d^3_{4,4}$	$p^4_{4,1}$	$q^4_{4,2}$	$d^4_{4,3}$	$d^4_{4,4}$

value of $p^1_{1,3}$ might be set to either $p^{1new}_{1,3} = d^{1old}_{1,1} \oplus d^{1new}_{1,1} \oplus p^{1old}_{1,3}$ or $p^{1new}_{1,3} = d^{1old}_{1,2} \oplus d^{1new}_{1,2} \oplus p^{1old}_{1,3}$, however, $p^1_{1,3}$ should reflect the outcome of both changes; $p^{1new}_{1,3} = p^{1old}_{1,3} \oplus d^{1diff}_{1,1} \oplus d^{1diff}_{1,2}$. A similar situation arises when updating $q^4_{1,4}$ to reflect simultaneous changes to $d^1_{1,1}$ and $d^1_{1,2}$. This is termed the lost update problem.

The lost update problem can be prevented by encapsulating each update inside a transaction. Let R and W represent reading and writing of the data block in parentheses. Read requests obtain a shared lock on the object being read. The lock is promoted to an exclusive lock when the object is updated. According to strict *two-phase locking (2PL)*, locks are held until the transaction commits using a *two-phase commit (2PC)* protocol, however, a less sophisticated protocol may be appropriate for this case, (example in Thomasian 1996) and (Ramakrishnan and Gehrke (2003)).

Transaction (update $d^{1new}_{1,2}$) = {

1. $R(d^{1old}_{1,1})$
2. $W(d^{1new}_{1,1})$
3. $d^{1diff}_{1,1} = d^{1new}_{1,1} \oplus d^{1old}_{1,1}$
4. $R(p^{1old}_{1,3}), R(q^{4old}_{1,1})$
5. $p^{1new}_{1,3} = d^{1diff}_{1,1} \oplus p^{1old}_{1,3}, q^{4new}_{1,1} = d^{1diff}_{1,1} \oplus q^{4old}_{1,1}, W(p^{1new}_{1,3})$
6. $q^{4diff}_{1,1} = q^{4new}_{1,1} \oplus q^{4old}_{1,1}, R(p^{4old}_{1,4}),$
7. $p^{4new}_{1,4} = p^{4old}_{1,4} \oplus q^{4diff}_{1,1}$
8. $W(p^{4new}_{1,4})$

}.

If disk 1 at SN_1 fails, rather than aborting the transaction, we reconstruct $d^{1old}_{1,1} = d^1_{1,2} \oplus p^1_{1,3} \oplus q^1_{1,4}$ via a fork-join request. This requires the locking of accessed objects to reconstruct $d^1_{1,1}$, that is, $d^1_{1,2}$ and $p^1_{1,3}$ (note that $d^1_{1,2}$ is also being updated). Similarly, there is no need to abort the transaction if disk 3 at SN_1 has failed (making $p^1_{1,3}$ unavailable) because the parity will be reconstructed via the rebuild process. In effect we postulate nested transactions such that an SN with failed disks can issue an appropriate sub-transaction to reconstruct the data. *Base Storage Transactions (BSTs)* proposed in (Amiri et al. 2000) uses a different semantic, where, reading from a failed disk results in an abort and "the parent task" will issue an appropriate BST for access in degraded mode.

Distributed dynamic locking with blocking may lead to distributed deadlocks, whose detection and resolution is costly. Lock conflicts can be resolved at the local level with wound-wait and wait-die locking methods or the time-stamp ordering method (see Thomasian 1996).

Storage Brick Projects

In IBM's Collective Intelligent Brick (CIB) project, the connectivity of a 3-D mesh-based data cube is treated

as a percolation problem (Fleiner et al. 2006). Simulation is used to determine the fraction of failures that renders a system unusable. A 3D (dimensional) mesh is operational as long as 70%of the bricks are working, while a 2D mesh requires 85% of bricks because fewer alternate paths are available (Wilcke et al. 2006).

Rao et al. (2005) describe an array of bricks, where each brick is one of RAID0, RAID5, or RAID6, and erasure coding is implemented across bricks. The performance metric of interest is "data loss events per petabyte-year'' (petabyte 10^{12}). The sensitivity of *Mean Time to Data Loss (MTTDL)* to MTTFs, rebuild block size, and link speed is investigated.

Federated Array of Bricks (FAB) is a distributed disk array, implemented at HP Labs, that attains the same reliability as enterprise disk arrays, at a lower cost. As described in Saito et al. (2004) FAB consists of a collection of bricks with a reconfiguration algorithm to move data when bricks are added or decommissioned. A novel feature of FAB is its majority voting based algorithm to replicate or erasure-code logical blocks across disks. This protocol allows linearizable accesses to replicated data, transparently bypassing failed bricks. RepStore, described by Zhang et al. (2004), is a prototype at Microsoft Research in China, which offers both replication and erasure coding. The choice is made at volume creation time in FAB, while RepStore makes the choice adaptively.

A comprehensive review of storage systems is given by Kenchmana-Hosekote (2004). Table 2 provides a classification of data paths, serialization, and atomicity. Serialization is attained by locking.

Xin (2005) studied the reliability mechanisms in very large storage systems with repair. Markov chain models are used to study the *Mean Time to Data Loss (MTTDL)* in 2- and 3-way mirroring and mirrored RAID5 arrays.

FUTURE TRENDS

While there are experimental brick systems: (i) *CIB* at IBM; (ii) *FAB* at HP; and (iii) RepStore at Microsoft Research in China, they are all still in the prototyping stage. It is expected that some of this projects will turn into products, but new software will be needed to make bricks in data warehousing a reality.

CONCLUSION

We have introduced design issues related to arrays of bricks. Multilevel RAID allows each SN to have an internal reliability mechanism, but the RAID paradigm is implemented across SNs to deal with failures.

KEY TERMS

Erasure Coding (EC): Erasure coding allows the reconstruction of the contents of a failed disk, whose position is known. Parity and Reed-Solomon codes are forms of EC.

Hierarchical RAID (HRAID): Higher level RAID controllers control lower level RAID controllers, which control disks. This scheme generalizes to more than two levels.

kDFT: *k* disk failure tolerant array.

Multilevel RAID (MRAID): It is similar to HRAID, except multiple RAID arrays are associated to each other logically, rather than physically. An examples is RAIDX(M)/RAIDY(N), where X/Y denote the RAID levels, and M/N denote the number of logical/physical disks at the higher/lower levels, e.g., RAID1(2)/RAID5(7) is two mirrored RAID5s with 7 disks each.

Parity Block: The bits of a parity block are computed by performing an exclusive OR between the corresponding bits of data blocks at the other disks. EVENODD and RDP are parity based schemes, which compute two check blocks using symbols of appropriate size. They are more efficient than Reed-Solomon codes from the viewpoint of exclusive-OR operations.

RAID: Redundant array of independent disks, which is achieved using replication or erasure coding.

Rebuild: Reconstructing the contents of a failed disk on a spare disk, while surviving disks process external requests.

Storage Node (SN or Brick): A self-contained collection of disks, a controller, a DRAM cache, which constitute the smallest replaceable unit. SNs are connected to each other, a power supply, and cooling system.

Storage Transactions: Ensure the correct updating of parity blocks as data blocks are being updated.

Striping: Partition a dataset into equal sized stripe units allocated in round-robin manner across the disks.

Subgraph Mining

Ingrid Fischer
University of Konstanz, Germany

Thorsten Meinl
University of Konstanz, Germany

INTRODUCTION

The amount of available data is increasing very fast. With this data, the desire for data mining is also growing. More and larger databases have to be searched to find interesting (and frequent) elements and connections between them. Most often the data of interest is very complex. It is common to model complex data with the help of graphs consisting of nodes and edges that are often labeled to store additional information. Having a graph database, the main goal is to find connections and similarities between its graphs. Based on these connections and similarities, the graphs can be categorized, clustered or changed according to the application area. Regularly occurring patterns in the form of subgraphs —called *fragments* in this context—that appear at least in a certain percentage of graphs, are a common method to analyze graph databases. The actual occurrence of a fragment in a database graph is called *embedding*. Finding the fragments and their embeddings is the goal of subgraph mining described in detail in this chapter.

The first published graph mining algorithm, called Subdue, appeared in the mid-1990s and is still used in different application areas and was extended in several ways. (Cook & Holder, 2000). Subdue is based on a heuristic search and does not find all possible fragments and embeddings. It took a few more years before more and faster approaches appeared. In (Helma, Kramer, & de Raedt, 2002) graph databases are mined for simple paths, for a lot of other applications only trees are of interest (Rückert & Kramer, 2004). Also Inductive Logic Programming (Finn et al., 1998) was applied in this area. At the beginning of the new millennium finally more and more and every time faster approaches for general mining of graph databases were developed that were able to find all possible fragments. (Borgelt & Berthold, 2002; Yan & Han, 2002; Kuramochi & Karypis, 2001; Nijssen & Kok, 2004).

Several different application areas for graph mining are researched. The most common area is mining molecular databases where the molecules are displayed by their two-dimensional structure. When analyzing molecules it is interesting to find patterns that might explain why a certain set of molecules is useful as a drug against certain diseases (Borgelt & Berthold, 2002). Similar problems occur for protein databases. Here graph data mining can be used to find structural patterns in the primary, secondary and tertiary structure of protein categories (Cook & Holder, 2000).

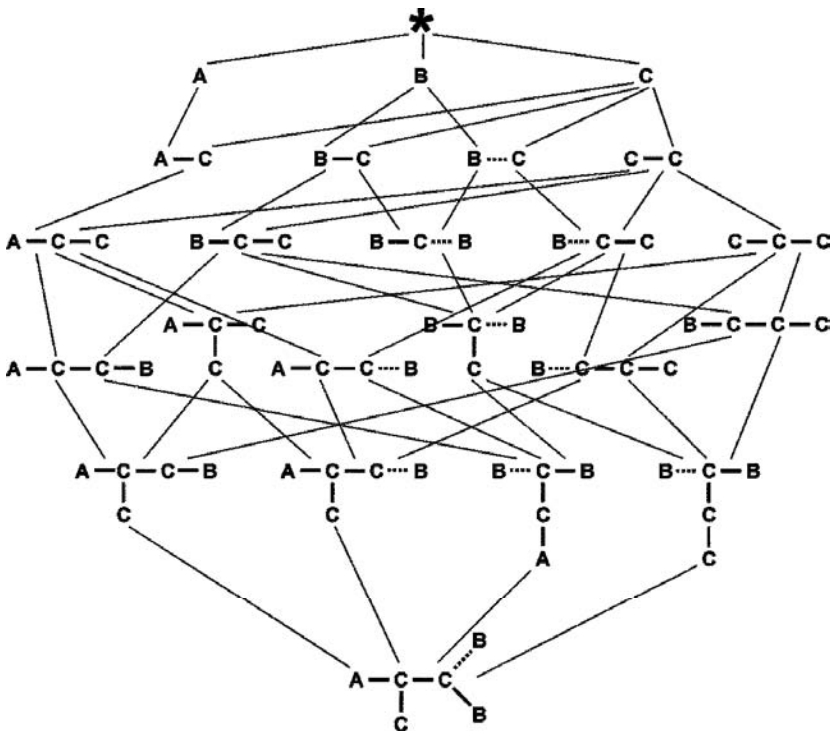
Another application area are web searches (Cook, Manocha, & Holder, 2003). Existing search engines use linear feature matches. Using graphs as underlying data structure, nodes represent pages, documents or document keywords and edges represent links between them. Posing a query as a graph means a smaller graph has to be embedded in the larger one. The graph modeling the data structure can be mined to find similar clusters.

Quite new is the application of subgraph mining in optimizing code for embedded devices. With the help of so-called procedural abstraction, the size of pre-compiled binaries can be reduced which is often crucial because of the limited storage capacities of embedded systems. There, subgraph mining helps identifying common structures in the program's control flow graph which can then be combined ("abstracted") into a single procedure (Dreweke et.al., 2007).

BACKGROUND

Theoretically, mining in graph databases can be modeled as the search in the lattice of all possible subgraphs. In Figure 1 a small example is shown based on one graph with six nodes labeled **A,B,C** as shown at the bottom of the figure. All possible subgraphs of this small graph are listed in this figure. At the top of the figure, the empty graph modeled with * is shown. In the next

Figure 1. The lattice of all subgraphs in a graph



row all possible subgraphs containing just one node (or zeros edges) are listed. The second row contains subgraphs with one edge. The "parent-child" relation between the subgraphs (indicated by lines) is the subgraph property. The empty graph can be embedded in every graph containing one node. The graph containing just one node labeled **A** can be embedded in a one edge graph containing nodes **A** and **C**. Please note, that in Figure 1 no graph with one edge is given containing nodes labeled **A** and **B**. As there is no such subgraph in our running example, the lattice does not contain a graph like this. Only graphs that are real subgraphs are listed in the lattice. In the third row, graphs with two edges are shown and so on. At the bottom of Figure 1, the complete graph with five edges is given. Each subgraph appearing in Figure 1 can be embedded in this graph. All graph mining algorithms have in common, that they search this subgraph lattice. They are interested in finding a subgraph (or several subgraphs) that can be embedded as often as possible in the graph to be mined. In Figure 1 the circled graph can be embedded twice in the running example.

When mining real life graph databases, the situation is of course much more complex. Not only one but a lot of graphs are analyzed leading to a very large lattice. Searching this lattice can be done depth or breadth first. When searching depth first in Figure 1, the first discovered subgraph will be **A** followed by **A-C**, **A-C-C** and so forth. Thus, first all subgraphs containing **A**, and in the next branch all containing **B** are found. If the lattice is traversed breadth first, all subgraphs in one level of the lattice, i.e. structures that have the same number of edges, are searched before the next level is started. The main disadvantage of breadth first search is the larger memory consumption because in the middle of the lattice a large amount of subgraphs has to be stored. With depth first search only structures which amount is proportional to the size of the biggest graph in the database have to be recorded during the search.

Building this lattice of frequent subgraphs involves two main steps: *Candidate Generation*, where new subgraphs are created out of smaller ones, and *Support Computation* where the frequency or support of the new subgraphs in the database is determined. Both steps are highly complex and thus various algorithms and techniques have been developed to find frequent subgraphs in finite time with reasonable resource consumptions.

MAIN THRUST OF THE CHAPTER

There are two popular ways of creating new subgraphs, new possible candidates for frequent fragments:

1. Merging smaller subgraphs that share a common core (Inokuchi et al., 2002; Kuramochi & Karypis, 2004), or
2. Extending subgraphs edge by edge (Borgelt & Berthold, 2002; Yan & Han, 2002).

The merge process can be explained by looking at the subgraph lattice shown in Figure 1. The circled subgraph has two parents, **A-C** and **C-C**. Both share the same core which is **C**. Thus the new fragment **A-C-C** is created by taking the core and adding the two additional edge-node pairs, one from each parent. There are two problems with this approach: First the common core needs to be detected somehow, which can be very expensive. Second a huge amount of subgraphs generated in this way may not even exist in the database. Merging e.g. **A-C** and **B-C** in the example will lead to **A-C-B** which does not occur in the database.

Extending fragments has the advantage that no cores have to be detected. New edge-node pairs (or sometimes only edges, if cycles are closed) are just added to an existing subgraph. In so called *embedding lists*, all embeddings of a fragment into the database graphs are stored. When extending a fragment with an edge (and a node probably), it is easy to check the current embeddings and find edges/nodes connected to these embeddings. This way only existing new fragments are generated. For example, in Figure 1, the embedding list of the circled fragment **A-C-C** contains two embeddings into the only database graph. Checking these embeddings and possible extensions in the database graph leads to new existing fragments.

The importance of a fragment depends on the number of times it appears in the database. If this number is given as a percentage of the number of database graphs, it is called *support*. If an absolute number is given, it is called *frequency*. Two ways of calculating the support/frequency are possible. First the graphs a fragment can be embedded in are counted, no matter how often it can be embedded in one graph. Second the embeddings itself are counted. In Figure 1 the circled fragment appears once in the database in the first case and twice in the second case. Counting embeddings can be done with subgraph isomorphism tests against all graphs in the database. These tests are NP-complete (Valiente, 2002). However there is a small improvement for this strategy, as it suffices to check for subgraph isomorphism only in the graphs where the parent graph(s) occur. Unfortunately this requires to keep a list of the graphs in which a subgraph occurs which can be quite memory consuming if the database is large.

The other way of calculating the support is by using the already introduced embeddings lists. An embedding can be thought of as a stored subgraph isomorphism i.e. a map from the nodes and edges in the subgraph to the corresponding nodes and edges in the graph. Now, if the support of a new extended subgraph has to be determined the position in the graph where it can occur is already known and only the additional node and edge have to be checked. This reduces the time to find the isomorphism but comes with the drawback of enormous memory requirements as all embeddings of a subgraph in the database have to be stored which can be millions for small subgraphs on even medium-sized databases of about 25,000 items. Using embedding lists the actual support for a structure can be determined by counting the number of different graphs that are referred to by the embeddings. This can be done in linear time.

Each possible fragment should only be created once, but it is obvious from the lattice in Figure 1, that there may exist several paths through the lattice to reach one fragment. These duplicates must be filtered out. For real life databases, it is also usually not possible to traverse the complete lattice because the number of subgraphs is too large to be handled efficiently. A mechanism is needed to prune the search tree that is built during the discovery process. If the support is calculated based on the number of graphs a fragment appears in, a supergraph of a graph that is infrequent must be infrequent, too. It cannot occur in more graphs than its parents in the lattice. This property is also known as the *antimonocity constraint*. Once the search reaches a point where a graph does not occur in enough items of the database any more this branch can be pruned. This leads to a drastic reduction of the number of subgraphs to be searched. When the support is calculated based on the embeddings, the antimonocity constraint holds for edge-disjoint embeddings. Therefore after each extension step, the biggest set of edge disjoint embeddings must be calculated. This problem equals the *Maximal Independent Set* problem for graphs, which is also NP-complete (Kuramochi & Karypis, 2005). An independent set is a set of vertices in a graph no two of which are adjacent.

To speed up the search even further various authors have proposed additional pruning strategies that shrink the search tree more efficiently while still finding all frequent fragments. Quite a few algorithms rely on so-called *canonical codes* that uniquely identify a subgraph. A subgraph's code is automatically built during the extension or merging process by e.g. recording the edges in the order as they were added to the graph. After each extension step, this code is compared to the canonical code for this subgraph, which is either the (lexicographically) smallest or biggest possible code. If the subgraph's code is not the canonical one, this branch in the search tree can be pruned, because the same subgraph will be found (or has already been found) in another branch (Borgelt, 2006).

FUTURE TRENDS

Despite the efforts of the last years, still several problems have to be solved. Memory and runtime are a challenge for most of the algorithms. Having real world graph databases containing millions of different graphs, various new algorithms and extensions of the existing ones are necessary. First thoughts concerning this topic can be found in (Wang, Wang, Pei, Zhu, & Shi, 2004). Another promising research direction are parallel and distributed algorithms. Distributing the graphs and their subgraph lattice onto different machines or using supercomputers with many processors and much memory can help in processing even larger databases than with current algorithms (Di Fatta & Berthold, 2006; Reinhard & Karypis, 2007).

In several application areas, it is not exact graph matching that is necessary. For example when mining molecules, it is helpful to search for groups of molecules having the same effect but not the same underlying graph. Well-known examples are the number of carbon atoms in chains or several carbon atoms in rings that have been replaced by nitrogen for example (Hofer, Borgelt & Berthold, 2003). In other areas, constraints must be imposed on the fragments to be found, not every possible fragment is helpful. Constraints can e.g. be the density of the graph or the minimal degree of nodes (Zhu, Yan, Han, & Yu, 2007).

Additionally visualization of the search and the results is difficult. A semi-automatic search can be helpful. A human expert decides whether the search in a subpart of the lattice is useful or if the search is more promising in another direction. To achieve this goal a visualization component is necessary that allows browsing in the graph database showing the embeddings of subgraphs.

Finally, another problem of most subgraph mining algorithms is the huge amount of frequent fragments they output. The user has then to scan them all and decide which ones are interesting for the specific application area. Such decision should be incorporated directly into the search process, making the result more understandable and often also the search faster.

CONCLUSION

Graph Data Mining is a currently very active research field. At the main data mining conferences of the ACM or the IEEE every year various new approaches appear. The application areas of graph data mining are widespread ranging from biology and chemistry to compiler construction. Wherever graphs are used to model data, data mining in graph data bases is useful.

KEY TERMS

Antimonicity Constraint: The antimonicity constraint states, that any supergraph of an infrequent graph must be infrequent itself.

Candidate Generation: Creating new subgraphs out of smaller ones; then it is checked how often this new subgraph appears in the analyzed graph data base.

Canonical Code: A unique linear representation of a graph that can be used to prune the search tree

Frequent Subgraph: a subgraph that occurs in a certain percentage of all graphs in the database.

Graph isomorphism: Two graphs which contain the same number of graph vertices connected in the same way by edges are said to be isomorphic. Determining if two graphs are isomorphic is thought to be neither

an NP-complete problem nor a P-problem, although this has not been proved (Valiente, 2000).

Search Tree Pruning: Cutting of certain branches of the (conceptual) search tree that is built during the mining process; pruning criteria may be the size of the graphs, the support of the graphs, or algorithm-specific constraints.

Subgraph: A graph G' whose vertices and edges form subsets of the vertices and edges of a given graph G. If G' is a subgraph of G, then G is said to be a supergraph of G'.

Subgraph Isomorphism: Decision whether a graph *G'* of is isomorphic to a subgraph another graph *G*. This problem is known to be NP-complete.

Support: The number of graphs or embeddings in the analysed database in which a subgraph occurs.

Subsequence Time Series Clustering

Jason Chen
Australian National University, Australia

INTRODUCTION

Clustering analysis is a tool used widely in the Data Mining community and beyond (Everitt et al. 2001). In essence, the method allows us to "summarise" the information in a large data set X by creating a very much smaller set C of representative points (called centroids) and a membership map relating each point in X to its representative in C. An obvious but special type of data set that one might want to cluster is a time series data set. Such data has a temporal ordering on its elements, in contrast to non-time series data sets. In this article we explore the area of time series clustering, focusing mainly on a surprising recent result showing that the traditional method for time series clustering is meaningless. We then survey the literature of recent papers and go on to argue how time series clustering can be made meaningful.

BACKGROUND

A time series is a set of data points which have temporal order. That is,

$$X = \{x_t \mid t = 1, ..., n\} \quad (1)$$

where t reflects the temporal order. Two types of clustering of time series has historically been undertaken: whole series clustering and subsequence clustering. In whole series clustering, one generally has a number of time series of equal length (say n) and one forms a vector space of dimension n so that each time series is represented by a single point in the space. Clustering then takes place in the usual way and groupings of similar time series are returned.

Whole series clustering is useful in some circumstances, however, often one has a single long time series data set X and the aim is to find a summary set of features in that time series, e.g. in order to find repeating features or particular repeating sequences of features (e.g. see the rule finding method proposed in (Das et al.1998)). In this case, what was historically done was to create a set Z of subsequences by moving a sliding window over the data in X, i.e.

$$z_{p-(w-1)} = x_{p-(w-1)}, x_{p-(w-2)}, ..., x_{p-2}, x_{p-1}, x_p \quad (2)$$

$z_p \in Z$, $p = w...n$. Each subsequence z_p (also called more generally a regressor or delay vector; see below) essentially represents a feature in the time series. These features live in a w-dimensional vector space, and clustering to produce a summarising set C of "centroid" features can proceed in the usual way. This technique has historically been called Subsequence Time Series (STS) Clustering, and quite a lot of work using the technique was published (see (Keogh et al. 2003) for a review of some of this literature). In this article we will focus on the area of subsequence time series clustering. For a review of whole time series clustering methods, see (Wang et al. 2004).

Given the widespread use of STS clustering, a surprising result in (Keogh et al. 2003) was that it is meaningless. Work in (Keogh et al. 2003) defined a technique as meaningless if the result it produced was essentially independent of the input. The conclusion that STS clustering was meaningless followed after it was shown that, if one conducted STS clustering on a range of even very distinct time series data sets, then the cluster centroids resulting from each could not be told apart. More specifically, the work clustered each time series multiple times and measured the average "distance" (see (Keogh et al. 2003) for details) between clustering outcomes from the same time series and between different time series. They found on average that the distance between clustering outcomes from the same and different time series were the same. Further, they discovered the strange phenomenon that the centroids produced by STS clustering are smoothed sine-type waves.

After the appearance of this surprising result, there was great interest in finding the cause of the dilemma and a number of papers on the topic subsequently appeared. For example, Struzik (Struzik 2003) proposed that the

"meaningless" outcome results only in pathological cases, i.e. when the time series structure is fractal, or when the redundancy of subsequence sampling causes trivial matches to hide the underlying rules in the series. They suggested autocorrelation operations to suppress the latter, however these suggestions were not confirmed with experiments.

In contrast, Denton (Denton, 2005) proposed density based clustering, as opposed to, for example, k-means or hierarchical clustering, as a solution. They proposed that time series can contain significant noise, and that density based clustering identifies and removes this noise by only considering clusters rising above a preset threshold in the density landscape. However, it is not clear whether noise (or only noise) in the time series is the cause of the troubling results in (Keogh et al. 2003). For example, if one takes the benchmark Cylinder-Bell-Funnel time series data set (see (Keogh et al. 2003)) without noise and applies STS clustering, the strange smoothed centroid results first identified there are still returned.

Another interesting approach to explain the dilemma was proposed by Goldin et. al. (Goldin et al. 2006). They confirmed that the ways (multiple approaches were tried) in which distance between clustering outcomes were measured in (Keogh et al. 2003) did lead to the conclusion that STS-clustering was meaningless. However, they proposed an alternative distance measure which captured the "shape" formed by the centroids in the clustering outcome. They showed that if one calculates the average shape of a cluster outcome over multiple clustering runs on a time series, then the shape obtained can be quite specific to that time series. Indeed if one records all the individual shapes from these runs (rather than recording the average), then in an experiment on a set of ten time series they conducted, one is able to match a new clustering of a time series back to one of the recorded clustering outcomes from the same time series. While these results suggest meaningfulness is possible in STS-clustering, it seems strange that such lengths are required to distinguish between clustering outcomes of what can be very distinct time series. Indeed we will see later that an alternative approach, motivated from the Dynamical Systems literature, allows one to easily distinguish between the clustering outcomes of different time series using the simple distance measure adopted in (Keogh et al. 2003).

Another approach proposed by Chen (Chen 2005, 2007a) to solve the dilemma forms the basis of work which we later argue provides its solution. They proposed that the metrics adopted in (Keogh et al. 2003) in the clustering phase of STS clustering were not appropriate and proposed an alternative clustering metric based on temporal and formal distances (see (Chen 2007a) for details). They found that meaningful time series clustering could be achieved using this metric, however the work was limited in the type of time series to which it could be applied. This work can be viewed as restricting the clustering process to the subset of the clustering space that was visited by the time series; a key tenet of later work that we argue below forms a solution to the STS-clustering dilemma.

Peker (Peker 2005) also conducted experiments in STS-clustering of time series. They identified that clustering with a very large number of clusters leads to cluster centroids that are more representative of the signal in the original time series. They proposed the idea of taking cluster cores (a small number of points in the cluster closest to the centroid) as the final clusters from STS clustering. The findings in this work concur with work in (Chen 2007a) and the work we explore below, since they are compatible with the idea of restricting clustering to the subset of the clustering space visited by the time series.

While each of the works just reviewed show interesting results which shed light on the problems involved with STS-clustering, none provides a clear demonstration for general time series of how to overcome them.

MAIN FOCUS

We now propose our perspective on what the problem with STS clustering is, and on a solution to this problem; based on a number of recent papers in the literature. Let us revisit the problems found in (Keogh et al. 2003) with the STS clustering method. This work proposed that STS-clustering was meaningless because:

A. One could not distinguish between the clustering outcomes of distinct time series, even when the time series themselves were very different, and
B. Cluster representatives were smoothed and generally did not look at all like any part of the original time series

They proposed that these two problems were one and the same, i.e. that one could not distinguish between cluster centres of different time series because they were all smoothed, and hence alike. This presumption turns out to be false, i.e. really these are two separate problems which need to be addressed and solved separately. For example, (Chen 2007b) showed how a time series clustering technique could produced distinguishable cluster centres (i.e. overcome (A)) but still produce centres that were smoothed (i.e. not overcome (B)). Hence, (Chen 2007b) proposed a new set of terminologies to reflect this fact. They proposed that a time series clustering method which overcomes problem (A) should be called meaningful, and one that overcomes problem (A) and (B) should be called useful. We will expand later on the motivation behind why these terms were adopted in each case.

Recall how it was shown in (Keogh et al. 2003) that STS-clustering is meaningless; the work clustered each time series multiple times and then measured the distance between clustering outcomes from the same time series and between different time series. Work in both (Chen 2007b) and (Simon et al. 2006) proposed that what was required to make the STS-clustering method meaningful was to introduce a lag q into the window forming process. That is, form subsequences as,

$$z_{p-(w-1)q} = x_{p-(w-1)q}, x_{p-(w-2)q}, ..., x_{p-2q}, x_{p-1q}, x_p \qquad (3)$$

$z_p \in Z$, $p = (w-1)q+1...n$ (i.e. so that now adjacent points in the subsequence are separated by q data points in the time series) where we call z_p a regressor or delay vector. The inspiration of both works was from the field of Dynamical Systems (Sauer et al. 1991, Ott et al. 1994) where it is well known that introducing a lag is required for the embedding of any real world (i.e. noisy and represented with limited precision) time series in a vector space using a sliding windows type process. Geometrically, not using a lag means subsequence vectors will be clumped along the diagonal of the space, and hence, even with a small amount of noise present in the time series, and reasonable precision, the "information" in the embedding that distinguishes one time series from another is lost. Work in (Simon et al. 2006) went on to conduct the same experiment as in (Keogh et al. 2003) (albeit with different time series), but using a lag, and found that cluster centres produced from distinct time series were then indeed distinguishable. Work in (Chen 2007b) confirmed the result in (Simon et al. 2006) using basically the same time series as used in (Keogh et al. 2003). For clarity, and to distinguish between what follows, we follow the terminology adopted in (Chen 2007b) and denote the STS-clustering technique where a lag is introduced into the sliding windows process as Unfolded Time Series (UTS) clustering.

According to the "meaningful" and "useful" terminology introduced above, the UTS clustering method produces meaningful clustering outcomes. That is, if we cluster two distinct time series using the method, then UTS clustering produces centroid sets in each case which are distinct from one another. In essence, the "information" existing in the original time series which made them distinct has been retained in the clustering outcome, and so the clustering outcome really can be described as meaningful. Hence, the problem of achieving meaningful time series clustering would seem solved, i.e. one must introduce a lag into the subsequence vector construction process.

This could mark the end of the dilemma. However, recall the second problem ((B) above) observed by Keogh with STS clustering; that centroids are smoothed and do not look like, or retain the properties of, the original time series. Work in (Chen 2007b) noted that the UTS-clustering method, although meaningful, was still prone to this second problem, i.e. according to our adopted terminology it is not a useful time series clustering method. The term "useful" was adopted in (Chen 2007b) based on the observation that one clusters a time series to produce a summary set of features in the time series. If these features do not look like any part of the time series, then the outcome, although meaningful, is not useful. Why should UTS clustering be meaningful, but not produce centroids representative of the time series?

To answer this question, (Chen 2007b) proposed that we need to look more fundamentally at what we are asking when we UTS (or STS) cluster a time series. If we UTS cluster with a sliding window length of d, then we form a d dimensional clustering space $\Re^d$. In its entirety, $\Re^d$ represents the full range of possible subsequence (i.e. feature) shapes and magnitudes that can exist. However, (Chen 2007b) noted that the underlying system producing the time series almost certainly will not live on all of $\Re^d$, or indeed even on a convex subset of $\Re^d$ (something assumed by typical clustering algorithms like k-means and Expectation Maximization used in STS clustering to date). What

sense does it make to include in the clustering process parts of $\Re^d$ that cannot be realised in the underlying system? Work proposing methods for clustering on subspaces (Haralick & Harpaz 2005), and manifolds (Breitenbach & Grundic 2005) exists and is motivated by exactly this line of thinking. Some simple experiments were conducted in (Chen 2007b) to show that this unrestricted approach to clustering in UTS (STS) clustering is the root cause of the smoothed centroid problem.

So we should cluster only in the subset of $\Re^d$ where valid outcomes from the underlying system exist. Unfortunately, given only a finite time series produced by the system, one cannot know the extent of this subset. However, this need not matter if the aim of clustering a time series is to (a) summarise the time series that was seen, rather than (b) to summarise the possible time series outcomes of an underlying system. (Chen 2007b) proposed that (a) is generally what we want to do when clustering a time series, and corresponds to asking the question: given the features observed in a time series, which k (for k clusters) of these features best "summarises" the time series. Given this observation, (Chen 2007b) went on to propose a method that restricts the clustering process to the region in $\Re^d$ visited by the time series. They proposed that this approach corresponds to the correct way to apply the clustering technique if indeed we want to ask the question corresponding to (a). They called the approach the Temporal-Formal (TF) clustering algorithm.

Details of the results of applying the technique can be found in (Chen 2007b), however in summary, the technique was applied on key time series data sets adopted from (Keogh et al. 2003) and (Simon et al. 2006). The results for all time series in the data set were,

1. Centroids were produced which remained in among data points in the cluster they represented, i.e. centroids looked like features from the original time series
2. Clustering outcomes were meaningful (as per the definition of meaningful above) in all cases.

The conclusion was therefore made that the TF clustering algorithm was a useful time series clustering method. Further, analysis of the clustering outcomes for a number of time series was conducted in (Chen 2007b), including the benchmark Cylinder-Bell-Funnel time series. In each case the TF-clustering algorithm lead to the intuitively correct or (in the case of the benchmark time series) required outcome.

FUTURE TRENDS

Subsequence clustering of time series has been the focus of much work in the literature, and often as a subroutine to higher level motivations such as rule discovery, anomaly detection, prediction, classification and indexing (see (Keogh et al. 2003) for details). With the discovery that STS-clustering is meaningless, much future work will involve revisiting and reviewing the results and conclusions made by this work. Of great importance then is the discovery of a meaningful subsequence time series clustering method. We have argued here that a means for the solution of the problem exists, and while the arguments made in this work seem both clear and cogent, this work is quite recent. The dust still has not settled in the time series clustering area of data mining research.

CONCLUSION

We have reviewed the area of time series clustering, focusing on recent developments in subsequence time series (STS) clustering. Prior to 2003, STS clustering was a widely accepted technique in data mining. With the discovery in (Keogh et al. 2003) that STS-clustering is meaningless, a number of articles were published to explain the dilemma. While interesting results were presented in all these papers, we argued that two papers provide a solution to the dilemma ((Simon et al. 2006) and (Chen 2007b)). Specifically, work in (Keogh et al. 2003) identified two problems with STS clustering: (A) and (B) as described above. Together the papers show that these problems can be solved (respectively) by (a) introducing a lag into the sliding windows part of the STS-clustering process, and (b) restricting the clustering process to only that part of the clustering space pertinent to the time series at hand. Hence, we propose that this work forms a solution to the STS-clustering dilemma first identified in (Keogh et al., 2003).

KEY TERMS

Delay Vector: Elements of the data set obtained in UTS clustering, i.e. by using Equation 3 above.

Lag: The sliding window used in UTS clustering need not capture, as a delay vector, a sequence of adjacent points in the time series. The lag is the value $q = p+1$ where p is the number of data points in the time series lying between adjacent points in the delay vector. So, for example, a lag $q = 3$ means the first delay vector will be x_1, x_4, x_7, ...

Meaningless: in general, an algorithm is said to be meaningless if its output is independent of its input. In the context of time series clustering, a time series clustering algorithm is said to be meaningless if one cannot distinguish between the clustering outcomes of distinct time series.

Regressor: Elements of the data set obtained in UTS clustering, i.e. by using Equation 3 above.

Subsequence Time Series (STS) Clustering: The process of applying standard clustering techniques to a dataset whose elements are constructed by passing a sliding window over (usually) a single (long) time series.

Subsequence Vector: Elements of the data set obtained in STS clustering, i.e. by using Equation 2 above.

Temporal-Formal (TF) Clustering: UTS clustering where the clustering process is restricted to the region in the clustering space that was visited by the time series.

Time Series: A data set containing elements which have a temporal ordering

Unfolded Time Series (UTS) Clustering: UTS clustering is STS clustering where a lag greater than unity has been introduced into the sliding windows process.

Whole Time Series Clustering: The process of applying standard clustering techniques to a dataset whose elements are distinct time series of equal length.

Summarization in Pattern Mining

Mohammad Al Hasan
Rensselaer Polytechnic Institute, USA

INTRODUCTION

The research on mining interesting patterns from transactions or scientific datasets has matured over the last two decades. At present, numerous algorithms exist to mine patterns of variable complexities, such as set, sequence, tree, graph, etc. Collectively, they are referred as **Frequent Pattern Mining** (FPM) algorithms. FPM is useful in most of the prominent knowledge discovery tasks, like classification, clustering, outlier detection, etc. They can be further used, in database tasks, like indexing and hashing while storing a large collection of patterns. But, the usage of FPM in real-life knowledge discovery systems is considerably low in comparison to their potential. The prime reason is the lack of interpretability caused from the enormity of the output-set size. For instance, a moderate size graph dataset with merely thousand graphs can produce millions of frequent graph patterns with a reasonable support value. This is expected due to the combinatorial search space of pattern mining. However, classification, clustering, and other similar Knowledge discovery tasks should not use that many patterns as their knowledge nuggets (features), as it would increase the time and memory complexity of the system. Moreover, it can cause a deterioration of the task quality because of the popular "*curse of dimensionality*" effect. So, in recent years, researchers felt the need to summarize the output set of FPM algorithms, so that the summary-set is *small*, *non-redundant* and *discriminative*. There are different summarization techniques: lossless, profile-based, cluster-based, statistical, etc. In this article, we like to overview the main concept of these summarization techniques, with a comparative discussion of their strength, weakness, applicability and computation cost.

BACKGROUND

FPM had been the core research topic in the field of data mining for the last decade. Since, its inception with the seminal paper of mining association rules by Argrawal *et al* (Agrawal & Srikant, 1994), it has matured enormously. Currently, we have very efficient algorithms for mining patterns with higher complexity, like sequence (Zaki, 2001), tree (Zaki, 2005) and graph (Yan & Han, 2002; Hasan, Chaoji, Salem & Zaki, 2005). The objective of FPM is as follows: Given a database D, of a collection of events (an event can be as simple as a set or as complex as a graph) and a user defined support threshold π^{min}; return all patterns (patterns can be set, tree, graph, etc. depending on D) that are frequent with respect to π^{min}. Sometimes, additional constraints can be imposed besides the minimum support criteria. For details on FPM, see data mining textbooks (Han & Kamber, 2001).

FPM algorithms search for patterns in a combinatorial search space, which is generally very large. But, the ***anti-monotone*** property allows fast pruning: which states, *"If a pattern is frequent, so is all it's sub-pattern; if a pattern is infrequent, so is all its super-pattern."* Efficient data structure and algorithmic techniques on top of this basic principle enable FPM algorithms to work efficiently on database of millions events. However, the usage of frequent patterns in knowledge discovery tasks requires the analysts to set a reasonable support value for the mining algorithms to obtain interesting patterns, which, unfortunately, is not that straightforward. Experience suggests that if the support value is set too high, only few common-sense patterns are obtained. For example, if the database events are recent movies watched by different subscribers, using a very high support will only return the set of super-hit movies which are liked by anybody. On the other hand, setting low support value returns enormously large number of frequent patterns that are difficult to interpret; many of those are redundant too. So, ideally one would like to set the support value at a comparably lower threshold and then adopt a summarization or compression technique to obtain a smaller *FP*-set, comprising interesting, non-redundant, and representative patterns.

Figure 1: An itemset database of 6 transactions (left). Frequent, Maximal and Closed patterns mined from the dataset in 50% support (right)

Transaction Database, D

4	A, D, T, AC, AW, CD, CT, ACW		CD, CT, ACW
3	AT, DW, TW, ACT, ATW, CDW, CTW, ACTW	CDW, ACTW	CDW, ACTW

MAIN FOCUS

The earliest attempt to compress the FPM result-set was to mine Maximal Patterns (Bayardo, 1998). A frequent pattern is called maximal, if it is not a sub-pattern of any other frequent pattern (see the example in figure 1). Depending on the dataset, maximal pattern can reduce the result-set substantially; especially for dense dataset, the compression ratio can be very high. And, maximal patterns can be mined in the algorithmic framework of FPM processes without a post-processing step. The limitation of maximal pattern mining is that the compression also loses the support information of the non-maximal patterns; for example, in figure 1, from the list of maximal patterns we can deduce that the pattern *CD* is also frequent (since *CDW* is frequent), but its support value is lost (which is 4, instead of 3). Support information is critical if the patterns are used for rule generation, as it is essential for confidence computation. To circumvent that, Closed Frequent Pattern Mining was proposed by Zaki (Zaki, 2000). A pattern is called closed, if it has no super-pattern with the same support. The compressibility of closed frequent mining is smaller than the maximal pattern mining, but for the earlier, all frequent patterns and also, their support information can be immediately retrieved (without further scan of the database). Closed frequent pattern can also be mined within the FPM process.

Pattern compression offered by maximal or closed mining framework is not sufficient, as the result-set size is still too large for human interpretation. So, many pattern summarization techniques have been proposed lately, each with different objective preference. It is difficult and sometimes, not fair, to compare them. For instance, in some cases, the algorithms try to preserve the support value of the frequent patterns; whereas, in other cases the support value is completely ignored and more emphasis is given in controlling the redundancy in patterns. In the following few paragraphs we discuss the main ideas of some of the major compression approaches, with their benefits and limitations. At the end of this section (see table 1), we show the benefits/limitations of these algorithms in tabular form for quick references.

Top-*k* Patterns

If the analyst has a predefined number of patterns in mind that (s)he wants to employ in the knowledge discovery tasks, *top-k patterns* is one of the best summarization technique. Han et al. (Han, Wang, Lu & TzVetkov, 2002) proposed one of the earliest algorithms that falls in this category. Their top-*k* patterns are *k* most frequent closed patterns with a user-specified minimum-length, *min_l*. Note that, minimum-length constraint is essential, since without it only length-1 patterns (or their corresponding closed super-pattern) will be reported, since they always have the highest frequency. The authors proposed efficient implementation of their proposed algorithm using FP-Tree; un-

fortunately, this framework works on itemset patterns only. Nevertheless, the summarization approach can be extended to other kind of patterns as well. Since, support is a criterion for choosing summary patterns; this technique is a support-aware summarization.

Another top-*k* summarization algorithm is proposed by Afrati et al. (Afrati, Gionis & Mannila, 2004). Pattern support is not a summarization criterion for this algorithm, rather high compressibility with maximal coverage is its primary goal. To achieve this, it reports maximal patterns and also, allows some false positive in the summary pattern set. A simple example from their paper is as follows: if the frequent patterns containing the sets *ABC, ABD, ACD, AE, BE,* and all their subsets, a specific setting of their algorithm may report *ABCD* and *ABE* as the summarized frequent patterns. Note that, this covers all the original sets, and there are only two false positive (*BCD, ABCD*). Afrati *et al.* showed that, the problem of finding the best approximation of a frequent itemsets that can be spanned by *k* set is NP-Hard. They also provided a greedy algorithm that guarantees an approximation ratio of at least $(1 - 1/e)$. The beauty of this algorithm is its high compressibility; authors reported that by using only 20 sets (7.5% of the maximal patterns), they could cover 70% of the total frequent set collection with only 10% false-positive. Also note, in such a high compression, there won't be much redundancy in the reported patterns; they, indeed, will be very different from each other. The drawbacks are: firstly, it is a post-processing algorithm, *i.e.*, all maximal patterns first need to be obtained to be used as an input to this algorithm. Secondly, the algorithm will not generalize well for complex patterns, like tree or graph, as the number of false-positives will be much higher and the coverage will be very low. So the approximation ratio mentioned above will not be achieved. Thirdly, it will not work if the application scenario does not allow false-positive.

Xin *et al.* (Xin, Cheng, Yan & Han, 2006) proposed another top-*k* algorithm. To be most effective, the algorithms strive for the set of patterns that collectively offer the best significance with minimal redundancy. Significance of a pattern is measured by a real value that encodes the degree of interestingness or usefulness of it and redundancy between a pair of patterns is measured by incorporating pattern similarity. Xin and his colleagues showed that to find such a set of top-*k* patterns is NP-Hard even for itemset, which is the simplest kind of pattern. They also proposed a greedy algorithm that approximates the optimal solution with $O(\ln k)$ performance bound. The major drawback of this approach is that the users need to find all the frequent patterns and evaluate their significances before the process of finding top-*k* patterns is initiated. Again, for itemset pattern the distance calculation is very straightforward, this might be very costly for complex patterns.

Support-Preserving Pattern Compression

We already discuss "Closed pattern mining", which is one approach of support preserving pattern compression. However, there are other support-preserving pattern mining algorithms that apply to itemset only. One of the most elegant among these is ***Non-Derivable Frequent Itemsets*** (Calders & Goethals, 2007). The main idea is based on *inclusion-exclusion principle*, which enables us to find a lower bound and upper bound on the support of an itemset based on the support of its subsets. These bounds can be represented by a set of derivable rules, which can be used to derive the support of the super itemset from its sub itemset. If the support can be derived exactly, the itemset are called *derivable itemsets* and need not be listed explicitly. For example, for the database in Figure 1, the itemset *CTW* is derivable, because the following two rules hold:

$$\sup(CTW) \geq \sup(TC) + \sup(TW) - \sup(T) \text{ and}$$
$$\sup(CTW) \leq \sup(TW).$$

From these, the support of CTW can be deduced exactly to be 3. Thus, a concise representation of frequent itemset consists of the collection of only *non-derivable itemsets*. Of course, the main limitation of this compression approach is that it applies only for itemset patterns; since, the inclusion-exclusion principle does not generalize for patterns with higher order structures. The compressibility of this approach is not that good either. In fact, Calders and Goethals proved that for some datasets, number of closed frequent patterns can be smaller in size than that of non-derivable frequent patterns. Moreover, there is no guarantee regarding redundancy in output set considering many of the frequent patterns are very similar to each other.

Cluster-Based Representative Pattern-Set

Pattern compression problem can be perceived as a clustering problem, if a suitable distance function between frequent patterns can be adopted. Then the summarization task is to obtain a set of representative patterns; each elements of the set resembles a cluster centroid. As typical clustering problem, this approach also leads to a formulation which is NP-Hard. So, sub-optimal solutions with known bounds are sought. Xin et al. (Xin, Han, Yan & Cheng, 2005) proposed greedy algorithms, named **RPglobal** and **RPlocal** to summarize itemset patterns. The distance function that they used considers both pattern object and its support. The representative element, P_r of a cluster containing elements, P_1, P_2… P_k, satisfies

$$\bigcup_{i=1}^{k} P_i \subseteq P_r.$$

And the distance is computed in transaction space. For instance, if two patterns P_1 and P_2 occur in transaction {1, 3, 5} and {1, 4, 5}, respectively, distance between them can be computed as,

$$1 - \frac{|\{1,3,5\} \cap \{1,4,5\}|}{|\{1,3,5\} \cup \{1,4,5\}|} = 0.5.$$

To realize a pattern cluster, a user defined $\boldsymbol{\delta}$ is chosen as distance threshold. If a pattern has a distance less than $\boldsymbol{\delta}$ from the representative, the pattern is said to be covered by the representative. **RPglobal** algorithm greedily selects the representative based on the remaining patterns to be covered. **RPlocal** finds the best cover set of a pattern by a sequential scan of the output set. For both the algorithms, the authors provided a bound with respect to the optimal number of representative patterns. For details, see the original paper (Xin, Han, Yan & Cheng, 2005). The attraction of cluster-based representative is that the algorithm is general and can easily be extended to different kinds of patterns. We just need to define a distance metric for that kind of pattern. The drawback is that user need to choose the right value of $\boldsymbol{\delta}$, which is not obvious.

Profile-Based Pattern Summarization

Yan *et al.* (Yan, Cheng, Han, & Xin, 2005) proposed profile-based pattern summarization, again, for itemset patterns. A profile-based summarization finds *k* representative patterns (named as Master patterns by Yan *et al*.) and builds a generative model under which the support of the remaining patterns can be easily recovered. A Master pattern is the union of a set of very similar patterns. To cover the span of the whole frequent patterns, a Master pattern is very different from another Master pattern. Note that, similarity considers both the pattern space and their support, so that they can be representative in the sense of FPM. The authors also built a profile for each Master pattern. Using the profile, the support of each frequent pattern that the corresponding Master pattern represents can be approximated without consulting the original dataset. The definition of Pattern profile is as follows: Firstly, for any itemset α, let D_α be the transaction-set that contains α; D be the entire dataset, and α_1, α_2,..., α_l be a set of similar patterns. Now, define

$$\mathsf{D}' = \bigcup_{i=1}^{l} \mathsf{D}_{\alpha_i}.$$

A profile M over α_1, α_2,..., α_l is a triple

$$\langle \mathsf{P}, \phi, \rho \rangle,$$

where, P is a probability distribution vector of the items α_1, α_2,..., α_l learned from the set D',

$$\varnothing = \bigcup_{i=1}^{l} \alpha_i$$

is taken as the Master pattern of α_1, α_2,..., α_l and

$$\rho = \frac{|\mathsf{D}'|}{|\mathsf{D}|}$$

is regarded as the support of the profile. For example, if itemset CT (D_{CT}={1,3,5,6}) and CW (D_{CW}={1,2,3.4,5}) of table 1 are to be merged in a profile, the Master pattern is CTW, its support is

$$\frac{|D'|}{|D|} = \frac{6}{6} = 100\%$$

(note that, original pattern CTW has a support of 83%) and $P = (4/6, 5/6)$. Profile based summarization is elegant due to its use of probabilistic generative model, but there are drawbacks. Authors did not proof any bound on the quality of results, so depending on the dataset, the summarization quality can vary arbitrarily. It is a post-processing algorithm, so all frequent patterns need to be obtained first. Finally, clustering is a sub-task of their algorithm; since, clustering itself is an NP-Hard problem, any solution adopting clustering algorithms, like k-means, hierarchical and etc. can only generate a local optimal solution.

Very recently, Wang and Parthasarathy (Wang & Parthasarathy, 2006) used probabilistic profile to summarize frequent itemsets. They used Markov Random Field (MRF) to model the underlying distribution that generates the frequent patterns. To make the model more concise, the authors considered only the non-derivable frequent itemsets instead of the whole set. Once the model is built, the list of frequent itemsets and associated count can be recovered using standard probabilistic inference methods. Probabilistic methods provide the most compact representation with very rough support estimation.

FUTURE TRENDS

Despite the numerous efforts in recent years, pattern summarization is not yet totally solved. Firstly, all the summarization algorithms were mainly designed to compress only the itemset patterns. But, unfortunately the problem of large output size of FPM algorithms is more severe for patterns, like trees, graphs, etc. Out of the existing algorithms, very few can be generalized to these kinds of patterns, although no attempt has been reported yet. Very recently, Hasan *et al.* proposed an algorithm, called ORIGAMI (Hasan, Chaoji, Salem & Zaki, 2007), which summarize graph patterns by following the idea of representative patterns. Since, finding representative patterns is NP-Hard, they adopted a local optimal algorithm to obtain the representatives. Their algorithm is also a post-processing one; but, they avoided the generation of entire frequent pattern set by finding a smaller collection of maximal patterns through a random walk along the frequent graph lattice. The walk terminates when a user chosen convergence condition is satisfied. This work is very different from all the previous works and it directs the future trends of pattern summarization. Since, generating entire pattern-set is not feasible, an ideal pattern summarization algorithm should avoid the post processing all-together and should find the representative patterns in an online fashion as the patterns are being generated. Some streaming data model can be adopted to solve this kind of problem. This data model also has the added benefit that all pairwise distances between the frequent patterns need not be computed, which, sometimes, is very costly.

CONCLUSION

Pattern summarization is a fascinating research direction with numerous attentions in recent years. To circumvent the problem of enormous output size of FPM algorithms that impede its application, summarization offers an elegant solution. With the invention of new summarization algorithms, many new concepts regarding pattern summarization has also emerged, like similarity, redundancy, significance and etc. These concepts enable to formalize the summarization techniques and many of these, also, provide criteria to evaluate the quality of summarization. This paper provides a gentle overview of different summarization algorithms and these concepts.

KEY TERMS

Closed Pattern: A pattern α is called closed if no pattern β exists, such that $\alpha \subset \beta$ *and transaction_set*(α) = *transaction_set*(β). It is a lossless pattern summarization technique.

Maximal Pattern: A pattern α is called maximal pattern, if no pattern β exists, such that $\alpha \subset \beta$ and β is frequent. It is a lossy summarization technique.

Non-Derivable Pattern: A pattern α is called derivable it its support can be exactly inferred from the support of its sub-patterns based on the inclusion-exclusion principle. Since, inclusion-exclusion principle works only for set, the non-derivable definitions is also applicable only for itemset pattern.

Pattern Profile: Ideally, pattern profile is a compressed representation of a set of very similar patterns, from where the original patterns and their support can be recovered. However, profiles are built using some probabilistic approaches, so the compression is always lossy; therefore, the recovered pattern and their support are usually approximations.

Pattern Significance: Pattern significance measures the importance of a specific pattern in respect to the application domain. For example, in case of itemset pattern which are, usually use to obtain association rule, the pattern significance can be measured in terms of the corresponding rule interestingness. For classification or clustering task, significance of a pattern is the effectiveness of that pattern as a feature to discriminate among different cluster or classes.

Pattern Similarity: Pattern similarity measures the closeness between two patterns. If α and β are two patterns, similarity can be computed as below:

$$sim(\alpha, \beta) = \frac{|\alpha \cap \beta|}{|\alpha \cup \beta|}.$$

Table 1. Comparison of different summarization algorithms, features that have an (↑) symbol are desirable and those that have (↓) are not desirable

Summarization Algorithms	Feature lists							
	Compress ratio↑	Post processing↓	Support preserving↑	Support aware↑	Pattern Redundancy↓	Fault tolerant↓	Coverage considered↑	Generalized↑
Maximal	Moderate	No	No	Yes	High	No	Yes	Yes
Closed	Moderate	No	Yes	Yes	Very High	No	Yes	Yes
Top-k with min length	User defined	No	No	Yes	Low	No	No	Yes
Fault-tolerant Top-k	User defined	Yes	No	No	Very Low	Yes	Yes	No
Redundancy-aware top-k	User defined	Yes	No	No	Very Low	No	Yes	Yes
Non-derivable	Moderate	No	Yes	Yes	High	No	Yes	No
Cluster based representatives	User defined	Yes	No	Yes	Low	No	Yes	Yes
Pattern profile	High	Yes	No	Yes	Very Low	Yes	No	No
Probabilistic profile	High	Yes	No	No	Very Low	Yes	No	No

The set union and intersection in the above definition can be extended naturally for complex pattern like, tree or graph. For instance, for graph pattern, intersection between two patterns can be the maximal common sub-graph between them. Generally, pattern similarity ranges from [0, 1]. Pattern distance is computed as 1–*Pattern Similarity.* Distance obeys the metric properties, like, $distance(\alpha,\alpha) = 0$ *and* $distance(\alpha,\beta) + distance(\beta,\gamma) \geq distance(\alpha,\gamma)$.

Pattern Summarization: FPM algorithms produce large results which is difficult for the end user to interpret. To circumvent the problem, frequent patterns are compressed to a smaller set, where the patterns are non-redundant, discriminative and representative. Effective summarizations are, generally, lossy *i.e.* the support information of the compressed patterns can not be recovered exactly. Different flavors of summarization techniques exist. Pattern profile is one of the summarization techniques.

Supporting Imprecision in Database Systems

Ullas Nambiar
IBM India Research Lab, India

INTRODUCTION

A query against incomplete or imprecise data in a database[1], or a query whose search conditions are imprecise can both result in answers that do not satisfy the query completely. Such queries can be broadly termed as ***imprecise queries***. Today's database systems are designed largely for precise queries against a database of precise and complete data. Range queries (*e.g., Age BETWEEN 20 AND 30*) and disjunctive queries (*e.g., Name="G. W. Bush" OR Name="George Bush"*) do allow for some imprecision in queries. However, these extensions to precise queries are unable to completely capture the expressiveness of an imprecise query. Supporting imprecise queries (*e.g., Model like "Camry" and Price around "$15000")* over databases necessitates a system that integrates a similarity search paradigm over structured and semi-structured data. Today's relational database systems, as they are designed to support precise queries against precise data, use such precise access support mechanisms as indexing, hashing, and sorting. Such mechanisms are used for fast selective searches of records within a table and for joining two tables based on precise matching of values in join fields in the tables. The imprecise nature of the search conditions in queries will make such access mechanisms largely useless. Thus, supporting imprecise queries over existing databases would require adding support for imprecision within the query engine and meta-data management schemes like indexes.

Extending a database to support imprecise queries would involve changing the query processing and data storage models being used by the database. But, the fact that databases are generally used by other applications and therefore must retain their behaviour could become a key inhibitor to any technique that relies on modifying the database to enable support for imprecision. For example, changing an airline reservation database will necessitate changes to other connected systems including travel agency databases, partner airline databases etc. Even if the database is modifiable, we would still require a domain expert and/or end user to provide the necessary distance metrics and domain ontology. Domain ontologies do not exist for all possible domains and the ones that are available are far from being complete. Therefore, a feasible solution for answering imprecise queries should neither assume the ability to modify the properties of the database nor require users (both lay and expert) to provide much domain specific information.

BACKGROUND

The problem of supporting imprecise queries has already attracted considerable interest from researchers including those in fuzzy information systems (Morrisey, 1990), cooperative query answering and query generalization (Motro, 1998). More recent efforts have focused on supporting imprecise queries over relational databases by introducing ADTs (abstract data types) – for allowing storage and retrieval of non-standard data such as images, documents etc., and extending the query processor with functions for measuring similarity between tuples (Aditya et al, 2002; Ortega-Binderberger, 2003). Recently, work has been done on providing ranked answers to queries over a relational database (Bruno, Gravano and Marian, 2002). However, all the proposed approaches for answering imprecise queries require large amounts of domain specific information either pre-estimated or given by the user of the query. Unfortunately, such information is hard to elicit from the users. Further, some approaches require changing the data models and operators of the underlying database. A recent survey outlining challenges in integrating DB (database) and IR (information retrieval) technologies discusses the pros and cons of four possible alternatives for combining the two models (Chaudhuri, Ramakrishnan and Weikum, 2005).

MAIN FOCUS

The task of supporting imprecise queries over a database can borrow several ideas from efforts at integrating DB & IR systems. However, the key difference is that the focus is only on bringing the IR style search and retrieval model to DB systems with the underlying data continuing to be structured. The motivation should be to reduce the burden on the user by striving to satisfy the users' imprecisely defined need (query) with minimal additional information from user. Given that the database contains tuples generated by humans, they must capture some amount of real-world semantics e.g., relationships between attributes (features of the domain), similarity between values, etc. Solutions for supporting imprecise queries should focus on using the inherent semantics to help the user in extracting relevant information. Any solution then should be judged based on how good is its estimation of the user need based on the query and underlying data, i.e., *How closely does it model the user's notion of relevance by using only the information available in the database?*

A domain independent solution for supporting imprecise queries over autonomous databases is given in Nambiar and Kambhampati, 2006. The solution unites the DB and IR technologies by bringing the similarity searching/ranked retrieval paradigm from IR systems into the structured, type-rich access paradigm of databases. Answers are ranked according to the degree of relevance automatically estimated using domain-independent similarity functions that can closely approximate the subjective interpretation of the user. An intuitive model for measuring the similarity between the query and the answer tuples is by measuring the similarity of common attributes between them. Not all attributes will be equally relevant to the user. Therefore, providing a ranked set of answers with minimal user input and domain related metrics would require techniques to automatically learn the similarity between values binding each attribute and also the importance of every attribute in a relation.

Measuring Value Similarity

A database system supporting imprecise queries must provide information about how close an answer tuple is to the given imprecise query. Two tuples (a selection query can be seen as a tuple with few missing values) are considered similar if they have *syntactical similarity* (e.g., same subset of attributes are bound in both queries, stems of a common word bind an attribute, etc) or if the binding values are *semantically similar*. Semantic similarity is a concept whereby a set of words (attribute values) are assigned a metric based on the closeness of their meaning. Similar words can be considered semantically related by virtue of their *synonymy* (e.g., bank – trust company), but dissimilar entities may also be semantically related by lexical relationships such as *meronymy* (e.g., car - wheel) and *antonymy* (e.g., hot - cold), or just by any kind of functional relationship or frequent association (e.g., pencil - paper, penguin - Antarctica, rain - flood). The definition of synonym by Leibniz - *"synonyms are words that are interchangeable in some contexts"* is considered more realistic. This definition forms the basis of the similarity estimation model developed in Nambiar and Kambhampati, 2006. Given a database of tuples, the authors assume that binding values that are semantically similar have similar distributional behaviour. Under this assumption, they treat the values that co-occur near a value as constituting features that describe the context in which the given value appears in the database. The semantic similarity between two values is then computed in terms of how similar is their contexts. This is accomplished by building a structure consisting of bags of words for all attributes in the relation not bound by the two values being considered. Only values that co-occur with the value under consideration is added to the bag of words. The similarity between two values is then computed as the level of commonality between the bags of words describing them (see Nambiar and Kambhampati, 2006 for details).

Learning Attribute Importance

Often users would like to see only the top-k answers to a query. To provide ranked answers to a query, we must combine similarities shown over distinct attributes of the relation into an overall similarity score for each tuple. Specifically, a measure of importance for the similarity shown over any attribute in the context of a given query may be necessary to determine the best k matches. While this measure may vary from user to user, most users usually are unable to correctly quantify the importance they ascribe to an attribute. In theory the tuples most similar to query will have differences only in the *least important attribute*. Nambiar and Kambhampati, 2006, define the least important at-

tribute as the attribute whose binding value, when changed, has minimal effect on values binding other attributes. They provide an algorithm for automatically measuring the importance of an attribute based on Approximate Functional Dependencies (Huhtala et al, 1998). Causal Bayesian Networks (Cooper, 1997) and Causal Association Rules (Silverstein et al, 1998) are alternative techniques that are useful in learning causal relationships among attributes.

FUTURE DIRECTIONS

This chapter has focussed only on answering imprecise queries over a single autonomous database and provides a solution (Nambiar and Kambhampati, 2006) for the same. But more than one database may project a given relation. Even if all these systems were extended to support imprecise queries, it is not feasible for the user to query all of them to obtain most of the relevant answers. Supporting imprecise queries over multiple sources will involve determining the number of relevant tuples each database is likely to contain for every possible imprecise query. Since learning and storing the statistics for all possible imprecise queries is infeasible, one will have to learn the same for classes of imprecise queries. The second step is to provide an efficient plan for accessing the databases, based on their likelihood of providing the best remaining set of answers. Nie et al, 2002, describe a solution for efficiently obtaining tuples from an overlapping set of autonomous databases. Some of those ideas could be used to tackle the problems in answering imprecise queries over a set of overlapping databases. Yu et al, 2003, give two algorithms for merging results from ranked databases. However, no overlap among databases is considered.

CONCLUSION

An increasing amount of database researchers envision the need for supporting imprecise queries over database systems. Such support would greatly enhance the ability of non-expert users to extract relevant information from databases. For example, users working with scientific databases such as the Web accessible repositories in archeology and biology can greatly benefit by being able to quickly explore the knowledge contained without having to worry about forming the right query to express their need. Supporting imprecise queries over autonomous databases entails overcoming critical challenges like developing techniques for efficiently extracting relevant tuples and measuring the similarity of the answers to the query. Overcoming these challenges necessitates developing techniques for estimating the importance to be ascribed to each attribute and for measuring the semantic similarity between categorical values.

KEY TERMS

Attribute: An attribute is a template for possible values and set of functions and operators that operate on these values and define the behavior.

Database: An information set with a regular structure. Databases based on the *relational model* are known as *relational databases*.

Data Integration System: A system that provides an automated method for querying across multiple heterogeneous databases in a uniform way. In a data integration system, the user asks a query over a common schema, called *mediated schema or global schema*, and the system reformulates this into a query over the *local schema* of the data sources.

Imprecise Query: A user query that does not insist on exact match (and only requires data closely matching the query constraint) is an imprecise query.

Information Retrieval (IR): The art and science of searching for information from free-form natural language text. An alternate definition is that of a process for identifying unstructured records satisfying a user query.

Precise Query: A user query that requires data exactly matching the query constraint is a precise query. A precise query contains only crisp conditions over the attributes.

Tuple: A tuple is a set of attributes, which are ordered pairs of domain and value. A *relation* is an unordered set of tuples.

ENDNOTE

[1] The term database is used to refer to all types of structured data stores including data warehouses.

A Survey of Feature Selection Techniques

Barak Chizi
Tel-Aviv University, Israel

Lior Rokach
Ben-Gurion University, Israel

Oded Maimon
Tel-Aviv University, Israel

INTRODUCTION

Dimensionality (i.e., the number of data set attributes or groups of attributes) constitutes a serious obstacle to the efficiency of most data mining algorithms (Maimon and Last, 2000). The main reason for this is that data mining algorithms are computationally intensive. This obstacle is sometimes known as the "curse of dimensionality" (Bellman, 1961).

The objective of Feature Selection is to identify features in the data-set as important, and discard any other feature as irrelevant and redundant information. Since Feature Selection reduces the dimensionality of the data, data mining algorithms can be operated faster and more effectively by using Feature Selection. In some cases, as a result of feature selection, the performance of the data mining method can be improved. The reason for that is mainly a more compact, easily interpreted representation of the target concept.

The filter approach (Kohavi , 1995; Kohavi and John ,1996) operates independently of the data mining method employed subsequently -- undesirable features are filtered out of the data before learning begins. These algorithms use heuristics based on general characteristics of the data to evaluate the merit of feature subsets. A sub-category of filter methods that will be refer to as rankers, are methods that employ some criterion to score each feature and provide a ranking. From this ordering, several feature subsets can be chosen by manually setting

There are three main approaches for feature selection: wrapper, filter and embedded.

The wrapper approach (Kohavi, 1995; Kohavi and John,1996), uses an inducer as a black box along with a statistical re-sampling technique such as cross-validation to select the best feature subset according to some predictive measure.

The embedded approach (see for instance Guyon and Elisseeff, 2003) is similar to the wrapper approach in the sense that the features are specifically selected for a certain inducer, but it selects the features in the process of learning.

BACKGROUND

Feature selection algorithms search through the space of feature subsets in order to find the best subset. This subset search has four major properties (Langley, 1994): starting point, search organization, evaluation strategy, and stopping criterion.

Starting Point: Selecting a point in the feature subset space from which to begin the search can affect the direction of the search.

Search Organization: A comprehensive search of the feature subspace is prohibitive for all but a small initial number of features.

Evaluation Strategy: How feature subsets are evaluated (filter, wrapper and ensemble).

Stopping Criterion: A feature selector must decide when to stop searching through the space of feature subsets.

FEATURE SELECTION TECHNIQUES

This section provides a survey of techniques for each strategy described on previous sections.

Feature Filters

The filter methods were the earliest approaches for feature selection. All filter methods use general properties of the data in order to evaluate the merit of feature subsets. As a result, filter methods are generally much faster and practical than wrapper methods, especially for using it on data of high dimensionality. Detailed experiments for each method presented below can be found in Hall's work (1999) and on Liu and Motoda (1998) book on Feature Selection.

FOCUS

Almuallim and Dietterich (1991) describe an algorithm originally designed for Boolean domains called FOCUS. FOCUS exhaustively searches the space of feature subsets until every combination of feature values is associated with one value of the class. After selecting the subset, it passed to ID3 (Quinlan, 1986), which constructs a decision tree.

LVF

Similar algorithm to FOCUS is LVF(Liu and Setiono, 1996) describe. LVF is consistency driven and can handle noisy domains if the approximate noise level is known a- priori. Every round of execution LVF generates a random subset from the feature subset space. If the chosen subset is smaller than the current best subset, the inconsistency rate of the dimensionally reduced data described by the subset is compared with the inconsistency rate of the best subset. If the subset is at least as consistent as the best subset, the subset replaces the best subset.

An Information Theoretic Feature Filter

Koller and Sahami (1996) described a feature selection algorithm based on information theory and probabilistic reasoning. The rationale behind this technique is that, since the goal of an induction algorithm is to estimate the probability distributions over the class values, given the original feature set, feature subset selection should attempt to remain as close to these original distributions as possible.

An Instance Based Approach to Feature Selection – RELIEF

RELIEF (Kira and Rendell, 1992) uses instance based learning to assign a relevance weight to each feature. The weight for each feature reflects its ability to single out the class values. The Features are ranked by its weights and chosen by using a user- specified threshold. RELIEF randomly choosing instances from the training data. For every instance RELIEF samples the nearest instance of the same class (nearest hit) and finds the opposite class (nearest miss). The weight for each feature is updating according to how well its values differentiate the sampled instance from its nearest hit and nearest miss. Feature will gain a high weight if it differentiates between instances from different classes and has the same value for instances of the same class.

Simba and G-Flip

Gilad-Bachrach et al. (2004), introduced a new approach called SIMBA (Iterative Search Margin Based Algorithm), which outperforms RELIF. This approach introduces the idea of measuring the quality of a set of features by the margin it induces. To overcome the drawback of iterative search, Gilad-Bachrach et al (2004), present A Greedy Feature Flip Algorithm called G-Flip. The G-Flip is a greedy search algorithm for maximizing the margin function

of a subset. The algorithm constantly iterates over the feature set and updates the set of chosen features. Each iteration G-Flip decides to eliminate or include the current feature to the selected subset by evaluating the margin with and without this feature.

Using Traditional Statistics Techniques

Mallows Cp (Mallows. 1973)

This method minimizes the mean square error of prediction:

$$C_p = \frac{RSS_\gamma}{\hat{\sigma}^2_{FULL}} + 2q_\gamma - n \qquad (1)$$

Where, RSS_γ is the residual sum of squares for the γ'*th* model and $\hat{\sigma}^2_{FULL}$ is the usual unbiased estimate of the variance based on the full model. The goal is to find the subset which has minimum *Cp*.

AIC, BIC and F Ratio

AIC (for Akaike Information Criterion) and BIC (for Bayesian Information Criterion) are criteria for choosing a subset of features. Letting $\hat{l}_g$ denote the maximum log likelihood of the γ'*th* model, AIC selects the model which maximizes ($\hat{l}_g - q_\gamma$) whereas BIC selects the model which maximizes ($\hat{l}_g$ - (logn)$q_\gamma/2$).

For the linear model, many of the popular selection criteria are a penalized sum of squares criterion that can provide a unified framework for comparisons. This criterion selects the subset model that minimizes:

$$RSS_\gamma / \hat{\sigma}^2 + Fq_\gamma \qquad (2)$$

Where *F* is a preset "dimensionality penalty". The above penalizes $RSS_\gamma / \hat{\sigma}^2$ by *F* times q_γ, the dimension of the γth model. AIC and minimum *Cp* are equivalent, corresponding to *F*=2, and BIC is obtained by *F* =*logn*. Using a smaller penalty, AIC and minimum *Cp* will select larger models than BIC (unless n is very small), (George, 2000).

Principal Component Analysis (PCA)

Principal component analysis (PCA) (known also as the singular value decomposition (SVD), the Karhunen-Loeve transform, the Hotelling transform, and the empirical orthogonal function (EOF) method.), is linear dimension reduction technique (Jackson, 1991). PCA based on the covariance matrix of the variables and it is a second-order method. PCA seeks to reduce the dimension of the data by finding a few orthogonal linear combinations (the PCs) of the original features with the largest variance. The first PC, s_1, is the linear combination with the largest variance. We have $s_1 = x^T w_1$, where the *p*-dimensional coefficient vector $w_1 = (w_{1,1},\ldots,w_{1,p})^T$ solves:

$$w_1 = \arg\max_{\|w=1\|} Var\left\{x^T w\right\} \qquad (3)$$

The second PC is the linear combination with the second largest variance and orthogonal to the first PC, and so on. There are as many PCs as the number of the original features. For many datasets, the first several PCs explain most of the variance, so that the rest can be ignored with minimal loss of information.

Factor Analysis (FA)

Factor analysis (FA) is a linear method, based on the second-order data summaries. FA assumes that the measured features depend on some unknown factors. Typical examples include features defined as various test scores of individuals; as such scores are thought to be related to a common "intelligence" factor. The goal of FA is to find out such relations, and thus can be used to reduce the dimension of datasets following the factor model.

Projection Pursuit

Projection pursuit (PP) is a linear method which is more computationally intensive than second-order methods. Given a projection index that defines the merit of a direction, the algorithm looks for the directions that optimize that index. As the Gaussian distribution is the least interesting distribution, projection indices usually measure some aspect of non-Gaussianity.

Feature Wrappers

The Wrapper strategy for feature selection uses an induction algorithm to evaluate feature subsets. The motivation for this strategy is that the induction method that will eventually use the feature subset should provide a better predictor of accuracy than a separate measure that has an entirely different inductive bias (Langley, 1994).

Feature wrappers are often better than filters. The reason for that is that they are tuned to the specific interaction between an induction algorithm and its training data. Nevertheless, they tend to be much slower than feature filters because they must repeatedly perform the induction algorithm. Detailed experiments for each method presented below can be found in Hall's work (1999) and on Liu and Motoda (1998) book on Feature Selection.

Wrappers for Decision Tree Learners

John, Kohavi, and Pfleger (1994) presented the wrapper as a general framework for feature selection in machine learning. This framework has two degrees of feature relevance definitions that used by the wrapper to discover relevant features. A feature X_i is said to be strongly relevant to the target concept(s) if the probability distribution of the class values, given the full feature set, changes when X_i is eliminated. A feature X_i is said to be weakly relevant if it is not strongly relevant and the probability distribution of the class values, given some subset which contains X_i, changes when X_i is removed. All features that are not strongly or weakly relevant are irrelevant.

Vafaie & De Jong (1995) and Cherkauer & Shavlik (1996) have both applied genetic search strategies in a wrapper framework in order to improve the performance of decision tree learners.

Wrappers for Instance Based Learning

OBLIVION (Langley and Sage, 1994) is a wrapper for instance based learning. OBLIVION performs backward elimination of features by using an oblivious decision tree as the induction algorithm. Moore and Lee (1994) suggest a similar approach to augmenting nearest neighbor algorithm but their system uses leave one out instead of *k*-fold cross validation and focuses on improving the prediction of numeric rather than discrete classes.

Domingos (1997) describes a context sensitive wrapper approach to feature selection for instance based learners. The motivation for the approach is that there may be features that are either relevant in only a restricted area of the instance space and irrelevant elsewhere, or relevant given only certain values (weakly interacting) of other features and otherwise irrelevant. In either case, when features are estimated globally (over the instance space). The irrelevant aspects of these sorts of features may overwhelm their entire useful aspects for instance based learners.

Wrappers for Bayes Classifiers

Langley and Sage (1994) note that the classifier performance on domains with redundant features can be improved by removing such features. In order to select features for use with naïve Bayes A forward search strategy is employed. The rationale for using a forward search is that it should immediately detect dependencies when redundant attributes are added.

Pazzani (1995) combines feature selection and simple constructive induction in a wrapper framework for improving the performance of naive Bayes. The algorithm considers not only to add features to the

current subset, but also to creating new features by joining one of the as yet unselected features with each of the selected features in the subset. More than that, the algorithm considers both deleting individual features and replacing pairs of features with a joined feature.

Provan and Singh (1996) have applied the wrapper to select features from which to construct Bayesian networks. Their results showed that while feature selection did not improve accuracy over networks constructed from the full set of features, the networks created after feature selection were considerably smaller and faster to learn.

Feature Ensemble

The main idea of ensemble methodology is to combine a set of models, each of which solves the same original task, in order to obtain a better composite global model, with more accurate and reliable estimates or decisions than can be obtained from using a single model. Some of the drawbacks of wrappers and filters can be solved by using ensemble (Rokach *et al.*, 2007). As mentioned above filters perform less than wrappers. Due to the voting process, noisy results are filtered. Secondly, the drawback of wrappers which "cost" computing time is solved by operating bunch of filters.

FUTURE TRENDS

All feature selection techniques mentioned above assume that some of features of the initial subset are redundant or irrelevant. But in some cases data mining techniques creates models that do not have any redundant or irrelevant features. Theoretical and empirical observations for this situation can be found on Chizi and Maimon (2002) work on dimensionality reduction of high dimensional data sets. It seems that when using any feature selector there is a point, (which called by the authors "Phase Transition Point") that further removing of features will cause significant damage to the accuracy of the model.

CONCLUSION

Feature selection is a common issue on statistics, pattern recognition and machine learning. This Chapter summarizes the main techniques and approaches for feature selection. The aim of any feature selector is to identify features in the data-set as important, and discard any other feature as irrelevant and redundant information. All three strategies mentioned on this chapter (Filter, Wrapper and Ensemble) contain a wide variety of techniques. The usefulness of each methods mainly depends on it ability to provide swift and accurate model. The following table summarizes the main properties of each strategy by ranking from 1 (best in the category) to 3 (worst in the category) (see Exhibit 1).

Exhibit 1.

Category	Filter	Wrapper	Ensemble
Computational Cost	1	3	2
Robustness	3	1	2
Best Accuracy	3	2	1
Simplicity	1	3	2

KEY TERMS

Attribute: A quantity describing an instance. An attribute has a domain defined by the attribute type, which denotes the values that can be taken by an attribute.

Classifier: A structured model that maps unlabeled instances to finite set of classes

Feature Selection: A process aims to identify the important attributes in a given database and discard any other feature as irrelevant and redundant information.

Filter Techniques : These techniques use heuristics based on general characteristics of the data to evaluate the merit of feature subsets.

Induction Algorithm: An algorithm that takes as input a certain set of instances and produces a model that generalizes these instances.

Instance: A single object of the world from which a model will be learned, or on which a model will be used.

Ranker Techniques: Rankers are methods that employ some criterion to score each feature. From

this ordering, several feature subsets can be chosen, either manually or by setting a threshold.

Wrapper Techniques: These techniques use induction algorithms along with statistical re-sampling techniques such as cross-validation to select the best feature subset for this specific learning algorithm.

Survival Data Mining

INTRODUCTION

Survival analysis (SA) consists of a variety of methods for analyzing the timing of events and/or the times of transition among several states or conditions. The event of interest can only happen at most once to any individual or subject. Alternate terms to identify this process include *Failure Analysis* (FA), *Reliability Analysis* (RA), *Lifetime Data Analysis* (LDA), *Time to Event Analysis* (TEA), *Event History Analysis* (EHA), and *Time Failure Analysis* (TFA) depending on the type of application the method is used for (Elashoff, 1997). Survival Data Mining (SDM) is a new term being coined recently (SAS, 2004). There are many models and variations on the different models for SA or failure analysis. This chapter discusses some of the more common methods of SA with real life applications. The calculations for the various models of SA are very complex. Currently, there are multiple software packages to assist in performing the necessary analyses much more quickly.

BACKGROUND

The history of SA can be roughly divided into four periods. The four periods are the Grauntian, Mantelian, Coxian and Aalenian paradigm (Harrington, 2003). The first paradigm dates back to the 17th century with Graunt's pioneering work which attempted to understand the distribution for the length of human life (Holford, 2002) through life tables. During World War II, early life table's analysis led to reliability studies of equipment and weapons and was called TFA.

The *Kaplan-Meier method,* a main contribution during the second paradigm, is perhaps the most popular means of SA. In 1958, a paper by Kaplan and Meier in the Journal of the American Statistical Association "brought the analysis of right-censored data to the attention of mathematical statisticians..." (Oakes, 2000, p.282). The Kaplan-Meir' *product limit method* is a tool used in SA to plot survival data for a given sample of a survival study. Hypothesis testing continued on these missing data problems until about 1972. Following the introduction by Cox of the *proportional hazards model*, the focus of attention shifted to examine the impact of survival variables (covariates) on the probability of survival through the period of third paradigm. This survival probability is known within the field as the "hazard function."

The fourth and last period is the Aalenian paradigm as Statsoft (2003) claims. Aalen used a martingale approach (exponential rate for counting processes) and improved the statistical procedures for many problems arising in randomly censored data from biomedical studies in the late seventies of last century.

MAIN FOCUS

The two biggest pitfalls in SA is the considerable variation in the risk across the time interval which demonstrates the need for shorter time intervals and censoring. Censored observations occur when there is a loss of observation. This most often arises when subjects withdraw or are lost from follow-up before the completion of the study. The effect of censoring often

renders a bias within studies based upon incomplete data or partial information on survival or failure times.

There are four basic approaches for the analysis of censored data: complete data analysis; the imputation approach; analysis with dichotomized data; and the likelihood-based approach (Leung et al., 1997). The most effective approach to censoring problems is to use methods of estimation that adjust for whether or not an individual observation is censored. These "likelihood-based approaches" include the *Kaplan-Meier estimator* and the *Cox-regression*, both popular methodologies. The *Kaplan-Meier estimator* allows for the estimation of survival over time even for populations that include subjects who enter at different times or drop out.

Having discovered the inapplicability of multiple regression techniques due to the distribution (exponential vs. normal) and censoring, Cox assumed "a multiplicative relationship between the underlying hazard function and the log-linear function of the covariates" (Statsoft, 2003) and arrived at the assumption that the underlying hazard rate (rather than survival time) is a function of the independent variables (covariates) by way of a nonparametric model.

As SA emerged and became refined through the periods, it is evident even from the general overview herein that increasingly more complex mathematical formulas were being applied. This was done in large measure to account for some of the initial flaws in the research population (i.e. censoring), to provide for the comparison of separate treatments, or to take entirely new approaches concerning the perceived distributions of the data. As such, the calculations and data collection for the various models of SA became very complex requiring the use of equally sophisticated computer programs.

In that vein, software packages capable of performing the necessary analyses have been developed and include but are not limited to: SAS/STAT software (compares survival distributions for the event-time variables, fits accelerated failure time models…and performs regression analysis based on the proportional hazards model) (SAS, 2003). Also available is software from NCSS 2004 Statistical Analysis System (NCSS, 2003) and SPSS (Pallant, 2007).

Multiple-Area Applications

The typical objective of SA in demography and medical research centers on clinical trials designed to evaluate the effectiveness of experimental treatments; the modeling of disease progression in an effort to take preemptive action; and also for the purpose of estimating disease prevalence within a population. The fields of engineering and biology found applicability of SA later. There is always a need for more data analysis. The information gained from a successful SA can be used to make estimates on treatment effects, employee longevity, or product life. As SA went through more advanced stages of development it started to be also used in business related fields like economics and social sciences. With regards to a business strategy, SA can be used to predict, and thereby improve upon, the life span of manufactured products or customer relations. For example, by identifying the timing of "risky behavior patterns" (Teredata, 2003) that lead to reduced survival probability (ending the business relationship) in the future, a decision can be made to select the appropriate marketing action and its associated cost. Lo, MacKinlay and Zhang (2002) of MIT Sloan School of Management developed and estimated an econometric model of limit-order execution times. They estimated versions for time-to-first-fill and time-to-completion for both buy and sell limit orders, and incorporated the effects of explanatory variables such as the limit price, limit size, bid/offer spread, and market volatility. Through SA of actual limit-order data, they discovered that execution times are very sensitive to the limit price, but are not sensitive to limit size. Hypothetical limit-order executions, constructed either theoretically from first-passage times or empirically from transactions data, are very poor proxies for actual limit-order executions.

Blandón (2001) investigated the timing of foreign direct investment in the banking sector which, among other things, leads to differential benefits for the first entrants in a foreign location, and to problem of reversibility. When uncertainty is considered, the existence of some ownership–location–internalization advantages can make foreign investment less reversible and/or more delayable. Such advantages are examined and a

model of the timing of foreign direct investment specified. The model is then tested for a case using duration analysis.

In many industries, alliances have become the organization model of choice. Having used data from the *Airline Business* annual surveys of airline alliances, Gudmundsson and Rhoades (2001) tested a proposed typology predicting survival and duration in airline alliances. They classified key activities of airline alliances by their level of complexity and resource commitment in order to suggest a series of propositions on alliance stability and duration. The results of their analysis indicate that alliances containing joint purchasing and marketing activities had lower risk of termination than alliances involving equity.

Kimura and Fujii (2003) conducted a Cox-type SA of Japanese corporate firms using census-coverage data. A study of exiting firms confirmed several characteristics of Japanese firms in the 1990s. They found that in order to increase the probability of survival, an efficient concentration on core competences, but not excessive internalization in the corporate structure and activities, is vital to a company. Also, they found that via carefully selected channels, a firm's global commitment helps Japanese firms be more competitive and more likely to survive.

SA concepts and calculations were applied by Hough, Garitta and Sánchez (2004) to consumers' acceptance/rejection data of samples with different levels of sensory defects. The lognormal parametric model was found adequate for most defects and allowed prediction of concentration values corresponding to 10% probability of consumer rejection.

The state of the psychotherapy termination literature to date might best be characterized as inconclusive. Despite decades of studies, almost no predictors of premature termination have emerged consistently. An examination of this literature reveals a number of recurrent methodological-analytical problems that likely have contributed substantially to this state. SA, which was designed for longitudinal data on the occurrence of events, not only circumvents these problems but also capitalizes on the rich features of termination data and opens brand new avenues of investigation (Corning and Malofeeva. 2004).

From measurement of relationship between income inequality and the time-dependent risk (hazard) of a subsequent pregnancy (Gold et al., 2004) to self-reported teenagers crash involvements and citations (McCartt, 2003), to investigation of the role of product features in preventing customer churn (Larivière & Poel, 2004), to the improvement of operations management process in the provision of service (Pagell, 2004), and factors affecting corporate survival rates (Parker, 2002), additional applicability of SA in the business setting was significant and varied from personnel management to accounting to equipment maintenance and repair.

Combination with Other Methods

SA can be combined with many other decision models in the real world. Each model has its share of advantages and shortcomings. The complimentary effects, supporting arguments and the different view points may strengthen the final results.

A *feedforward neural network* architecture aimed at survival probability estimation is presented by Eleuteri, A. et al. (2003) which generalizes the standard, usually linear, models described in literature. The network builds an approximation to the survival probability of a system at a given time, conditional on the system features. The resulting model is described in a hierarchical *Bayesian* framework. Experiments with synthetic and real world data compare the performance of this model with the commonly used standard ones.

With the introduction of compulsory long-term care (LTC) insurance in Germany in 1995, a large claims portfolio with a significant proportion of censored observations became available. Czado and Rudolph (2002) presented an analysis of part of this portfolio using the *Cox proportional hazard* model to estimate transition intensities. In contrast to the more commonly used *Poisson regression* with graduation approach, where censored observations and time dependent risk factors are ignored, this approach allows the inclusion of both censored observations as well as time dependent risk factors such as time spent in LTC. Furthermore, they calculated premiums for LTC insurance plans in a multiple state *Markov process* based on these estimated transition intensities.

Vance and Geoghegan (2002) of US EPA National Center for Environmental Economics took as its point of departure a simple *utility-maximizing* model that suggests many possible determinants of deforestation in an economic environment characterized by missing or thin markets. Hypotheses from the model are tested on a data set that combines a time series of satellite imagery with data collected from a survey of farm households whose agricultural plots were geo-referenced using a *Global Positioning System* (GPS). Model results suggest that the deforestation process is characterized by non-linear duration dependence, with the probability of forest clearance first decreasing and then increasing with the passage of time.

Theoretical Improvements

Molinaro et al. (2004) proposed a unified strategy for estimator construction, selection, and performance assessment in the presence of censoring. A number of common estimation procedures follow this approach in the full data situation, but depart from it when faced with the obstacle of evaluating the loss function for censored observations. They argue that one can, and should, also adhere to this estimation road map in censored data situations.

While traditionally, SA included all of the information on a subject during a particular interval, period analyses look at just at survival experience in a recent time interval. Therefore it allows the researcher to limit or cut off the "survival experience" at the beginning and end of any chose interval, and allows it to be adapted to studies where short term survival is common. The idea is that therefore the results are less biased as Smith et al. (2004) proved. It is possible that this technique will be more widely used in the future as it seems to be more practical.

Multivariate survival data arises when subjects in the same group are related to each other or when there are multiple recurrences of the disease in the same subject. A common goal of SA is to relate the outcome (time to event) to a set of covariates. Gao, Manatunga and Chen (2004) focused on prognostic classification for multivariate survival data where identifying subgroups of patients with similar prognosis is of interest. They proposed a computationally feasible method to identify prognostic groups with the widely used Classification and Regression Trees (CART) algorithm, a popular one in data mining.

Limitations of SA

Underlying assumptions in the models, dealing with censored data and statistical power have been problems in this area. According to Fiddell & Tabachnick (2001, p.805), the challenging issues in SA "include testing the assumption of proportionality of hazards, dealing with censored data, assessing strength of association of models and individual covariates, choosing among the variety of statistical tests for differences among treatment groups and contributions of covariates, and interpreting odds ratios". Missing data is a common problem with SA. Larger samples are required for testing with covariates. Normality of sampling distributions, linearity, and homoscedasticity can lead to the results in better increased predictability, and less difficulty dealing with outliers. Censored cases should be systematically similar to those remaining in the study; otherwise the selection can no longer be considered randomly assigned. The conditions ought to remain constant throughout the experiment. Those assumptions are challengeable.

As with any scientific method there is an element of art that needs to be added in order to make the theory more usable. Certainly, SA is subject to GIGO (Garbage In, Garbage Out) because the results of a SA can be strongly influenced by the presence of error in the original data. As with any form of data gathering and analysis it is important that the researchers use only information that can be considered as relevant to the subject at hand.

FUTURE TRENDS

The past centuries have shown great strides in the development of the field of SA and there is no reason for their use to become anything but more important. As the computer age continues and advanced mathematical problems are able to be solved with the stroke of a few

keys, the use of SA will only become more important and play a greater role in our everyday lives.

Certainly, using incorrect models will lead to erroneous results/conclusions. We can imagine in the future, a single and unified model may dramatically increase the power for all SA studies. Also, SDM as a new branch of data mining may integrate with other data mining tools.

SA is based on a foundation of common principles and a common goal, there is no end in sight to transformations of SA methodologies, and there are constantly new variations on the theme and new applications for those variations. The use of SA is a significant contribution to society and will increase longevity of populations in the future.

CONCLUSION

Aside from mathematics and economics, SA is mostly used in the medical field. Gradually, SA has also been widely used in the social sciences where interest is on analyzing time to events such as job changes, marriage, birth of children and so forth. To the extent that the second paradigm of Mantel began a mere 50 years ago, the expansion and development of SA today is indeed remarkable. The progress of Kaplan-Meier, Mantel, Cox, Aalen as well as others not even mentioned here have proven SA is a reliable scientific tool susceptible to the rigors of modern mathematics. In order to properly administer treatment, caregivers and pharmaceutical providers should incorporate SA into the decision-making process. The same holds true for the effective management of business operations. It demonstrates that SA or SDM is a dynamic field, with many advances since its inception, as well as many opportunities for evolving in the future.

Technology and SA must simply enjoy a symbiotic relationship for both to flourish. SA is a dynamic and developing science that has no boundaries, other than those which are imposed upon it by human limitations.

KEY TERMS

Censored: Censored cases are those in which the survival times are unknown.

Cumulative Proportion Surviving: This is the cumulative proportion of cases surviving up to the respective interval. Since the probabilities of survival are assumed to be independent across the intervals, this probability is computed by multiplying out the probabilities of survival across all previous intervals. The resulting function is also called the survivorship or survival function.

Failure Analysis: computing the time it takes for a manufactured component to fail.

Hazard Function: A time to failure function that gives the instantaneous probability of the event (failure) given that it has not yet occurred.

Life Tables: describing the survival rate as a function of time, referred to as the survivor function.

Lifetime (or failure time, survival data): Data that measure lifetime or the length of time until the occurrence of an event.

Proportion Failing: This proportion is computed as the ratio of the number of cases failing in the respective interval, divided by the number of cases at risk in the interval.

Survival Time: The time to the occurrence of a given event.

Symbiotic Data Miner

Kuriakose Athappilly
Western Michigan University, USA

Alan Rea
Western Michigan University, USA

INTRODUCTION

Symbiotic data mining is an evolutionary approach to how organizations analyze, interpret, and create new knowledge from large pools of data. Symbiotic data miners are trained business and technical professionals skilled in applying complex data-mining techniques and business intelligence tools to challenges in a dynamic business environment.

BACKGROUND

Most experts agree (Piatetsky-Shapiro, 2000; Thearling, 2007) that data mining began in the 1960s with the advent of computers that could store and process large amounts of data. In the 1980s, data mining became more common and widespread with the distribution of relational databases and SQL. In the 1990s, business saw a boom in data mining as desktop computers and powerful server-class computers became affordable and powerful enough to process large amounts of data in data warehouses (Havenstein, 2007) as well as real-time data via online analytical processing (OLAP). Today we see an increasing use of advanced processing of data with the help of artificial intelligence technology tools such as fuzzy logic, decision trees, neural networks, and genetic algorithms (Brachman, et al., 1996; Gargano & Raggad, 1999). Moreover, current trends are moving organizations to reclassify data mining as business intelligence using such tools as Cognos (Cognos, 2007).

We also see three distinct theoretical approaches to data mining: statistical (classical), Artificial Intelligence (heuristics), and machine learning (blended AI and statistics). The three approaches do not adhere to the historical boundaries applied to data mining; rather, they are embarkation points for data-mining practitioners (Thuraisingham, 1999; Kudyba & Hoptroff, 2001; Kepner & Kim, 2003; Padmanabhan & Tuzhilin, 2003). It is not the intent of this discussion to argue which approach best informs data mining. Instead, we note that many software platforms adhere to one or more methods for solving problems via data-mining tools.

Most organizations agree that sifting through data to create business intelligence, which they can use to gain a competitive edge, is an essential business component (Lee & Siau, 2001; Brown, 2004; MacInnis, 2004; Burns, 2005). Whether it is to gain customers, increase productivity, or improve business processes, data mining can provide valuable information if it is done correctly. In most cases, a triad of business manager, information technology technician, and statistician is needed to even begin the data-mining process. Although this combination can prove useful if a symbiotic relationship is fostered, typically the participants cannot effectively work with one another because they do not speak the same language. The manager is concerned with the business process, the technician with software and hardware performance, and the statistician with analyses of data and interpretations of newfound knowledge. While this may be an overgeneralization, it is not far from the truth (O'Hara, 2007).

What is needed, then, is an individual who can pull all three components together: a symbiotic data miner trained in business, technology, and statistics.

MAIN FOCUS

In this chapter we will discuss how an individual trained not only in business but also in technology and statistics can add value to any data mining and business intelligence effort by assisting an organization to choose the right data-mining techniques and software, as well as interpret the results within an informed business context.

Data Mining in Contemporary Organizations

Data mining is the "semi-automatic discovery of patterns, associations, changes, anomalies, rules, and statistically significant structures and events in data" (Dhond, et al., 2000, p. 480). Analyzed data is many times larger than the sum of its parts. In other words, data mining can find new knowledge from observing relationships among the attributes in the form of predictions, clustering, or associations that many experts might miss. The new knowledge in a continuously changing environment is the most potent weapon for organizations to become and remain competitive (Inmon, 1996; Amato-McCoy, 2006; Corbitt, 2006).

In today's business organizations intelligence is necessary to anticipate economic trends, predict potential revenue streams, and create processes to maximize profits and efficiency. This is especially true for strategic and other mid-level managers (Athappilly, 2003). In the past, many decisions were made using corporate experience and knowledge experts. This is still true today. However, with the increased influx of data—some experts argue that the amount of information in the world doubles every 20 months (Dhond, et al., 2000; Tallon & Scannell, 2007)—many high-level managers now turn to data-mining software in order to more effectively interpret trends and relationships among variables of interest (Deal, 2004).

To support data mining an increasing amount of funds are invested in complex software to glean the data for patterns of information; hardware is purchased that can effectively run the software and distribute the results, and personnel are continually retrained or hired. The personnel include IT technicians, knowledge experts, statisticians, and various business managers. The mix of personnel needed to effectively collect, glean, analyze, interpret, and then apply data-mined knowledge ultimately can lead to one of the biggest data-mining challenges: communicating results to business managers so that they can make informed decisions. Although the managers are the ones who ultimately make the decisions, they do not have the necessary skills, knowledge base, and techniques to assess whether the heuristics, software, and interpreted results accurately inform their decisions. There is ultimately a disjunction between theoretical interpretation and pragmatic application (Athappilly, 2004).

The Challenge for Contemporary Organizations

The challenge is two-fold: 1. A shortcoming of many data-mining tools is the inability of anyone except experts to interpret the results. Business managers must be able to analyze the results of a data-mining operation to "help them gain insights . . . to make critical business decisions" (Apte, et al., 2002, p. 49) and 2. Business managers must rely on IT technicians to apply rules and algorithms, and then rely on statisticians and other experts to develop models and to interpret the results before applying them to a business decision. This process adds at least two layers between the decision and the data. Moreover, there are numerous opportunities for miscommunication and misinterpretation among the team members (O'Hara, 2007).

In order to flatten the layers between the requisite gleaned knowledge and its interpretation and application, a new type of business IT professional is needed to create a symbiotic relationship, which can sustain itself without the triadic team member requirements and the inherent polarities among them.

The Solution for Contemporary Organizations

The solution to the complex data-mining process is symbiotic data miners. The symbiotic data miner is a trained business information system professional with a background in statistics and logic. A symbiotic data miner not only can choose the correct data-mining software packages and approaches but also analyze and glean knowledge from large data warehouses. Combined with today's complex analysis and visualization software, such as Clementine (SPSS, 2007) and Enterprise Miner (SAS, 2007), the symbiotic data miner can create illustrative visual displays of data patterns and apply them to specific business challenges and predictions.

Just as today's business managers use spreadsheets to predict market trends, analyze business profits, or manage strategic planning, the symbiotic data miner can fulfill the same functions on a larger scale using complex data-mining software. Moreover, the miner can also directly apply these results to organizational missions and goals or advise management on how to apply the gleaned knowledge.

Figure 1 demonstrates how the symbiotic data miner (Athappilly, 2002) is situated at the crux of data-mining technology, statistics, logic, and application. These components of business (corporate needs, actionable decisions, and environmental changes), technology (relational databases, AI, and interactive tools), and statistical and theoretical models (math/stat and visualization tools) all flow into the symbiotic data miner's immediate working space of Model Base software, such as SAS Enterprise Miner (SAS, 2007) and SPSS Clementine (SPSS, 2007). Interacting directly with the model-based application software, the symbiotic miner develops reliable models for explorative, as well as predictive purposes. After obtaining reliable models, the symbiotic data miner provides business intelligence through multilayer charts, tables, and graphs via dashboards or other devices to inform business executives making actionable decisions.

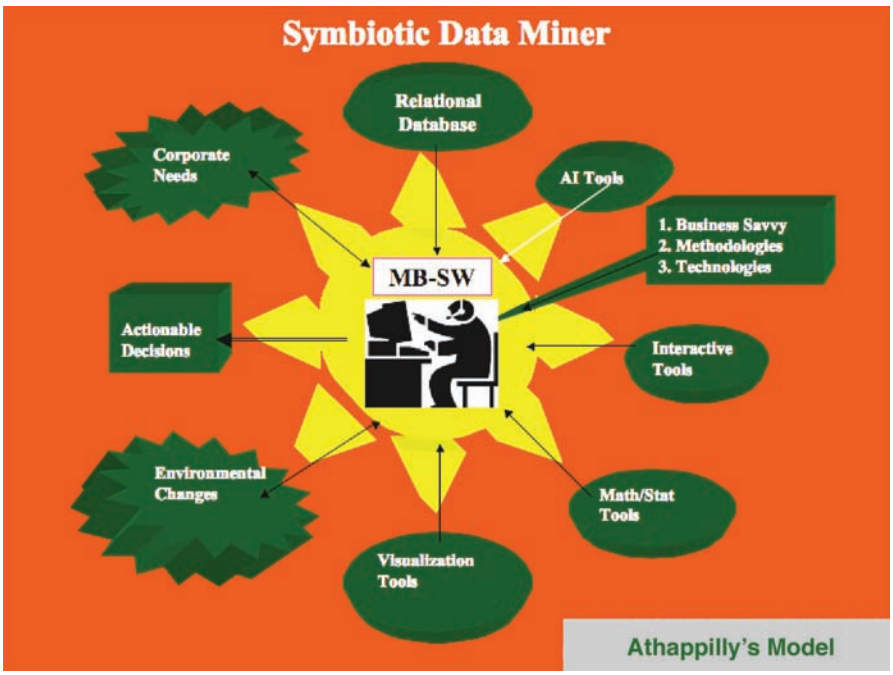
Ideal model-based application software should also have a built-in expert system capability. Using this capability, the symbiotic data miner can also provide recommendations after assessing several models. Thus, having these two sources of information—the business intelligence and recommendations—readily available from the symbiotic miner, executives can make informed decisions efficiently and effectively, thereby gaining a competitive advantage in today's highly competitive global business environment.

The symbiotic data miner plays a crucial role in flattening the layers between data-mining theory and statistics, technical support, and business acumen. The symbiotic miner can reduce miscommunication and bring applicable knowledge to a business challenge more quickly than a triadic team of business manager, technician, and statistician. Businesses should not replace all managers, technician, and statisticians with miners. However, organizations must infuse their data-mining decisions and business intelligence departments with symbiotic data miners to bridge the chasm between theory and practice.

FUTURE TRENDS

In the near future, organizations will have allocated positions for symbiotic data miners. Whatever their nomenclature, these business-informed technologically adept individuals will play a crucial role in strategic management decisions and long-term mission planning initiatives. The fledging business intelligence departments of today will continue to grow and integrate themselves into every aspect of the organizational

Figure 1. Symbiotic data miner



structure. Through sheer success, these departments will be subsumed into every department with symbiotic data miners specializing in particular business aspects.

Even further into the future, symbiotic data mining will simply become a way of doing business. No longer will the distinction among manager, technician, and statistician be as distinguishable. As software infused with business protocols and data-mining technology increases (Rea & Athappilly, 2004), business will implement data-mining systems on the desktop. Business managers at all levels will use symbiotic data-mining software as easily as many use office suite software (e.g., Microsoft Office) today. Software infused and linked with various data-mining systems and data sources will generate complex visual graphs, tables, and diagrams that can be mined according to one's desired results. We are already seeing the kernels of interconnected symbiotic mining in such applications as Microsoft Dynamics (Microsoft, 2007) and SAP's Business Warehouses (SAP, 2007).

The software that supports data mining will be user friendly, transparent and intuitive. Simultaneously, users will have experienced increased exposure to higher education, become more familiar with quantitative methods and technology tools, and will be better informed of the business culture and environment. As a result, data mining will be an inevitable routine activity implemented to make more informed decisions.

The catalysts for this movement will be a collective force comprised of educators, students, software vendors, and business professionals. Through internships, continued research, and increased business and academic partnerships and collaborations, the integration of business, data-mining technology, statistics, and theory into practical business software will become a reality. The realm of the symbiotic data miner will become a shared discipline in the information-rich business environment.

CONCLUSION

Symbiotic data miners are trained in business, information technology, and statistics. They are able to implement data mining solutions, interpret the results, and then apply them to business challenges. Without people with these skills, businesses will not be able to take full advantage of the vast stores of data available to them in order to make informed decisions.

However, the symbiotic data miner will not come about without changes in how individuals are trained in higher education and on the job. Without a combination of business, information technology, statistics, and logic we cannot look for an infusion of symbiotic data miners anytime soon. Today, businesses have begun to realize the need to tap into the vast knowledge stores available to them. As organizations move more toward business intelligence we will witness the emergence of more symbiotic data miners even though we may not identify them by this name.

KEY TERMS

Artificial Intelligence: A field of information technology that studies how to imbue computers with human characteristics and thought. Expert systems, natural language, and neural networks fall under the AI research area.

Business Intelligence: Information that enables high-level business managers and executives to make strategic and long-term business decisions.

Clementine: Data-mining software owned by SPSS Corporation that consists of supervised and unsupervised learning algorithms to create application models to solve business challenges.

Cognos: Business intelligence software that enables organizations to monitor performance and develop strategic business solutions based on collected data.

Decision Trees: Tree-shaped structures that represent sets of decisions. Different types of decisions trees, such as Classification and Regression Trees (CART), allow experts to create validated decision models that can then be applied to new data sets.

Enterprise Miner: Data-mining software developed by SAS Corporation that consists of supervised and unsupervised learning algorithms to create application models to solve business challenges.

Fuzzy Logic: A type of logic that does not rely on a binary yes or no. Instead computer systems are able to rank responses on a scale of 0.0 to 1.0 with 0.0 being false to 1.0 being true. This allows computer systems to deal with probabilities rather than absolutes.

Genetic Algorithms: A large collection of rules that represent all possible solutions to a problem. Inspired by Darwin's theory of evolution, these rules are simultaneously applied to data using powerful software on high-speed computers. The best solutions are then used to solve the problem.

Heuristics: A set of rules derived from years of experience to solve problems. These rules can be drawn from previous examples of business successes and failures. Artificial intelligence models rely on these rules to find relationships, patterns, or associations among variables.

Machine Learning: This involves a combination of AI and statistics. Software programs are able to predict and learn approaches to solve problems after repeated attempts.

Neural Networks: An artificial intelligence program that attempts to learn and make decisions much like the human brain. Neural networks function best with a large pool of data and examples from which they can learn.

Online Analytical Processing (OLAP): OLAP tools allow users to analyze different dimensions of multidimensional data.

Structured Query Language (SQL): This is a standardized query language used to pull information from a database.

Symbiotic Data Miner: An individual trained in business, information technology, and statistics. The symbiotic data miner is able to implement data mining solutions, interpret the results, and then apply them to business challenges.

Tabu Search for Variable Selection in Classification

Laura Nuñez Letamendía
Instituto de Empresa, Spain

INTRODUCTION

Variable selection plays an important role in classification. Before beginning the design of a classification method, when many variables are involved, only those variables that are really required should be selected. There can be many reasons for selecting only a subset of the variables instead of the whole set of candidate variables (Reunanen, 2003): (1) It is cheaper to measure only a reduced set of variables, (2) Prediction accuracy may be improved through the exclusion of redundant and irrelevant variables, (3) The predictor to be built is usually simpler and potentially faster when fewer input variables are used and (4) Knowing which variables are relevant can give insight into the nature of the prediction problem and allows a better understanding of the final classification model. The importance of variables selection before using classification methods is also pointed out in recent works such as Cai et al.(2007) and Rao and Lakshminarayanan (2007).

The aim in the classification problem is to classify instances that are characterized by attributes or variables. Based on a set of examples (whose class is known) a set of rules is designed and generalised to classify the set of instances with the greatest precision possible. There are several methodologies for dealing with this problem: Classic Discriminant Analysis, Logistic Regression, Neural Networks, Decision Trees, Instance-Based Learning, etc. Linear Discriminant Analysis and Logistic Regression methods search for linear functions and then use them for classification purposes. They continue to be interesting methodologies.

In this work an "ad hoc" new method for variable selection in classification, specifically in discriminant analysis and logistic regression, is analysed. This new method is based on the metaheuristic strategy tabu search and yields better results than the classic methods (stepwise, backward and forward) used by statistical packages such as SPSS or BMDP, as it's shown below. This method is performed for 2 classes.

BACKGROUND

Research in variable selection started in the early 1960s (Lewis, 1962 and Sebestyen, 1962). Over the past four decades, extensive research into feature selection has been conducted. Much of the work is related to medicine and biology (e.g. Inza et al., 2002; Shy and Suganthan, 2003). The selection of the best subset of variables for building the predictor is not a trivial question, because the number of subsets to be considered grows exponentially with the number of candidate variables, which means that feature selection is a NP (Nondeterministic Polynomial) -Hard computational problem (see Cotta et al., 2004). When the size of the problem is large finding an optimum solution in practice is not feasible.

Two different methodological approaches have been developed for variable selection problems: optimal or exact techniques (enumerative techniques), which can guarantee an optimal solution, but are applicable only in small sets; and heuristic techniques, which can find good solutions (although they cannot guarantee the optimum) in a reasonable amount of time. Among the former, the Narendra and Fukunaga (1977) algorithm is one of the best known, but as Jain and Zongker (1997) pointed out, this algorithm is impractical for problems with very large feature sets. Recent references about implicit enumerative techniques of selection features adapted to regression models could be found in Gatu and

Kontoghiorghes (2005) and (2006). On the other hand, among the heuristic techniques we find works based on genetic algorithms (see Bala et al. (1996), Jourdan et. al. (2001)), Oliveira et al, 2003 and Wong and Nandi, (2004)) and the recent work by García et al. (2006) who present a method based on Scatter Search. As found in other optimization problems metaheuristic techniques have proved to be superior methodologies.

However, although there are many references in the literature regarding selecting variables for their use in classification, there are very few key references on the selection of variables for their use in discriminant analysis and logistic regression. For this specific purpose the *Stepwise* method (Efroymson, 1960*)* and all its variants, such as O'Gorman's (2004), as well as the *Backward* and *Forward* methods, can be found in the literature. These are simple selection procedures based on statistical criteria which have been incorporated into some of the best known statistical packages such as SPSS or BMDP. As highlighted by Huberty (1994) these methods are not very efficient, and when there are many original variables the optimum is rarely achieved.

SOLVING THE PROBLEM

Setting Out the Problem

We can formulate the problem of selecting the subset of variables with superior classification performance as follows: V being a set of m variables, such that $V = \{1, 2,..., m\}$ and A being a set of instances, (also named "training" set). For each case we also know the class it belongs to. Given a predefined value $p \in \mathrm{N}$, $p < m$, we have to find a subset $S \subset V$, with a size p with the greatest classification capacity, $f(S)$.

To be precise, for the discriminant analysis the function $f(S)$ is defined as a percentage of hits in A obtained through the variables of S with Fisher's classifier (Fisher, 1936).

For logistic regression the classification capacity, *f(s),* is obtained as follows: let's consider $S = \{1, 2, \ldots, p\}$ without loss of generality; let x_{ij} be the value of variable j for case i, $i \in A$, $j \in S$, and $y_i = 1$ if case i belongs first class and 0 otherwise; this classifier is obtained by calculating vector $\mathbf{c} = (c_0. c_1. \ldots. c_p)$ by maximizing the next expression

$$L(\mathbf{c}) = \prod_{i=1}^{n} p_i^{\,y_i} \cdot (1 - p_i)^{1-y_i}$$

where

$$p_i = \frac{1}{1 + e^{-z_i}}$$

and $z_i = c_o + c_1 x_{i1} + c_2 x_{i2} + \ldots + c_p x_{ip}$;

then, once vector **c** is obtained, every case i is classified to class 1 if $p_i > 0.5$ and in class 2 otherwise. Function L is usually named as likelihood function.

Solution Approach: Tabu Search

Tabu Search (TS) is a strategy proposed by Glover (1989 and 1990). A comprehensive tutorial on Tabu Search can be found in Glover and Laguna (2002).

Our Tabu Search algorithm includes a method for building an initial solution and a basic procedure for exploring the space of solutions around this initial solution The performance of the Tabu Algorithm is outlined as follows:

Tabu Search Procedure
Build an initial solution
Repeat
Execute Basic Tabu Search
until a stopping condition is reached

In this work a limit of 30 minutes of computational time is used as stopping condition. Next these elements are described.

Initial Solution

The initial solution is built as follows: starting from the empty initial solution, a variable is added in each iteration until the solution S reaches p variables ($|S| = p$). To decide which variable is added to the solution in each iteration the value of f is used.

Description of a Basic Algorithm

Our Tabu Search algorithm uses neighbouring moves which consist in exchanging an element that is in solu-

tion *S* for an outside element at each step. In order to avoid repetitive looping when a move is performed, consisting in exchanging *j* from *S* for *j'* from *V-S*, element *j* is prevented from returning to *S* for a certain number of iterations. We define *vector_tabu* (*j*) = the number of the iterations in which element *j* leaves *S*.

Some 'tabu' moves can be permitted under specific conditions ("aspiration criterion"), for example, to improve the best solution found. The basic Tabu Search method is described next, where *S* is the current solution and *S** the best solution. The *Tabu_Tenure* parameter indicates the number of iterations during which an element is not allowed to return to *S*. After different tests, *Tabu_Tenure* was set as *p*.

Basic Tabu Search Procedure
(a) *Read initial solution S*
(b) Do vector_tabu(j) = - Tabu_Tenure, j =1..m; niter =0, iter_better=0 and S = S*
(c) Repeat
(c.1) niter = niter+1
(c.2) Calculate $v_{jj'} = f(S \cup \{j'\} - \{j\})$
(c.3) Determine $v_{j^*j'^*} = max \{v_{jj'} / \forall\ j \in S, j' \notin S$ *verifying:*
niter > vector_tabu(j) + Tabu_Tenure or $v_{jj'} > f(S^*)$ *('aspiration criterion')}*
(c.4) Do $S = S \cup \{j'^*\} - \{j^*\}$ *and vector_tabu (j*) = niter*
(c.5) If f (S) > f(S) then do: S* = S, f* = f and iter_better = niter;*
until niter > iter_better+2·m

That is, this procedure terminates when $2 \cdot m$ iterations have taken place without improvement.

Computational Results

To check and compare the efficacy of these new method a series of experiments was run with different test problems. Specifically six data sets were used. These data sets can be found in the well-known data repository of the University of California, UCI, (see Murphi and Aha. 1994). This can be found at: www.ics.uci.edu/~mlearn/MLRepository.html. The following databases were used:

- *Spambase Database*: 57 variables, 2 classes and 4,601 cases.
- *Mushrooms Database*: 22 variables, 2 classes and 8,100 cases. The 22 nominal variables were transformed into 121 binary variables: 1 for each binary variable and 1 per possible answer for the remaining variables. *Covertype Database*: This is a forestry database, with 54 explanatory variables, 8 classes and more than 580,000 cases or instances. *Conect-4 Opening Database:* 42 nominal variables, 3 classes and 67,557 cases. The 42 nominal variables were transformed into 126 binary variables.
- *Waveform Database:* 40 variables with continuous values, 3 classes and 5,000 instances. We have considered the two first classes.
- *Nursery Database*: 8 nominal variables, 5 classes and 12,960 cases. The 8 nominal variables were transformed into 28 binary variables. The 5 classes are grouped together in two classes ("not_recom" and the rest).

From each database we have randomly selected 10 sets of 200 cases as test sets for evaluating the model with independent data .

Our Tabu Search is compared to the classic *Stepwise, Backward* and *Forward* procedures used in some well-known statistical software packages such as SPSS or BMDP.

The experiments were divided into two groups. The first group is devoted to compare our Tabu Search with the traditional *Stepwise, Forward* and *Backward* methods for discriminant analysis and the second group for logistic regression. All the experiments were done on a Pentium IV 2.4 GHz PC using the BORLAND DELPHI compiler (version 5.0).

We apply our Tabu Search algorithm to different training sets from the above mentioned databases and subsecuently we evaluate the models thus obtained with independent data (test sets).

Discriminant Analysis

Table 1 presents a summary of the solutions obtained with the test sets for each value of p considered (classification capacity in the intermediary steps). Specifically, the data we use are 10 test sets obtained from each database which have been described previously. The results of *Forward* method are omitted because they are the same as the ones obtained by *Stepwise* method.

The following points can be made regarding Table2:

- The *Backward* method seems to work similar to the *Stepwise* and *Forward* method.
- Our Tabu Search algorithm improves the solutions of the classic methods for most of the cases.

FUTURE TRENDS

This work proposes an "ad hoc" new method for variable selection in classification, in particular in discriminant analysis and logistic regression. This method is performed for 2 classes but in the future it could be adapted to higher number of classes.

Also, as a continuity of this work, another metaheuristic strategies for variable selection in logistic regression and discriminant analysis will be designed and implemented to check and compare their efficacy.

CONCLUSIONS

A Tabu Search method to select variables that are subsequently used in discriminant analysis and logistic regression models is proposed and analysed. Although there are many references in the literature regarding variable selection for their use in classification, there are very few key references on the selection of variables for their use in discriminant analysis and logistic regression. After performing some tests it is found that Tabu Search obtains better results than the *Stepwise*, *Backward* or *Forward* methods used by classic statistical packages such as SPSS or BMDP.

KEY TERMS

Backward: A variable selection method which begins by selecting all the variables and then, at each step, the variable that contributes least to the prediction of group membership is eliminated. Thus, as the result, those variables that contribute the most to the discrimination between groups are obtained.

Classification Methods: Methods used for designing a set of rules which let us to classify a set of instances with the greatest precision possible. These methods are based on a set of examples whose class is known.

Forward: A variable selection method which begins by selecting the most discriminant variable according to some criterion. It continues by selecting the second most discriminant variable and so on. The algorithm stops when none of the non-selected variables discriminates in a significant way.

Metaheuristics: Metaheuristics are high level procedures that coordinate simple heuristics, such as local search, to find solutions that are of better quality that those found by the simple heuristics.

Stepwise: A variable selection procedure which introduces or eliminates variables at each step, depending on how significant their discriminating capacity is. It also allows for the possibility of changing decisions taken in previous steps, by eliminating from the selected set a variable introduced in a previous step of the algorithm or by selecting a previously eliminated variable.

Tabu Search (TS): Is a metaheuristic strategy based on the premise that problem solving, in order to qualify as intelligent, must incorporate adaptive memory and responsive exploration. TS explores the solution space beyond de local optimum. Once a local optimum is reached, upward moves and those worsening the solutions are allowed. Simultaneously, the last moves are marked as tabu during the following iterations to avoid cycling.

Variable Selection Problem: This problem consists in finding from a set of *m* variables a subset of them that can carry out the classification task in an optimum way.

Techniques for Weighted Clustering Ensembles

Carlotta Domeniconi
George Mason University, USA

Muna Al-Razgan
George Mason University, USA

INTRODUCTION

In an effort to achieve improved classifier accuracy, extensive research has been conducted in classifier ensembles. Very recently, cluster ensembles have emerged. It is well known that off-the-shelf clustering methods may discover different structures in a given set of data. This is because each clustering algorithm has its own bias resulting from the optimization of different criteria. Furthermore, there is no ground truth against which the clustering result can be validated. Thus, no cross-validation technique can be carried out to tune input parameters involved in the clustering process. As a consequence, the user is not equipped with any guidelines for choosing the proper clustering method for a given dataset.

Cluster ensembles offer a solution to challenges inherent to clustering arising from its ill-posed nature. Cluster ensembles can provide more robust and stable solutions by leveraging the consensus across multiple clustering results, while averaging out emergent spurious structures that arise due to the various biases to which each participating algorithm is tuned.

In this chapter, we discuss the problem of combining multiple *weighted clusters*, discovered by a locally adaptive algorithm (Domeniconi, Papadopoulos, Gunopulos, & Ma, 2004) which detects clusters in different subspaces of the input space. We believe that our approach is the first attempt to design a cluster ensemble for subspace clustering (Al-Razgan & Domeniconi, 2006).

Recently, several subspace clustering methods have been proposed (Parsons, Haque, & Liu, 2004). They all attempt to dodge the curse of dimensionality which affects any algorithm in high dimensional spaces. In high dimensional spaces, it is highly likely that, for any given pair of points within the same cluster, there exist at least a few dimensions on which the points are far apart from each other. As a consequence, distance functions that equally use all input features may not be effective.

Furthermore, several clusters may exist in different subspaces comprised of different combinations of features. In many real-world problems, some points are correlated with respect to a given set of dimensions, while others are correlated with respect to different dimensions. Each dimension could be relevant to at least one of the clusters.

Global dimensionality reduction techniques are unable to capture local correlations of data. Thus, a proper feature selection procedure should operate locally in input space. Local feature selection allows one to embed different distance measures in different regions of the input space; such distance metrics reflect local correlations of data. In (Domeniconi, Papadopoulos, Gunopulos, & Ma, 2004) we proposed a *soft* feature selection procedure (called LAC) that assigns weights to features according to the local correlations of data along each dimension. Dimensions along which data are loosely correlated receive a small weight, which has the effect of elongating distances along that dimension. Features along which data are strongly correlated receive a large weight, which has the effect of constricting distances along that dimension. Thus the learned weights perform a directional local reshaping of distances which allows a better separation of clusters, and therefore the discovery of different patterns in different subspaces of the original input space.

The clustering result of LAC depends on two input parameters. The first one is common to all clustering algorithms: the number of clusters k to be discovered in the data. The second one (called h) controls the strength of the incentive to cluster on more features. The setting of h is particularly difficult, since no domain knowledge

for its tuning is likely to be available. Thus, it would be convenient if the clustering process automatically determined the relevant subspaces.

In this chapter we discuss two cluster ensemble techniques for the LAC algorithm. We focus on setting the parameter h and assume that the number of clusters k is fixed. We leverage the diversity of the clusterings produced by LAC when different values of h are used, in order to generate a consensus clustering that is superior to the participating ones.

BACKGROUND

In many domains it has been shown that a classifier ensemble is often more accurate than any of the single components. This result has recently initiated further investigation in ensemble methods for clustering. In (Fred & Jain, 2002) the authors combine different clusterings obtained via the *k*-means algorithm. The clusterings produced by *k*-means are mapped into a co-association matrix, which measures the similarity between the samples. Kuncheva et al. (Kuncheva & Hadjitodorov, 2004) extend the work in (Fred & Jain, 2002) by choosing at random the number of clusters for each ensemble member. The authors in (Zeng, Tang, Garcia-Frias, & Gao, 2002) introduce a meta-clustering procedure: first, each clustering is mapped into a distance matrix; second, the multiple distance matrices are combined, and a hierarchical clustering method is introduced to compute a consensus clustering. In (Hu, 2004) the authors propose a similar approach, where a graph-based partitioning algorithm is used to generate the combined clustering. Ayad et al. (Ayad & Kamel, 2003) propose a graph approach where data points correspond to vertices, and an edge exists between two vertices when the associated points share a specific number of nearest neighbors. In (Fern & Brodley, 2003) the authors combine random projection with a cluster ensemble. EM is used as clustering algorithm, and an agglomerative approach is utilized to produce the final clustering. Greene et al. (Greene, Tsymbal, Bolshakova, & Cunningham, 2004) apply an ensemble technique to medical diagnostic datasets. The authors focus on different generation and integration techniques for input clusterings to the ensemble. *K-means*, *K*-medoids and fast *weak clustering* are used as generation strategies. The diverse clusterings are aggregated into a co-occurrence matrix. Hierarchical schemes are then applied to compute the consensus clustering. Greene's approach follows closely Fred and Jain's approach (Fred & Jain, 2002). However, they differ in the generation strategies. Similarly, in (Boulis & Ostendorf, 2004) the association between different clusterings produced by various algorithms is investigated. Techniques based on constrained and unconstrained clustering and on SVD are considered. (Gionis, Mannila, & Tsaparas, 2005) approach finds an ensemble clustering that agrees as much as possible with the given clusterings. The proposed technique does not require the number of clusters as an input parameter, and handles missing data.

In (Strehl & Ghosh, 2003) the authors propose a consensus function aimed at maximizing the normalized mutual information of the combined clustering with the input ones. Three heuristics are introduced: Cluster-based Similarity Partitioning Algorithm (CSPA), HyperGraph Partitioning Algorithm (HGPA), and Meta-Clustering Algorithm (MCLA). All three algorithms transform the set of clusterings into a hypergraph representation.

In CSPA, a binary similarity matrix is constructed for each input clustering. An entry-wise average of all the matrices gives an overall similarity matrix S. S is utilized to recluster the data using a graph-partitioning based approach. HGPA constructs a hypergraph in which each hyperedge represents a cluster of an input clustering. The algorithm seeks a partitioning of the hypergraph by cutting a minimal number of hyperedges. The partition gives k unconnected components of approximately the same size. MCLA is based on the clustering of clusters. It provides object-wise confidence estimates of cluster membership. Hyperedges are grouped, and each data point is assigned to the collapsed hyperedge in which is participates most strongly.

MAIN FOCUS

In the following we introduce two consensus functions to identify an emergent clustering that arises from multiple clustering results. We reduce the problem of defining a consensus function to a graph partitioning problem (Dhillon, 2001; Fern & Brodley, 2004; Strehl & Ghosh, 2003). In fact, the *weighted clusters* computed by the LAC algorithm offer a natural way to define a similarity measure to be integrated as weights associated to

the edges of a graph. The overall clustering ensemble process is illustrated in Figure 1.

Locally Adaptive Clustering (LAC)

We briefly describe our locally adaptive clustering algorithm (Domeniconi, Papadopoulos, Gunopulos, & Ma, 2004). Consider a set of points in some space of dimensionality D. A *weighted cluster* C is a subset of data points, together with a vector of weights $\mathbf{w} = (w_1, ..., w_o)$, such that the points in C are closely clustered according to the L_2 norm distance weighted using $\mathbf{w}$. The component w_j measures the degree of correlation of points in C along feature j.

Our approach progressively improves the quality of initial centroids and weights, by investigating the space near the centers to estimate the dimensions that matter the most. We start with *well-scattered* points in a dataset S as the k centroids: we choose the first centroid at random, and select the others so that they are far from one another, and from the first chosen center. We initially set all weights to $1/D$. Given the initial centroids c_j, for $j = 1, ..., k$, we compute the corresponding sets

$$S_j = \left\{ x \mid \left(\sum_{i=1}^{D} w_{ji}(x_i - c_{ji})^2\right)^{1/2} < \left(\sum_{i=1}^{D} w_{li}(x_i - c_{li})^2\right)^{1/2}, \forall l \neq j \right\}$$

where w_{ji} and c_{ji} represent the ith components of vectors $\mathbf{w}_j$ and $\mathbf{c}_j$ respectively (ties are broken randomly). We then compute the average distance along each dimension from the points in S_j to $\mathbf{c}_j$:

$$X_{ji} = \frac{1}{|S_j|} \sum_{x \in S_j} (c_{ji} - x_i)^2,$$

where $|S_j|$ is the cardinality of set S_j. The smaller X_{ji} is, the larger is the correlation of points along dimension i. We use the value X_{ji} in an exponential weighting scheme to credit weights to features (and to clusters), as given in

$$w_{ji}^* = \frac{\exp(-X_{ji}/h)}{\sum_{i=1}^{D} \exp(-X_{ji}/h)}$$

(the parameter h controls the strength of the incentive for clustering on more features). The computed weights are used to update the sets S_j, and therefore the centroids' coordinates as given in

$$c_{ji}^* = \frac{1}{|S_j|} \sum_{x \in S_j} x_i.$$

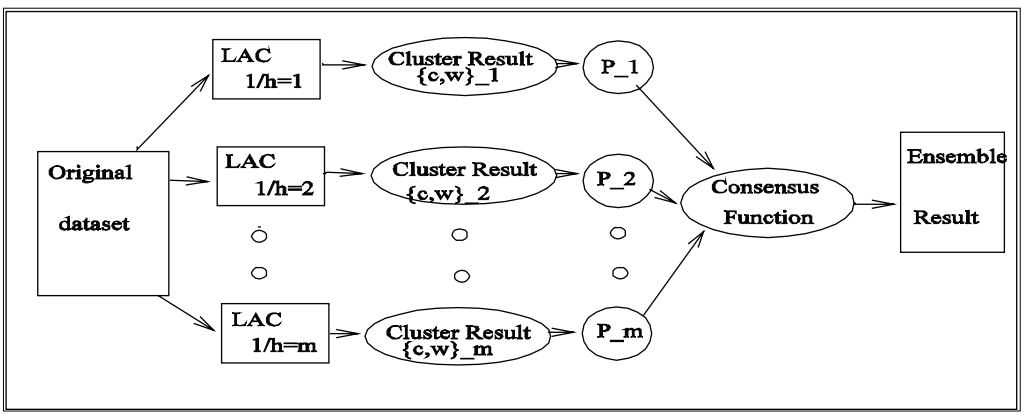
The procedure is iterated until convergence is reached. The resulting algorithm is called LAC.

Weighted Similarity Partitioning Algorithm (WSPA)

LAC outputs a partition of the data, identified by the two sets $\{\mathbf{c}_1,...,\mathbf{c}_k\}$ and $\{\mathbf{w}_1,...,\mathbf{w}_k\}$.

Our aim here is to generate robust and stable solutions via a consensus clustering method. We can generate contributing clusterings by changing the parameter h (as illustrated in Figure 1).

Figure 1. The clustering ensemble process



The objective is then to find a consensus partition from the output partitions of the contributing clusterings, so that an ``improved'' overall clustering of the data is obtained. The details of our approach are as follows**.**

For each data point $\mathbf{x}_i$, the weighted distance from cluster C_l is given by

$$d_{il} = \sqrt{\sum_{s=1}^{D} w_{ls}(x_{is} - c_{ls})^2}.$$

Let $D_i = \max_l\{d_{il}\}$ be the largest distance of $\mathbf{x}_i$ from any cluster. We want to define the probability associated with cluster C_l given that we have observed $\mathbf{x}_i$. At a given point $\mathbf{x}_i$, the cluster label C_l is assumed to be a random variable from a distribution with probabilities $\{P(C_l \mid \mathbf{x}_i)\}_{l=1}^{k}$. We provide a nonparametric estimation of such probabilities based on the data and on the clustering result. We do not make any assumption about the specific form of the underlying data distributions, thereby avoiding parameter estimations of models.

In order to embed the clustering result in our probability estimations, the smaller the distance d_{il} is, the larger the corresponding probability credited to C_l should be. Thus, we can define $P(C_l \mid \mathbf{x}_i)$ as follows:

$$P(C_l \mid \mathbf{x}_i) = \frac{D_i - d_{il} + 1}{kD_i + k - \sum_l d_{il}} \tag{1}$$

where the denominator serves as a normalization factor to guarantee $\sum_{l=1}^{k} P(C_l \mid \mathbf{x}_i) = 1$. We observe that $\forall l = 1, ..., k$ and $\forall i = 1, ..., n$ $P(C_l \mid \mathbf{x}_i) > 0$. In particular, the added value of 1 in (1) allows for a non-zero probability $P(C_L \mid \mathbf{x}_i)$ when $L = \arg\max_l\{d_{il}\}$.In the last case $P(C_l \mid \mathbf{x}_i)$ assumes its minimum value

$$P(C_L \mid \mathbf{x}_i) = \frac{1}{(kD_i + k + \sum_l d_{il})}.$$

For smaller distance values d_{il}, $P(C_l \mid \mathbf{x}_i)$ increases proportionally to the difference $D_i - d_{il}$: the larger the deviation of d_{il} from D_i, the larger the increase. As a consequence, the corresponding cluster C_l becomes more likely, as it is reasonable to expect based on the information provided by the clustering process. Thus, equation (1) provides a nonparametric estimation of the posterior probability associated to each cluster C_l.

We can now construct the vector P_i of posterior probabilities associated with $\mathbf{x}_i$:

$$P_i = (P(C_1 \mid \mathbf{x}_i), P(C_2 \mid \mathbf{x}_i), ..., P(C_k \mid \mathbf{x}_i))^t \tag{2}$$

where *t* denotes the transpose of a vector. The transformation $\mathbf{x}_i \rightarrow P_i$ maps the *D* dimensional data points $\mathbf{x}_i$ onto a new space of *relative coordinates* with respect to cluster centroids, where each dimension corresponds to one cluster. This new representation embeds information from both the original input data and the clustering result.

We then define the similarity between $\mathbf{x}_i$ and $\mathbf{x}_j$ as the cosine similarity between the corresponding probability vectors:

$$s(\mathbf{x}_i, \mathbf{x}_j) = \frac{P_i^t P_j}{\| P_i \| \| P_j \|} \tag{3}$$

We combine all pairwise similarities (3) into an $(n \times n)$ similarity matrix *S*, where $S_{ij} = s(\mathbf{x}_i, \mathbf{x}_j)$. We observe that each clustering may provide a different number of clusters, with different sizes and boundaries. The size of the similarity matrix *S* is independent of the clustering approach, thus providing a way to align the different clustering results onto the same space, with no need to solve a label correspondence problem.

After running the LAC algorithm *m* times for different values of the *h* parameter, we obtain the *m* similarity matrices $S_1, S_2, ..., S_m$. The combined similarity matrix Ψ defines a *consensus function* that can guide the computation of a consensus partition:

$$\Psi = \frac{1}{m}\sum_{l=1}^{m} S_l \tag{4}$$

Ψ_{ij} reflects the average similarity between $\mathbf{x}_i$ and $\mathbf{x}_j$ (through P_i and P_j) across the *m* contributing clusterings.

We now map the problem of finding a consensus partition to a graph partitioning problem. We construct a complete graph $G = (V, E)$, where $|V|=n$ and the vertex V_i identifies $\mathbf{x}_i$. The edge E_{ij} connecting the vertices V_i and V_j is assigned the weight value Ψ_{ij}. We run METIS (Kharypis & Kumar, 1995) on the resulting graph to compute a *k*-way partitioning of the *n* vertices that minimizes the edge weight-cut. This gives the consensus clustering we seek. The size of the resulting

graph partitioning problem is n^2. We call the resulting algorithm WSPA (Weighted Similarity Partitioning Algorithm).

Weighted Bipartite Partitioning Algorithm (WBPA)

Our second approach maps the problem of finding a consensus partition to a bipartite graph partitioning problem. This mapping was first introduced in (Fern & Brodley, 2004). In (Fern & Brodley, 2004), however, 0/1 weight values are used. Here we extend the range of weight values to [0, 1].

In this context, the graph models both instances and clusters, and the graph edges can only connect an instance vertex to a cluster vertex, thus forming a bipartite graph.

Suppose, again, that we run the LAC algorithm m times for different values of the h parameter. For each instance $\mathbf{x}_i$, and for each clustering $\nu = 1, ..., m$ we then can compute the vector of posterior probabilities P_i^ν, as defined in equations (1) and (2). Using the P vectors, we construct the following matrix A:

$$A = \begin{pmatrix} (P_1^1)^t (P_1^2)^t ... (P_1^m)^t \\ (P_2^1)^t (P_2^2)^t ... (P_2^m)^t \\ \vdots \\ (P_n^1)^t (P_n^1)^t ... (P_n^m)^t \end{pmatrix}$$

Note that the $(P_i^\nu)^t$s are row vectors (t denotes the transpose). The dimensionality of A is therefore $n \times km$, under the assumption that each of the m clusterings produces k clusters. (We observe that the definition of A can be easily generalized to the case where each clustering may discover a different number of clusters.)

Based on A we can now define a bipartite graph to which our consensus partition problem maps. Consider the graph $G = (V, E)$ with V and E constructed as follows. $V = V^C \cup V^I$, where V^C contains km vertices, each representing a cluster of the ensemble, and V^I contains n vertices, each representing an input data point. Thus $|V| = km + n$. The edge E_{ij} connecting the vertices V_i and V_j is assigned a weight value defined as follows. If the vertices V_i and V_j represent both clusters or both instances, then $E(i, j) = 0$; otherwise, if vertex V_i represents an instance $\mathbf{x}_i$ and vertex V_j represents a cluster C_j^ν (or vice versa) then the corresponding entry of E is $A(i, k(\nu - 1) + j)$.

Note that the dimensionality of E is $(km + n) \times (km + n)$, and E can be written as follows:

$$E = \begin{pmatrix} 0 & A^t \\ A & 0 \end{pmatrix}$$

A partition of the bipartite graph G partitions the cluster vertices and the instance vertices simultaneously. The partition of the instances can then be output as the final clustering. Due to the special structure of the graph G (sparse graph), the size of the resulting bipartite graph partitioning problem is kmn. Assuming that $(km) < n$, this complexity is much smaller than the size n^2 of WSPA.

We again run METIS on the resulting bipartite graph to compute a k-way partitioning that minimizes the edge weight-cut. We call the resulting algorithm WBPA (Weighted Bipartite Partitioning Algorithm).

FUTURE TRENDS

In our future work we will consider utilizing our consensus function as a similarity matrix for hierarchical and spectral clustering. This approach will eliminate the requirement for balanced clusters. We will extend our approach to be used with any subspace clustering technique. In addition, we aim at designing an ensemble that preserves a subspace clustering structure. One possibility is to leverage the weight vectors associated with the input clustering that shares the highest NMI with the clustering produced by the ensemble (this can be performed using the RAND statistic). Another possibility is to infer a set of dimensions for each cluster from the clustering result of the ensemble.

The diversity-accuracy requirements of the individual clusterings, in order for the ensemble to be effective, will be also investigated. It is expected that the accuracy of the ensemble improves when a larger number of input clusterings is given, provided that the contributing clusterings are diverse.

CONCLUSION

We have discussed the cluster ensemble learning paradigm and introduced two cluster ensemble techniques

for the LAC algorithm. Our algorithms leverage the diversity of the clusterings produced by LAC when different values of *h* are used, in order to generate a consensus clustering that is superior to the participating ones.

KEY TERMS

Clustering: The process of grouping objects into subsets, such that those within each cluster are more closely related to one another than objects assigned to different clusters, according to a given similarity measure.

Clustering Ensembles: Learning paradigm that aggregates a collection of clustering components to produce a consensus partition that is more accurate than the individual clusterings.

Curse of Dimensionality: Phenomenon that refers to the fact that, in high-dimensional spaces, data become extremely sparse and are far apart from each other. As a result, the sample size required to perform an accurate prediction in problems with high dimensionality is usually beyond feasibility.

Subspace Clustering: Simultaneous clustering of both row and column sets in a data matrix.

K-Way Graph Partitioning: Given a weighted graph $G = (V, E)$, partitioning G into k parts means to find a partition of V into k disjoint clusters of vertices. The sum of the weights of the crossed edges is defined as the cut of the partition. The general goal of graph partitioning is to find a k-way partition that minimizes the cut.

Locally Adaptive Clustering (LAC): Algorithm that discovers clusters in subspaces, spanned by different combinations of dimensions, via local weighting of features.

Weighted Bipartite Partition Algorithm (WBPA): Maps the problem of finding a consensus partition to a bipartite graph partitioning problem. The graph models both data points and clusters as vertices, and an edge can only connect an instance vertex to a cluster vertex, thus forming a bipartite graph. The algorithm utilizes the weighted features provided by LAC to map each data point onto a new space of posterior probabilities where each dimension corresponds to a cluster. The resulting posterior probability $P(C_l|\mathbf{x}_i)$ is the weight associated with the edge connecting vertex C_l with vertex $\mathbf{x}_i$.

Weighted Graph: A weighted graph is represented by $G = (V, E)$, where V is a set of vertices and E is a nonnegative and symmetric $|V|\times|V|$ matrix that characterizes the similarity between each pair of vertices.

Weighted Similarity Partition Algorithm (WSPA): Defines a consensus function for an ensemble of clusterings by mapping the problem onto a k-way partitioning problem. The algorithm utilizes the weighted features provided by LAC to define pairwise similarity measures between data points. It then constructs a weighted graph in which vertices correspond to data points and edges embed similarities between the corresponding pairs of points.

Temporal Event Sequence Rule Mining

Sherri K. Harms
University of Nebraska at Kearney, USA

INTRODUCTION

The emergence of remote sensing, scientific simulation and other survey technologies has dramatically enhanced our capabilities to collect temporal data. However, the explosive growth in data makes the management, analysis, and use of data both difficult and expensive. Methods that characterize interesting or unusual patterns from the volumes of temporal data are needed (Roddick & Spiliopoulou, 2002; Han & Kamber, 2005).

The association rule mining methods described in this chapter provide the ability to find periodic occurrences of inter-sequential factors of interest, from groups of long, non-transactional temporal event sequences. Association rule mining is well-known to work well for problems related to the recognition of frequent patterns of data (Han & Kamber, 2005). Rules are relatively easy for humans to interpret and have a long history of use in artificial intelligence for representing knowledge learned from data.

BACKGROUND

A time series database contains sequences of values typically measured at equal time intervals. There are two main categories of temporal sequences: *transaction-based sequences* and *event sequences*. A transaction-based sequence includes an identifier such as a customer ID, and data mining revolves around finding patterns within transactions that have matching identifiers. An example pattern is "A customer who bought Intel stock is likely to buy Google stock later." The transaction has a definite boundary around known items of interest. There are many techniques that address these problems (Han & Kamber, 2005).

Data analysis on event sequences is enormously more complex than transactional data analysis. Event sequences are often long streams of data where interesting patterns occur either within the sequence or across multiple sequences. There are no inherently defined boundaries (or identifiers) around factors that might be of interest. Temporal event sequence algorithms must be able to compute inference from volumes of data, find the interesting events involved, and define the boundaries around them. An example pattern is "A La Niña weather pattern is likely to precede drought in the western United States". La Niña weather data is based on Pacific Ocean surface temperatures and atmospheric values, and drought data is based on precipitation data from weather stations throughout the western United States. The sheer number of possible combinations of interesting factors and relationships between them can easily overwhelm human analytical abilities. Often there is a delay between the occurrence of an event and its influence on dependent variables. These factors make finding interesting patterns difficult.

Many different methods have been applied to temporal event sequences. In statistics, event sequence data is often called a marked point process. However, traditional methods for analyzing marked point processes are ill suited for problems with long, non-transactional sequences with numerous event types (Mannila et al. 1997). The association rule mining methods described in this chapter extract meaningful inter-sequential patterns in this type of data. Additionally, the mined rules provide much richer information than correlation coefficients from correlating entire sequences. The methods described in this chapter are similar to inductive logic programming, but with an emphasis on time-limited occurrences of sequential data. Similarities also exist to algorithms used in string matching and bioinformatics, but the classes of patterns differ (Mannila et al. 1997).

MAIN FOCUS

Mining association rules is typically decomposed into three sub-problems: 1) prepare the data for analysis, 2) find frequent patterns and 3) generate association rules from the sets representing those frequent patterns (Agrawal et al., 1993).

Preparing Event Sequences for Analysis

To prepare sequential data for association rule mining, the data is discretized and partitioned into sequences of events. Typically, the data is normalized and segmented into partitions that have similar characteristics within a given interval. Each partition identifier is called an event type. Different partitioning methods and interval sizes produce diverse discretized versions of the same dataset. Proper discretization relies on domain-expert involvement. When multivariate sequences are used, each is normalized and discretized independently.

Partitioning methods include symbolizing (Lin et al., 2003) and intervals (Hoppner, 2002). The assignment of values to a certain state is somewhat arbitrary near the decision boundaries. Mörchen & Ultsch (2005) presented a method for meaningful unsupervised discretization that reduces the vulnerability to outliers in the data and reduces the problems that occur when intervals are cut in high density regions of data values.

Mielikäinen et al. (2006) proposed a discretization technique that segments data by aggregating the results of several segmentation algorithms and choosing the discretization that agrees as much as possible with the underlying structure of the data.

Finding Frequent Episodes based on Sliding Window Technologies

A discretized version of the time series is referred to as an *event sequence*. An event sequence $\hat{S}$ is a finite, time-ordered sequence of events (Mannila et al., 1995). That is, $\hat{S} = (e_1, e_2, \ldots e_n)$. An event is an occurrence of an event type at a given timestamp. The time that a given event e_i occurs is denoted i, and $i \leq i+1$ for all i timestamps in the event sequence. A sequence includes events from a single finite set of event types. An event type can be repeated multiple times in a sequence. For example, the event sequence $\hat{S}_1 = AABCAB$ is a sequence of 6 events, from a set of 3 event types {A,B,C}. In this event sequence, an A event occurs at time 1, followed by another A event, followed by a B event, and so on. The step size between events is constant for a given sequence.

An *episode* in an event sequence is a combination of events with partially specified order (Mannila et al., 1997). It occurs in a sequence if there are occurrences of events in an order consistent with the given order, within a given time bound. Formally, an episode α is a pair *(V, ordering)*, where *V* is a collection of events and the ordering is *parallel* if no order is specified, and *serial* if the events of the episode have fixed order. The episode length is defined as the number of events in the episode.

Finding frequent episodes in sequences was first described by Mannila et al. (1995). Frequent episodes are discovered by using a sliding window approach, *WINEPI*. A *window* on an event sequence $\hat{S}$ is an event subsequence, $w = e_i, e_{i+1}, \ldots e_{i+d}$ where the width of window *w*, denoted *d*, is the time interval of interest. The set of all windows *w* on $\hat{S}$, with a width of *d* is denoted $\hat{W}(\hat{S},d)$. In this system, the value of the window width is user-specified, varying the closeness of event occurrences. To process data, the algorithm sequentially slides the window of width *d* one step at a time through the data. The *frequency* of an episode α is defined as the fraction of windows in which the episode occurs. For example, in the sequence $\hat{S}_1$ above, if a sliding window of width 3 is used, serial episode α = AB occurs in the first window (AAB), the second window (ABC), and the fourth window (CAB). The guiding principle of the algorithm lies in the "downward-closed" property of frequency, which means every subepisode is at least as frequent as its superepisode. Candidate episodes with *(k+1)* events are generated by joining frequent episodes that have *k* events in common, and episodes that do not meet a user-specified frequency threshold are pruned.

The closure principle was first applied to the event sequences by Harms et al. (2001) to use only a subset of frequent episodes, called frequent closed episodes. A closed sequential pattern is a sequential pattern which has no super-sequence with the same occurrence frequency. A frequent closed episode is the intersection of all frequent episodes containing it. For example, in the $\hat{S}1$ sequence, using a window width d = 3, and a minimum frequency of three windows, serial episode α = AB is a frequent closed episode since no larger frequent episode contains it, and it meets the minimum frequency threshold. Using closed episodes results in a reduced input size and in a faster generation of the episodal association rules, especially when events occur in clusters. Casas-Garriga (2005) added post-processing of closed sequences to generate classical partial orders, without dealing directly with input data.

Hoppner & Klawonn (2002) divided multivariate sequences into small segments and discretized them based on their qualitative descriptions (such as increas-

ing, high value, convexly decreasing, etc.). Patterns are discovered in the interval sequences based on Allen's (1983) temporal interval logic. For example, pattern "A meets B" occurs if interval A terminates at the same point in time at which B starts. For any pair of intervals there is a set of 13 possible relationships: after, before, meets, is-met-by, starts, is-started-by, finishes, is-finished-by, overlaps, is-overlapped-by, during, contains and equals. This approach also finds frequent patterns by using sliding windows and creating a set of candidate *(k+1)*-patterns from the set of frequent patterns of size *k*. Moerchen (2006) enhanced this line of research by presenting a hierarchical language for expressing concise patterns that represent the underlying temporal phenomena, using coincidence and partial orders. Winarko & Roddick (2007) also used Allen's temporal relations to discover interval-based relationships.

Ng & Fu (2003) mined frequent episodes using a tree-based approach for event sequences. The process is comprised of two phases: 1) tree construction and 2) mining frequent episodes. Each node in the tree is labeled by an event, and also contains a count and a node type bit. First, the frequencies of each event are gathered and sorted by descending frequencies. The tree is built similar to the FP-Growth method (Han et al., 2000) but uses sliding windows rather than transactions.

An approach that finds patterns related to a user-specified target event type is introduced in (Sun et al., 2003). Because a sliding window approach may exclude useful patterns that lie across a window boundary, this approach moves the window to the next event of interest. That is, a window always either starts from or ends with a target event. Interesting patterns are those that frequently occur together with the target event and are relatively infrequent in the absence of the target event.

Generating Rules based on Sliding Window Technologies

As introduced by Mannila et al. (1995), association rules are generated in a straightforward manner from the frequent episodes. An episodal association rule *r* is a rule of the form $X \Rightarrow Y$, where X is *antecedent* episode, Y is the *consequent* episode, and $X \cap Y = \varnothing$. For sliding window approaches used on a set of event sequences T, the *support* of rule $X \Rightarrow Y$ is the percentage of windows in T that contain $X \cup Y$. The rule holds in T with *confidence c* if *c%* of the windows in T that contain X also contain Y.

Harms et al. (2001) used *representative episodal association rules*, to reduce the number of rules while maintaining rules of interest to the user. A set of representative episodal association rules is a minimal set of rules from which all rules can be generated. Usually, the number of representative episodal association rules is much smaller than the total number of rules.

Other Event Sequence Rule Mining Technologies

MINEPI, an approach that uses minimal occurrence of episodes rather than a sliding window was developed by Mannila et al. (1997). A *minimal occurrence* of an episode α in an event sequence $\hat{S}$, is a window $w=[t_s, t_e]$, such that 1) α occurs in the window w, 2) α does not occur in any proper subwindow of w, and 3) the width of window w is less than the user-specified maximum window width parameter. In this definition, timestamp t_s records the starting time of the occurrence of the episode, and t_e records it's ending time, and $t_s \leq t_e$. The width of window w equals $t_e - t_s + 1$. The minimal occurrence window widths are not constant for a given episode, but are the minimal amount of elapsed time between the start of the episode occurrence and the end of the episode occurrence. The support of an episode α is the number of minimal occurrences of α in $\hat{S}$. An episode α is considered frequent if its support conforms to the given minimum support threshold.

Meger & Rigotti (2004) presented *WinMiner*, an algorithm based on *MINEPI*, which extracts episode rules satisfying frequency, confidence and maximum gap constraints. They also find the smallest window size that corresponds to a local maximum of confidence for the rule (i.e., confidence is locally lower, for smaller and larger windows).

Harms & Deogun (2004) introduced *MOWCATL*, which finds inter-sequential patterns, with respect to user-specified constraints. The method finds rules of the form $\alpha_{[wina]} \Rightarrow_{lag} \beta_{[winc]}$, where the antecedent episode α occurs within a given maximum antecedent window width win_a, the consequent episode β occurs within a given maximum consequent window width win_c, and the start of the consequent follows the start of the antecedent within a given time *lag*. The rule confidence is the conditional probability that β occurs, given that

α occurs, under the time constraints specified by the rule. The support of the rule is the number of times the rule holds in the dataset. The *MOWCATL* algorithm first stores the occurrences of the event types (single event episodes) that meet the user-specified inclusion constraints. Larger episodes are built from smaller episodes by joining episodes with overlapping minimal occurrences, which occur within the maximum window width. After finding the supported episodes for the antecedent and the consequent independently, they are combined to form episodal association rules, where the start of the consequent follows the start of the antecedent within a *lag* in time between the occurrences of the antecedent and the respective occurrences of the consequent.

Laxman et al. (2007) presented frequent episode discovery under the notion of non-overlapped occurrences of episodes within an event sequence. Two occurrences of an episode are said to be non-overlapped if no event corresponding to one occurrence appears between events corresponding to the other. The corresponding episode frequency is defined as the cardinality of the largest set of non-overlapped occurrences of the episode in the given event sequence.

Gwadera et al. (2005) presented an approach to detect suspicious subsequences with low false alarm rates that depends on the probabilistic characteristics of the event stream. The most likely number of occurrences of an episode is calculated, as well as the probability of deviating from it. From this, a threshold is derived and used to detect suspicious subsequences. With this approach, the probability of missing real unusual activities is small.

FUTURE TRENDS

Not only are the rules generated by the above techniques useful by themselves, they could be analyzed in more detail with other methods, such as marked point process, rule induction or classification trees to provide global models of the data (Mannila, et al., 1997).

Often, temporal sequences have a spatial component. For future work, the methods described here should be expanded to consider the spatial extent of the relationships. Additionally, the rule discovery process will need to spatially interpolate areas that do not have observed data.

Another problem with most temporal data is that it occurs in the form of data streams, which are potentially unbounded in size. Research issues in data stream mining are presented in Gabor et al. (2005) and Jiang & Gruenwald (2006). Materializing all data is unrealistic and expensive if it could be stored; techniques that retrieve approximate information are needed. Additionally, parallel and distributed algorithms will be needed to handle the volume of data.

CONCLUSION

Various techniques have been applied to the three association mining sub-problems used to find inter-sequential patterns within non-transactional event sequences. Partitioning and discretization methods prepare the data for analysis while closely matching the underlying structure of the data. Window-based methods with closure or temporal relations are used to find frequent patterns and generate rules. Alternative approaches use minimal occurrences to discover time-lagged relationships between multiple event sequences or use probabilistic characteristics of the event sequence to detect suspicious subsequences.

However, analysis techniques that capture the global model of the data and incorporate the spatial or streaming component of temporal event sequences are in their infancy. This research area is a rich and largely unexplored field.

KEY TERMS

Episode: A combination of events with a partially specified order. The episode ordering is *parallel* if no order is specified, and *serial* if the events of the episode have a fixed order.

Episodal Association Rule: A rule of the form $X \Rightarrow Y$, where X is antecedent episode, Y is the consequent episode and $X \cap Y = \varnothing$. The confidence of an episodal association rule is the conditional probability that the consequent episode occurs, given the antecedent episode occurs, under the time constraints specified. The support of the rule is the number of times it holds in the database.

Event: An occurrence of an event type at a given timestamp.

Event Sequence: A finite, time-ordered sequence of events. A sequence of events $\hat{S}$ includes events from a single finite set of event types.

Event Type: A discretized partition identifier that indicates a unique item of interest in the database. The domain of event types is a finite set of discrete values.

Minimal Occurrence: A minimal occurrence of an episode α in an event sequence $\hat{S}$, is a window $w=[t_s, t_e]$, such that 1) α occurs in the window w, 2) α does not occur in any proper subwindow of w, and 3) the width of window w is less than the user-specified maximum window width parameter. Timestamps t_s and t_e records the starting and ending time of the episode, respectively, and $t_s \leq t_e$.

Window: An event subsequence, e_i, e_{i+1}, …e_{i+d} in a event sequence, where the width of the window, denoted d, is the time interval of interest. In algorithms that use sliding windows, the frequency of an episode is defined as the fraction of windows in which the episode occurs.

Temporal Extension for a Conceptual Multidimensional Model

INTRODUCTION

Data warehouses integrate data from different source systems to support the decision process of users at different management levels. Data warehouses rely on a multidimensional view of data usually represented as relational tables with structures called *star* or *snowflake schemas*. These consist of *fact tables*, which link to other relations called *dimension tables*. A fact table represents the focus of analysis (e.g., analysis of sales) and typically includes attributes called *measures*. Measures are usually numeric values (e.g., quantity) used for performing quantitative evaluation of different aspects in an organization. Measures can be analyzed according to different analysis criteria or *dimensions* (e.g., store dimension). Dimensions may include *hierarchies* (e.g., month-year in the time dimension) for analyzing measures at different levels of detail. This analysis can be done using on-line analytical processing (OLAP) systems, which allow dynamic data manipulations and aggregations. For example, the roll-up operation transforms detailed measures into aggregated data (e.g., daily into monthly or yearly sales) while the drill-down operations does the contrary.

Multidimensional models include a time dimension indicating the timeframe for measures, e.g., 100 units of a product were sold in March 2007. However, the time dimension cannot be used to keep track of changes in other dimensions, e.g., when a product changes its ingredients. In many cases the changes of dimension data and the time when they have occurred are important for analysis purposes. Kimball and Ross (2002) proposed several implementation solutions for this problem in the context of relational databases, the so-called *slowly-changing dimensions.* Nevertheless, these solutions are not satisfactory since either they do not preserve the entire history of data or are difficult to implement. Further, they do not consider the research realized in the field of temporal databases.

Temporal databases are databases that support some aspects of time (Jensen & Snodgrass, 2000). This support is provided by means of different temporality types[1], to which we refer in the next section. However, even though temporal databases allow to represent and to manage time-varying information, they do not provide facilities for supporting decision-making process when aggregations of high volumes of historical data are required. Therefore, a new field called *temporal data warehouses* joins the research achievements of temporal databases and data warehouses in order to manage time-varying multidimensional data.

BACKGROUND

Temporal support in data warehouses is based on the different temporality types used in temporal databases. *Valid time* (VT) specifies the time when data is true in the modeled reality, e.g., the time when a specific salary was paid for an employee. Valid time is typically provided by users. *Transaction time* (TT) indicates the time when data is current in the database and may be retrieved. It is generated by the database management system (DBMS). Both temporality types, i.e., valid time and transaction time, can be combined defining *bitemporal time* (BT). Finally, changes in time defined for an object as a whole define the *lifespan* (LS) of an object, e.g., the time when an employee was working for a company.

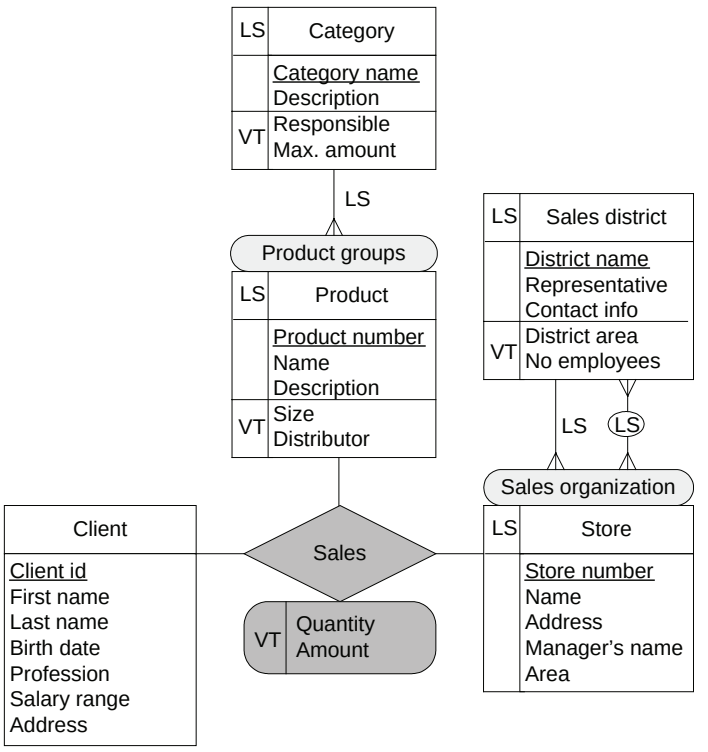
One characteristic of temporality types is their precision or *granularity*, indicating the duration of the time units that are relevant for an application. For example, the valid time associated to an employee's salary may be of granularity month. On the other hand, transaction time being system defined is typically of a millisecond granularity.

There is still lack of an analysis determining which temporal support is important for data warehouse ap-

plications. Most works consider valid time (e.g., Body, Miquel, Bédard, & Tchounikine, 2003; Wrembel & Bebel, 2007; Mendelzon & Vaisman, 2003). To our knowledge, no work includes lifespan support in temporal data warehouses. However, lifespan is important since it can help to discover, e.g., how the exclusion of some products influences sales. On the other hand, very few works relate to transaction time. For example, Martín and Abelló (2003) transform transaction time from source systems to represent valid time. This approach is semantically incorrect because data may be included in databases after their period of validity has expired. Further, transaction time coming from source system plays an important role in temporal data warehouses when traceability is required, e.g., for fraud detection. Other authors consider transaction time generated in temporal data warehouses in the same way as transaction time in temporal databases (e.g., Martín & Abelló, 2003; Mendelzon & Vaisman, 2003; Ravat & Teste, 2006). However, since data in temporal data warehouses is neither modified nor deleted, transaction time in a data warehouse represents the time when data was loaded into a data warehouse. Therefore, we propose to call it *loading time* (LT) (Malinowski & Zimányi, 2006a). LT can differ from transaction time or valid time of source systems due to the delay between the time when the changes have occurred in source systems and the time when these changes are integrated into a temporal data warehouse. Another approach (Brucker & Tjoa, 2002) considers valid time, transaction time, and loading time. However, they limit the usefulness of these temporality types for only active data warehouses, i.e., for data warehouses that include event-condition-action rules (or triggers).

The inclusion of temporal support raise many issues, such as efficient temporal aggregation of multidimensional data (Moon, Vega, & Immanuel, 2003), correct aggregation in presence of data and schema changes (Body *et al.*, 2003; Eder, Koncilia, & Morzy, 2002; Wrembel & Bebel, 2007; Mendelzon & Vaisman, 2003; Golfarelli, Lechtenbörger, Rizzi, & Vossen, 2006), or temporal view materialization from non-temporal sources (Yang & Widom, 1998). Even though the works related to schema and data changes define models for temporal data warehouses, what is still missing is a conceptual model that allows decision-making

Figure 1. An example of a multidimensional schema for a temporal data warehouse



users to represent data requirement for temporal data warehouses. This model should allow specifying multidimensional elements, i.e., dimensions, hierarchies, facts, and measures, and allow users to clearly indicate which elements they want to be time invariant and for which the changes in time should be kept.

MAIN FOCUS

In this section we present the MultiDim model, a conceptual multidimensional model (Malinowski & Zimányi, 2008a)[2] extended with temporal support (Malinowski & Zimányi, 2006a, 2006b). This model allows users and designers to represent at the conceptual level all elements required in temporal data warehouse applications.

Multidimensional Model for Temporal Data Warehouses

The MultiDim model supports different temporality types: lifespan (LS), valid time (VT), transaction time (TT), and bitemporal time (BT) coming from source systems (if available) and additionally, loading time (LT) generated in a data warehouse.

To describe our model we use the example shown in Figure 1. It includes a set of levels organized into dimensions and a fact relationship. A *level* corresponds to an entity type in the entity-relationship model and represents a set of instances called *members* that have common characteristics. For example, Product, Category, and Store are some of the levels in Figure 1. Levels contain one or several *key attributes* (underlined in Figure 1), identifying uniquely the members of a level, and may also have other *descriptive* attributes.

A *temporal level* is a level for which the application needs to keep the lifespan of its members (e.g., inserting or deleting a product). A *temporal attribute* is an attribute that keeps the changes in its value (e.g., changing a product's size) and the time when they occur. For example, the Product level in Figure 1 is a temporal level that includes temporal attributes Size and Distributor.

A *fact relationship* expresses the focus of analysis and represents an n-ary relationship between levels. For example, the Sales fact relationship between the Product, Store, and Client levels in Figure 1 is used for analyzing sales in different stores.

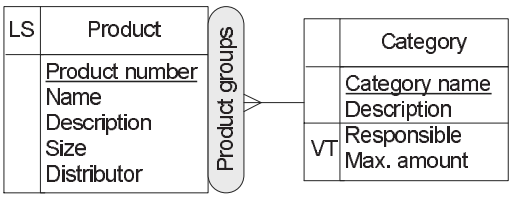
A fact relationship may contain attributes commonly called *measures*. They contain data (usually numerical) that are analyzed using the different dimensions. For example, the Sales fact relationship in Figure 1 includes the measures Quantity and Amount. In the MultiDim model measures are *temporal*, i.e., they always require a temporality type (VT, TT, BT, and/or LT).

A *dimension* allows to group data that shares a common semantic meaning within the domain being modeled, e.g., all data related to a product. It is composed of either a level or one or more hierarchies. For example, Client in Figure 1 is a one-level dimension.

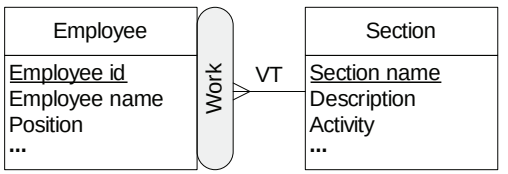
Hierarchies are required for allowing users to analyze data at different levels of detail. A hierarchy contains several related levels, e.g., Product and Category in Figure 1. Given two related levels of a hierarchy, one of them is called *child* and the other *parent* depending on whether they include more detailed or more general data, respectively. In Figure 1, the Product level is a child level while the Category level is a parent level. Key attributes of a parent level define how child members are grouped for the roll-up operation. For example, in Figure 2 since Category name is the key of the Category level, products will be grouped according to the category to which they belong.

The relationships composing the hierarchies are called *child-parent relationships*. These relationships are characterized by *cardinalities* that indicate the minimum and the maximum number of members in one level that can be related to a member in another level. Child-parent relationships may include temporal support. For example, in Figure 1 the LS symbol between Product and Category indicates that the evolution on time of assignments of products to categories will be kept. Temporal support for relationships leads to two interpretations of cardinalities. The *snapshot cardinality* is valid at every time instant whereas the *lifespan cardinality* is valid over the entire member's lifespan. The former cardinality is represented using the symbol indicating temporality type next to the link between levels while the lifespan cardinality includes the LS symbol surrounded by a circle. In Figure 1, the snapshot cardinality between Product and Category levels is many-to-one while the lifespan cardinality is many-to-many. They indicate that a product belongs to only one category at every time instant but belongs to many categories over its lifespan, i.e., its assignment to categories may change. The relationship between levels may include different temporality types: LS, TT, combination of both, and/or LT.

Figure 2. Examples of temporal hierarchies: a) non-temporal relationship between a temporal and a non-temporal levels, and b) temporal relationship between non-temporal levels



(a)



(b)

Since hierarchies in a dimension may express different conceptual structures used for analysis purposes, we use a *criterion name* to differentiate them, such as Product groups or Sales organization in Figure 1.

Modeling Temporal Aspects

Our model supports temporality in an orthogonal way, i.e., hierarchies may contain temporal or non-temporal levels associated with temporal or non-temporal links. Similarly, temporal or non-temporal levels may have temporal or non-temporal attributes. This approach differs from the one used in many temporal models. We consider that it is important to allow users to choose which elements should be temporal or not.

For example, Figure 2 (a) represents a hierarchy composed by a temporal level (Product) and a non-temporal level (Category) with a temporal attribute associated with a non-temporal link. Therefore, the lifespan of products as well as the changes of responsible and maximum amount of categories are kept; on the other hand, other attributes of the levels either do not change or only the last modification is kept. The example in Figure 2 (b) shows a hierarchy with two non-temporal levels associated with a temporal link. This keeps track of the evolution of relationships between employees and sections but we do not store the changes in levels, e.g., when an employee changes its position.

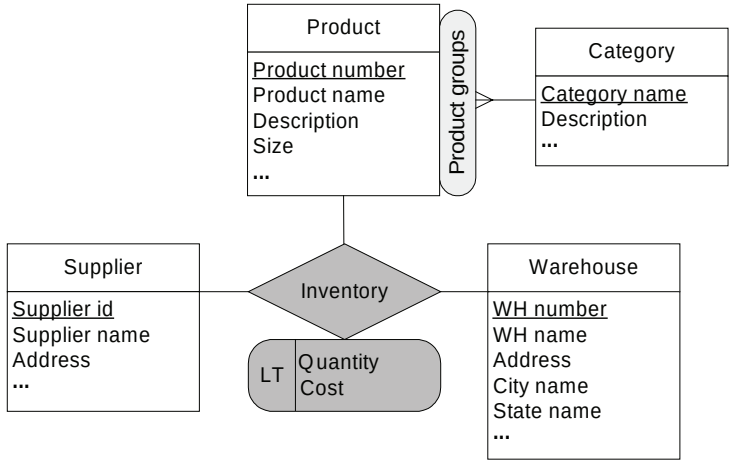
However, to ensure correct management of hierarchies in temporal data warehouses and avoid dangling references, i.e., references to non-existing elements, several constraints should be ensured (Malinowski & Zimányi, 2006a).

Another characteristic of our model is that it uses a consistent approach for providing temporal support for the different elements of a multi-dimensional model, i.e., for levels, hierarchies, and measures. Our model avoids mixing two different approaches where dimensions include explicit temporal support while measures require the presence of the traditional time dimension for keeping track of changes. Since measures are attributes of fact relationships, we provide temporal support for them in the same way as it is done for levels' attributes.

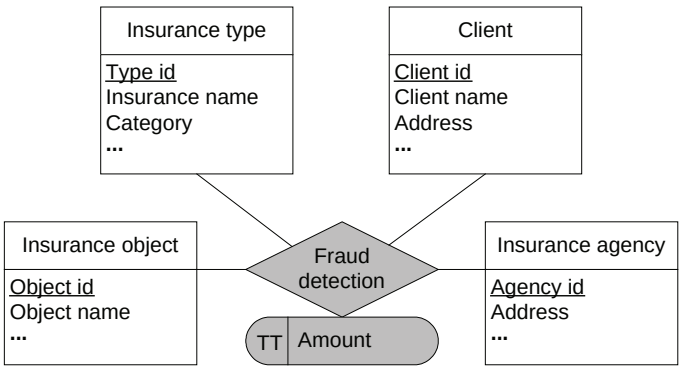
An important question is thus whether it is necessary to have a time dimension in the schema when including temporality types for measures. If all attributes of the time dimension can be obtained by applying time manipulation functions, such as the corresponding week, month, or quarter, this dimension is not required anymore. However, in some temporal data warehouse applications this calculation can be very time-consuming, or the time dimension contains data that cannot be derived, e.g., events such as promotional seasons. Thus, the time dimension is included in a schema depending on users' requirements and the capabilities provided by the underlying DBMS.

Another aspect is the inclusion of different temporality types for measures. The usual practice in temporal data warehouses is to associate valid time support with measures. However, different temporal support can be available in source systems. In Malinowski and Zimányi (2006b), we present several real-world scenarios that include different temporality types for measures enriching the analysis spectrum. The examples in Figure 3 show simplified schemas that include, respectively, loading time and transaction time for measures. The former is used when users require the history of how source data has evolved, but sources are either non-temporal or temporal support is implemented in an ad-hoc manner that can be both inefficient and difficult to automate (Yang & Widom, 1998). The schema in Figure 3 b) is used for an insurance company having as analysis focus the amount of insurance payments. Such a schema

Figure 3. Examples of schemas with a) LT and b) TT support for measures



(a)



(b)

could be used, e.g., to track internal frauds that modify the amount of insurance paid to clients, since the time when the measure values change is kept.

In Malinowski and Zimányi (2006b) we discuss several problems that may occur when data from source systems is aggregated before being loaded into temporal data warehouses. These include different time granularities between source systems and a data warehouse, measure aggregations with different time granularities, and temporal support for aggregated measures.

FUTURE TRENDS

An important issue in temporal data warehouses is the aggregation in the presence of changes in dimension data, schema, or both. Different solutions have already been proposed (e.g., Eder *et al.*, 2002; Mendelzon & Vaisman, 2003; Wrembel & Bebel, 2007; Body *et al.*, 2003). Nevertheless, these proposals require specific software and query languages for implementing and manipulating multidimensional data that vary over time. Further, they do not consider different aspects as mentioned in this paper, e.g., different temporal support in hierarchies and measures.

Another issue is the implementation of temporal data warehouses in current DBMSs, which do not yet provide temporal support. To our knowledge, there are very few proposals for implementing temporal data warehouses in current DBMSs (e.g., Martín & Abelló, 2003; Malinowski & Zimányi, 2006c; Ravat *et al.*, 1999; Mendelzon & Vaisman, 2003). However, only the latter authors provide manipulation features for the proposed structures.

CONCLUSION

Combining the two research areas of data warehouses and temporal databases, allows one to combine the achievements of each of them leading to the emerging field of temporal data warehouses. The latter raises several research issues, such as the inclusion of different temporal support, conceptual modeling, and measure aggregations, among others.

In this paper, we first proposed the inclusion of four different temporality types: three of them come from source systems (if they are available), i.e., valid time, transaction time (or combination of both), and lifespan. A new temporality type, called loading time, is generated in temporal data warehouses. It indicates when data was stored in a temporal data warehouse.

We also presented a conceptual model that is able to express users' requirements for time-varying multidimensional data. The MultiDim model allows temporal support for levels, attributes, relationships between levels forming a hierarchy, and measures. For temporal hierarchies and measures, we discussed different issues that are relevant to ensure the correct data management in temporal data warehouses.

The inclusion of temporality types in a conceptual model allows users, designers, and implementers to include temporal semantics as an integral part of temporal data warehouses. In this way, temporal extensions offer more symmetry to multidimensional models representing in a symmetric manner changes and the time when they occur for all elements of a data warehouse. Since conceptual models are platform independent, logical and physical models can be derived from such a conceptual representation.

KEY TERMS

Bitemporal: A combination of both transaction and valid time.

Conceptual Model: A model for representing schemas that are designed to be as close as possible to users' perception, not taking into account any implementation considerations.

Loading Time: A temporal specification that keeps the information when a data element is stored in a data warehouse.

Granularity: A partitioning of a domain in groups of elements where each group is perceived as an indivisible unit (a granule) at a particular abstraction level.

Lifespan: The record of the evolution of the membership of an instance into its type.

Multidimensional Model: A model for representing the information requirements of analytical applications. A multidimensional model comprises facts, measures, dimensions, and hierarchies.

Temporality Types: Different temporal support that can be provided by a system. They include transaction time, valid time, lifespan, and loading time.

Transaction Time: A temporal specification that keeps the information on when a data element is stored in and deleted from the database.

Valid Time: A temporal specification that keeps information on when a data element stored in the database is considered valid in the perceived reality from the application viewpoint.

ENDNOTES

1 They are usually called time dimensions; however, we use the term "dimension" in the multidimensional context.

2 We only include some elements of the MultiDim model in order to focus on its temporal extension.

Text Categorization

INTRODUCTION

Text categorization (TC) is a data mining technique for automatically classifying documents to one or more predefined categories. This paper will introduce the principles of TC, discuss common TC methods and steps, give an overview of the various types of TC systems, and discuss future trends.

TC systems begin with a group of known categories and a set of training documents already assigned to a category, usually by a human expert. Depending on the system, the documents may undergo a process called dimensionality reduction, which reduces the number of words or features that the classifier evaluates during the learning process. The system then analyzes the documents and "learns" which words or features of each document caused it to be classified into a particular category. This is known as supervised learning, because it is based on human knowledge of the categories and their criteria. The learning process results in a classifier which can apply the rules it learned during the training phase to additional documents.

PREPARING THE CLASSIFIER

Before classifiers can begin categorizing new documents, there are several steps required to prepare and train the classifier. First, categories must be established and decisions must be made about how documents are categorized. Second, a training set of documents must be selected. Finally and optionally, the training set often undergoes dimensionality reduction, either through basic techniques such as stemming or, in some cases, more advanced feature selection or extraction. Decisions made at each point in these preparatory steps can significantly affect classifier performance.

TC always begins with a fixed set of categories to which documents must be assigned. This distinguishes TC from text clustering, where categories are built on-the-fly in response to similarities among query results. Often, the categories are a broad range of subjects or topics, like those employed in some of the large text corpora used in TC research such as Reuters news stories, websites, and articles (for example, as the Reuters and Ohsumed corpora are used in Joachims [1998]). Classifiers can be designed to allow as many categories to be assigned to a given document as are deemed relevant, or they may be restricted to the top k most relevant categories. In some instances, TC applications have just one category, and the classifier learns to make yes/no decisions about whether documents should or should not be assigned to that category. This is called binary TC. Examples include authorship verification (Koppel & Schler, 2004) and detecting system misuse (Zhang & Shen, 2005).

The next step in preparing a classifier is to select a training set of documents which will be used to build the classification algorithm. In order to build a classifier, a TC system must be given a set of documents that are already classified into the desired categories. This training set needs to be robust and representative, consisting of a large variety of documents that fully represent the categories to be learned. TC systems also often require a test set, an additional group of pre-classified documents given to the classifier after the training set, used to test classifier performance against a human indexer. Training can occur all at once, in a batch process before the classifier begins categorizing new documents, or training can continue simultaneously with categorization; this is known as online training.

One final, optional step for TC systems is to reduce the number of terms in the index. The technique for doing so, known as dimensionality reduction, is taken from research in information retrieval and is applicable to many data mining tasks. Dimensionality reduction entails reducing the number of terms (i.e., dimensions in the vector space model of IR) in order

to make classifiers perform more efficiently. The goal of dimensionality reduction is to streamline types of classifiers such as naïve Bayes and kNN classifiers, which employ other information retrieval techniques such as document similarity. It can also address the problem of "noisy" training data, where similar terms (for example, forms of the same word with different suffixes) would otherwise be interpreted by the classifier as different words.

Standard techniques for reducing the number of index terms, such as stemming and removing stop words, can address some of these issues. However, more advanced forms of dimensionality reduction are required to more closely simulate the human ability to understand relationships between terms, such as phrases, synonymy, and the importance of particular terms. Berger et al.'s (2006) PARTfs classifier used decision trees, normally a method for building classifiers, as a tool for identifying the phrases that contribute strongly to classification decisions. Another, more advanced, technique is latent semantic indexing (LSI), a natural language processing technique that calculates the synonymy of terms based on their co-occurrence in similar documents in the document corpus. Theoretically, employing LSI creates a classifier that operates on concepts instead of terms; even if terms do not co-occur in a particular document, they can be perceived by the system as referring to the same idea. Cristianini et al. (2002) were the first to develop an SVM classifier that employed LSI. LSI is receiving a great deal of interest in other areas of IR (Dumais, 2004) and shows promise for improving TC in the future.

TYPES OF CLASSIFIERS

Several types of classifiers have been proposed in the literature on text categorization. There are five types of classifier that appear in the majority of the literature and exemplify most current TC scholarship. Those five types are: naïve Bayes, the Rocchio method, *k* nearest neighbor (kNN), decision trees, and support vector machines (SVM).

Naïve Bayesian classifiers (McCallum & Nigam, 1998) calculate the probability that a document belongs to a particular category based on the presence of the same index terms in other documents assigned to that category. For example, if most documents containing the terms "information" and "retrieval" belong to a category C, other documents containing those terms are likely to be categorized in C as well. Classifiers are referred to as "naïve" because they assume that the occurrence of each term is independent of any other term; in other words, they do not account for phrases unless additional feature selection techniques are applied. Overall, naïve Bayesian classifiers perform relatively weakly compared to other methods (Joachims, 1998; Yang & Liu, 1999).

Another common classifier is the Rocchio method, which uses training data to construct a profile of documents that fit a particular category. A Rocchio classifier consists of a list of positive terms and a list of negative terms for each category, and a document is categorized based on the presence and/or absence of these terms (Hull, 1994). For example, the classifier is trained to learn that positive terms for the category "finance" include "bank" and "money," and that "river" is a negative term. New documents containing the terms "bank" and "money" but not "river" will be categorized as "finance." The algorithm for calculating similarity can be adjusted to weigh positive or negative examples more strongly. If the weight for the negative examples is set to zero, the profile of the category can be thought of as the "centroid" of the training documents classified in that category—a cluster of points in the term space where all of the positive examples are positioned. A Rocchio-like classifier proposed by Han and Karypis (2000) was found to outperform a number of other classifiers, including Bayesian, in a single-label categorization task.

kNN classifiers (Yang, 1994) assign a document to one or more categories by finding the *k* most similar documents in the training set. They are sometimes called "lazy learners" because they do not learn the categories and their criteria during the training process, but at the time when a new document is to be categorized. New documents are compared to the other categorized documents within the system. The categories assigned to those documents are taken as candidate categories for the new document, and the similarity scores are the category weights. In an evaluation of five different types of text classifiers, Yang and Liu (1999) found that kNN was one of the top performers in terms of both recall and precision when tested on a corpus of news stories from Reuters, although they also found that performance was significantly improved when multiple categories should be assigned to a document.

Naïve Bayes, Rocchio, and kNN classifiers are all

based on the vector space model from information retrieval, where each term in the document is a factor in classification decisions. As a result, they are particularly susceptible to the dimensionality problem and are often slow and computationally expensive. A more efficient classifier would be able to select and consider only the features that are meaningful to the categorization of a particular document. These classifiers, which include decision tree classifiers and support vector machines, are less susceptible to the problems of high-dimensional term space.

Decision tree classifiers hierarchically organize documents along a tree, each leaf of which represents a category. The structure was proposed in TC by Lin et al (1994), who developed the TV (telescoping vector) tree model. TV trees identify the minimum number of features necessary to classify documents into a given set of categories and make these features nodes on a decision tree. Documents to be classified are compared to each node and divided hierarchically into the classes represented by the ends of each branch (Figure 1). When documents are added that require additional features to discriminate them, more nodes are added to the tree as needed. Because classification uses only the minimum possible number of features required for accuracy, TV trees mitigate the problem of high dimensionality of term space. However, one criticism of decision trees is that they are susceptible to overfitting, or developing classification rules that are specifically suited to the training documents but cannot be generalized to a full document corpus. Training of decision trees often requires an optimization or "pruning" step, in which overly specific branches are removed from the tree (Berger et al, 2006).

Currently, the most popular and commonly used classifiers are support vector machines (SVM) (Joachims, 1998). SVM classifiers find the best decision surface (a hyperplane) in term space between terms that contribute to a document being classified into a particular category and those that do not. Then they use only the terms nearest to that decision surface (called "support vectors") to decide whether a new document belongs to the category. Joachims (1998) compared SVM to four other types of classifier and found that SVM outperformed all four, with kNN being the second best performer. Since Joachims's introduction of SVM to text categorization, many other studies have treated SVMs as the benchmark for performance in the field and have focused on finding ways to enhance SVM. One problem with SVM, however, is that it is particularly susceptible to noisy training data (i.e., errors in the training data, such as those that result from human classification errors). Chen et al. (2005) claimed that this causes SVM not to perform well outside experimental settings and introduced a technique to filter out noise in the training data by identifying and eliminating outliers (positives that are not similar to other positives) before training the SVM. Zhang and Shen (2005) refined SVM to make it more applicable to environments where real-time training and classification are crucial. They used SVM adaptations intended to compensate for noisy training data and further modified the classifier using a technique called online SVM. Online SVM allows the classifier to be trained document by document instead

Figure 1. A simple decision tree

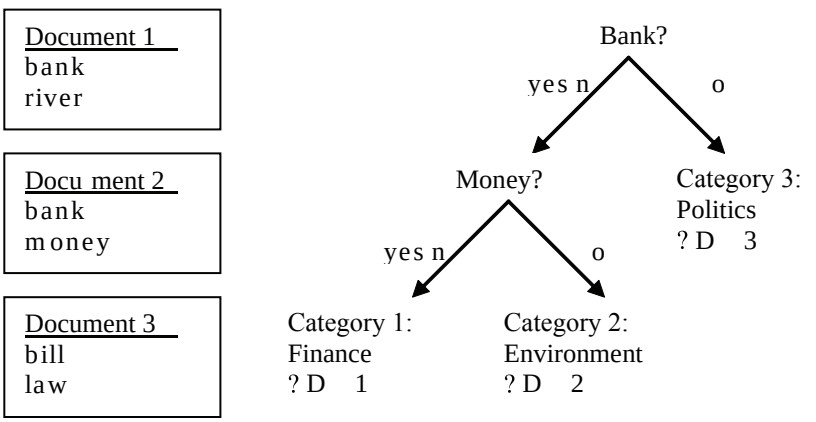

Table 1. Comparison of TC algorithms

Classifier	Method	Performance
Naïve Bayes	Calculates probability of a document belonging to a category based on the presence of the same words in other documents in that category.	Poor compared to other models.
Rocchio Method	Compares document to a list of positive and negative terms for each category and classifies according to presence or weight of those terms.	Poor, especially at classifying into categories with many representative terms.
k Nearest Neighbor	Finds *k* most similar documents and assigns document to the category(ies) those documents are assigned to.	Good, especially with multiple category assignments, but slow, because each document must be compared to all others.
Decision Tree	Separates documents hierarchically in a tree structure, where each node is a relevant term and the end of each branch is a category.	Good, but requires optimization to correct overfitting.
Support Vector Machines	Delineates between terms that do and do not contribute to a document being assigned to a particular category. Categorizes based on presence of the terms that contribute.	Currently the best method, although highly susceptible to errors in training data.

of in a batch, reducing the need for the classifier to be trained offline.

FUTURE TRENDS

With the explosive growth of unstructured data corpora on the Internet, we can expect a growing emphasis on developing new techniques that improve the accuracy and efficiency of TC. Since there is already a proliferation of classifier types that perform relatively well, research in the near future should focus on strategies to improve these techniques. On the practical side, we can also expect to see adaptations of TC methods to familiar systems such as search engines and document indexing systems.

Recent research suggests a trend toward making classifier performance more accurate, efficient, and dynamic through several techniques. As we have seen, high dimensionality is the main cause of many problems for some types of classifiers. Therefore, the most promising strategy for improving performance is to improve techniques for dimensionality reduction. Recent studies using distributional clustering (Al-Mubaid & Umair, 2006), latent semantic analysis (Ishii et al., 2006), and a feature extraction method called angular measures (Combarro et al., 2006) suggest that dimensionality reduction will continue to be a major research focus in the future.

Another significant strategy for improving classifier performance is to reduce the amount of supervised learning required to train a classifier. This procedure is sometimes called bootstrapping. Not only does bootstrapping make training faster, it also opens up more possibilities for the environments in which TC can be applied because it requires fewer manually classified examples from which the classifier can learn. Gliozzo et al. (2005) recently approached this problem by supplying the system with a few terms that exemplify each category instead of supplying a set of manually classified documents. Fung et al. (2006) have attempted to improve classifier performance on unlabeled training examples. Since the vast majority of text corpora contain very few, if any, manually labeled examples, reducing the amount of supervision required is a critical research area for the future of TC.

One final area for future TC research is to develop practical applications that employ TC methods in the types of environments where unstructured text data is currently found. These applications may include Web search engines, digital libraries, and corporate intranets among others. For several years, researchers have been working on search engines that can categorize search results; Chen et al.'s (2002) "personal view agent,"

which can learn which categories a user is interested in, is an early example of such an attempt. More recently, Kules et al. (2006) suggested a "lean" classifier that can use the metadata available in existing digital libraries such as the Open Directory Project to categorize search results. For interest in TC to be sustained, research must continue on practical applications to compete with other commercially available products that employ similar techniques, such as clustering.

CONCLUSION

Text categorization simulates human classification in a wide range of decision tasks, from subject classification to spam filtering. TC begins with a group of categories and a set of pre-classified documents from which a classifier learns to make categorization decisions for additional documents. The major types of classifiers include naïve Bayesian, Rocchio, *k* nearest neighbor, decision trees, and Support Vector Machines; of these, SVM classifiers show the most promise in terms of accurate and efficient performance. With the proliferation of promising TC algorithms, future research should focus on making these algorithms more efficient and accurate, reducing the amount of supervision required in training, and developing practical applications for use on existing corpora of unstructured text data.

KEY TERMS

Bootstrapping: Method for reducing the amount of training data required for a TC system by providing the classifier with a few examples from which to learn, instead of a full set of categorized documents.

Dimensionality Reduction: Data mining technique that reduces the number of features (words) in the term space, either through simple techniques such as stemming or by grouping words into phrases or concepts.

Latent Semantic Indexing: Dimensionality reduction technique that reduces dimensions to concepts rather than words by calculating the synonymy of terms based on their co-occurrence in similar documents in the document corpus.

Overfitting: Development of a classifier that is too specific to the training data; fixed by optimization or "pruning."

Text Clustering: Unsupervised learning technique in which a set of documents resulting from a query is categorized on the fly, based on internal similarities, as opposed to by a predefined set of categories as in text categorization.

Vector Space Model: Model for document representation in information retrieval, in which each term is considered a vector or weight in multidimensional term "space."

Text Mining by Pseudo-Natural Language Understanding

Ruqian Lu
Chinese Academy of Sciences, China

INTRODUCTION

Text mining by pseudo natural language understanding (TM by PNLU for short) is a technique developed by the AST group of Chinese Academy of Sciences, as part of the project automatic knowledge acquisition by PNLU, which introduces a partial parse technique to avoid the difficulty of full NLU. It consists of three parts: PNL design, PNL parser implementation and PNLU based automatic knowledge acquisition. Its essence is twofold: a trade-off between information gain and feasibility of parsing, and a rational work division between human and computer,

BACKGROUND

Experts in knowledge engineering have been agreeing on the basic point of view that the most challenging problem in the construction of knowledge based systems is how to acquire enough and high quality domain knowledge. People usually use natural language understanding techniques to acquire knowledge from technical literature. As it was shown by practice, natural language understanding has always been a very difficult problem.

Experiences have shown that many practical applications do not need a complete and perfect understanding of the natural language texts. By lowering down the requirement of NLP a bit and providing the computer with human help a bit we can let the computer process and understand "natural language" texts, including acquiring knowledge from it, massively, automatically and efficiently. This was the goal of developing the technique of TM by PNLU.

MAIN FOCUS

Definition of PNL

Let's use the notation PNL for pseudo natural language and PNLU for PNL understanding. The former denotes a class of languages, while the latter denotes a kind of technique for processing PNL. Generally speaking, PNL looks very similar to natural language, but can be understood, analyzed and compiled by computer to an extent by which it can meet the need of some application, for example compiling a text book in a knowledge base for expert consultation.

Design of a PNL

The process of designing a PNL is as follows:

1. Determine a set of semantic constructs of the application domain. For example, if the domain is mathematics, then the semantic constructs are case frames providing sentence semantics frequently used in mathematics textbooks, like concept definition, theorem proving, exercise presentation, etc.
2. Select a natural language, e.g. English, as background language;
3. Look for sentence patterns in this language, whose meaning corresponds to the semantic constructs selected in the first step. These sentence patterns may look like: **if * then * is called ***; **since * is true and * is not true we can infer from * that * is true**.
4. Organize the set of selected sentence patterns in grammar form and call it the key structure of the language, which is now called pseudo-natural. That means: not every combination of sentence patterns is a legal key structure. All parts marked with stars will be skipped by any PNL parser. We call these parts "don't care".

PNL Grammar

As an example, the following tiny grammar implies the key structure of a general classification statement:

⟨Classification Sentence⟩::=[⟨Leading word⟩<***Don't care***>,]⟨classification leading sentence⟩
⟨Leading word⟩::=**According to | Based on**
⟨classification leading sentence⟩::=⟨***Don't care***⟩⟨classification word⟩[⟨number⟩[**main**]⟨type word⟩[,⟨sequence of ***Don't care***⟩]] | There⟨be word⟩⟨number⟩[**main**]⟨type word⟩of⟨***Don't care***⟩. They are⟨sequence of ***Don't care***⟩.
⟨classification word⟩::=⟨be word⟩**classified into** | ⟨mood word⟩**be classified into**
⟨be word⟩⟩::= **is | are**
⟨type word⟩::= **classes | types | sorts | kinds** ……

This grammar may recognize sentences like: *Blood cells* **are classified into two types,** *red blood cells*, *white blood cells***.**

Parsing a PNL Text

While parsing a PNL text, the computer tries to understand the text, based (and only based) on the semantics of the underlying key structure. This understanding is necessary superficial in the sense that no information other than that implied by the key structure will be gained by the computer. It abstracts away all unnecessary details regarding the current application and thus makes the language understanding much easier. For example: consider the sentence:

If the color of the blood cell is red **than** the blood cell **is called** erythrocyte.

This is a (shallow) definition of red blood cell. But here we can already see the abstraction principle of PNL. With this knowledge, a computer can answer questions like "what is erythrocyte?," "How do we call a blood cell when the color of the blood cell is red?" etc. even without knowing the meaning of "red" or "cell."

Mechanism of TM by PNLU

The mechanism of TM by PNLU can be roughly described as follows:

1. Design a PNL;
2. Implement a compiler, which can parse PNL texts, acquiring knowledge from it and organizing it in a domain knowledge base;
3. Each time when knowledge is to be acquired, use an OCR device to scan the documents into the computer. Modify the scanned texts slightly to turn them in their PNL form;
4. Let the computer parse and analyze the PNL texts and produce a knowledge base (, which may need to be integrated with an existing knowledge base).

A series of PNL in different domains have been developed for automatic knowledge acquisition and system prototyping, including BKDL for expert systems, EBKDL and SELD for ICAI systems, DODL/ BIDL for Management Information Systems and KUML/WKPL for knowware engineering.

Layers of PNL

For the same application domain, one can divide the key structure of a PNL in several layers. There are three basic layers: the core layer, which contains sentence patterns used in all domains; the domain layer, which contains technical expressions used in a particular domain; and the jargon layer, which contains professional expressions used by a particular group of users. Each time when one designs a new PNL, the core layer, which occupies the major part of the key structure, does not have to be modified. Only part of the domain layer should be renewed. The jargon layer is usually very small and does not play an important role. Of course it is also possible to define intermediate layers between the basic layers.

Spectrum of PNL

It is easy to see that if we enlarge the key structure of PNL, then the computer will acquire more detailed knowledge from a PNL text. For example, if we add the sentence pattern "**color of * is ***" to the key structure, then the computer may additionally know that color is an attribute, which can be used to describe physical objects. On the other hand, if we reduce the key structure, then the knowledge acquired by the computer will have a larger granule. In this way, PNL defined with different key structure form a spectrum, which is a partial order. The upper limit of this spectrum is the natural

language, while the lower limit is the formal language consisting of meaningless strings of symbols.

Degree of Pseudo-Naturality

It is interesting to consider the quantitative characterization of this PNL spectrum. We assign to each PNL a degree of pseudo naturality (DPN for short). In this way the PNL spectrum is reduced from a partial order to a total order. There are different ways of defining this degree. One possibility is to define the DPN of each PNL text as the ratio of the number of keywords contained in it to the number of all words in this text. The DPN of the PNL is then the statistically averaged value of DPN of texts written in this PNL. Since it is impossible to count all such texts, an empirical calculation based on a limited set of selected representative texts can be performed to obtain an estimate. Another possibility of defining DPN is to calculate the ratio of cumulative length of keywords to the length of the text itself instead of calculating the ratio of word numbers. According to this definition, the DPN of a natural language is one, whereas the DPN of a formal language is zero. The larger the DPN of a PNL is, the more difficult is its parsing, and the more information we will obtain from parsing its sentences. We estimate the DPN of BKDL between 10% and 15%.

FUTURE TRENDS

In the 2003 special issue of JACM, when looking into the future of computer science research, at least three authors proposed the topic of letting computer read massive texts and acquire knowledge from them. It is to expect that the TM by PNLU technique will be helpful in completing this job.

Future research includes applying PNLU to NL directly; defining rigorous semantics for PNL and a through study on PNL spectrum.

CONCLUSION

A comparison of PNLU vs. NLU technique is given in Table 1.

The first use of TM by PNLU technique is in the work about CONBES and BKDL (1990-1991). The first PNL was BKDL (Book Knowledge Description Language) published in (Lu, R., Cao, C., 1990), which 'incorporates a built-in natural language frame, which makes its programs look very much like Chinese texts while keeping the semantic unambiguity'. In (Lu, R., 1994), another PNL, called BIDL and used in PROMIS system, was defined as "natural-like language". The first appearance of the term "pseudo-natural language" was in (Lu, R., 1994.6). There is only little literature mentioning the term PNL. Among them the two recent examples are Metalog (2004) and ORM-ML (2002). From which the former is used to enrich a markup language, while the latter is used in some query logic. Thus their techniques and results achieved are different from the first 10 references cited after the end of this chapter.

TM by PNLU is a promising technique. However, improvement of this technique is needed for many potential new applications. Web text mining is one of the examples.

Table 1. PNL/PNLU vs. NL/NLU

	Language Generating Structure	This Structure covers	Parsing Procedure works on	Knowledge acquired by TM	Granule of acquired Knowledge	Relation to each other
NL/NLU Technique	A NL grammar	All Sentences of the NL	Every Sentence of a text	Data, Term, Concept, Relation	Usually small	NL is limit of PNL Spectrum
PNL/PNLU Technique	A PNL Key Structure	A subset of the NL	Only key Structure of the text	Theory, Domain Knowledge	Usually large	Each PNL is an approximation of NL

KEY TERMS

Degree of Pseudo Naturality (DPN): A measure to reduce the partial order of PNL spectrum to a linear order that may be based on either of the two formulae:

$$DPN1 = \frac{Number(Key-Words-\dot{n}-Text)}{Number(Words-\dot{n}-Text)}$$

$$DPN2 = \frac{Length(Key-Words-\dot{n}-Text)}{Length(Text)}$$

Layers of PNL: Set of subsumpting PNL ordered according to their generality of application. It is often possible to define semantics of higher layer PNL key structure by using that of lower layers.

Key Structure: The grammatical form of legal keyword combination in a PNL.

Pseudo Natural Language (PNL): Subset of a natural language with a predefined key structure.

Pseudo Natural Language Understanding (PNLU): Parsing of a PNL by only analyzing the syntax, semantics and pragmatics of key structure contained in it.

Spectrum of PNL: Partial ordering of all PNL according to subsumption of their key structures.

Text Mining by PNLU (TM by PNLU): Using PNLU techniques to acquire knowledge from written documents automatically.

INTRODUCTION

Nowadays, business executives understand that timely and accurate knowledge has become crucial factor for making better and faster business decisions and providing in this way companies a competitive advantage. Especially, with the vast majority of corporate information stored as text in various databases, the need to efficiently extract actionable knowledge from these assets is growing rapidly. Existing approaches are incapable of handling the constantly increasing volumes of textual data and only a small percentage can be effectively analyzed.

Business Intelligence (BI) provides a broad set of techniques, tools and technologies that facilitate management of business knowledge, performance, and strategy through automated analytics or human-computer interaction. It unlocks the "hidden" knowledge of the data and enables companies to gain insight into better customers, markets, and business information by combing through vast quantities of data quickly, thoroughly and with sharp analytical precision.

A critical component that impacts business performance relates to the evaluation of competition. Measurement and assessment of technological and scientific innovation and the production of relative indicators can provide a clear view about progress. Information related to those activities is usually stored to large databases and can be distinguished in: research information stored in publications or scientific magazines and development-production information stored in patents.

Patents are closely related to *Technology Watch*, the activity of surveying the development of new technologies, of new products, of tendencies of technology as well as measuring their impact on actual technologies, organizations or people. Statistical exploitation of patent data may lead to useful conclusions about technological development, trends or innovation (Chappelier et al., 2002).

Traditional methods of extracting knowledge from patent databases are based on manual analysis carried out by experts. Nowadays, these methods are impractical as patent databases grow exponentially. *Text Mining (TM)* therefore corresponds to the extension of the more traditional Data Mining approach to unstructured textual data and is primarily concerned with the extraction of information implicitly contained in collections of documents. The use of automatic analysis techniques allows us to valorize in a more efficient way the potential wealth of information that the textual databases represent (Hotho et al., 2005).

This article describes a methodological approach and an implemented system that combines efficient TM techniques and tools. The BI platform enables users to access, query, analyze, and report the patents. Moreover, future trends and challenges are illustrated and some new research that we are pursuing to enhance the approach are discussed.

BACKGROUND

Patents are closely related to technological and scientific activities (Narin, 1995). They give an indication of the structure and evolution of innovative activities in countries, regions or industries. In this framework, patents are linked to Research and Development (R&D) and can be considered as indicators of R&D activities (Schmoch et al. 1998).

A patent is a legal title granting its holder the exclusive right to make use of an invention for a limited area and time by stopping others from, amongst other things, making, using or selling it without authorization (EPO, 2006). The patent applicant has to provide a detailed technical description of its invention but also mention the points that render it an original application with innovative elements.

A patent can be decomposed and described by several fields (table 1). Each field contains specific information while each patent is described by a code (or in many cases more than one codes) depicting its technical characteristics. These codes are given to patents based on the International Patents Classification system (IPC) or other classification systems. We should also mention that patent documents can be either retrieved from on-line patent databases, or patent databases available on CD-ROMs.

Tools from various vendors provide the user with a query and analysis front-end to the patent data. Some of these tools perform only simple analysis and produce tables, charts or reports e.g. PatentLab II (http://www.wisdomain.com/download.htm), BizInt Smart Charts for Patents 3.0 (http://www.bizcharts.com/patents/index.html), MapOut Pro (http://www.mapout.se/ MapOut.html), etc. Other tools demonstrate enhanced capabilities by using advanced TM techniques e.g. Management and Analysis of Patent Information Text or MAPIT (http://www.mnis.com/mpt.html), VantagePoint (http://www.thevantagepoint.com), Aureka (http://www.micropat.com/static/aureka.htm), Technology Opportunities Analysis or TOA (http://www.tpac.gatech.edu/toa.php), etc.

Table 1. Patent fields in the ESPACE ACCESS database

PN	Priority Number (number of the patent).
AN	Application Number.
PR	Priority Year.
DS	Designated States.
MC	Main Classification Codes.
IC	All Classification.
ET	English Title.
FT	French Title.
IN	Inventor.
PA	Applicant (name of the company depositor).
AB	English Abstract.
AF	French Abstract.

A BUSINESS INTELLIGENCE PLATFORM FOR PATENT MINING

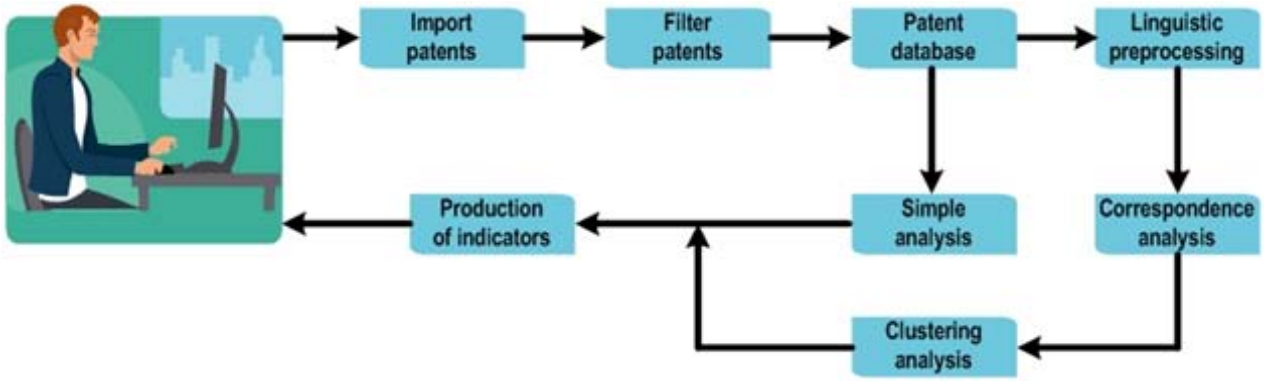
Research and development investment in knowledge discovery and management technologies has made significant progress. However, there still exists a need for an approach that combines efficient and innovative tools for the analysis of patent data, which will guide users (e.g. R&D planners, business analysts, patents analysts, national and international patent offices, economic organizations, national statistical offices, venture capitalists, industrial bodies, etc.) to extract only necessary information and exploit it in an informative way in order to draw useful conclusions.

Our platform was designed to fill this need by quickly analyzing large collections of patents, utilizing multiple algorithms and visualizations, and producing indicators concerning the scientific and technological progress (Markellos et al., 2003). These indicators provide a global understanding of the patent collection and help users to make conclusions about on-going changes and their effects. The methodological approach is depicted in figure 1.

Patents Preparation

The system enables data importing through an easy-to-use dialog box. After downloading a data file in .txt format from MIMOSA search engine a new project to work with can be created. In this step, to reduce the patents representation for efficiency of computation and scalability purposes, while maintaining the maximum of information, several techniques are used. We browse the patent records, read their contents, modify

Figure 1. Methodological approach.



their fields or filter the data in order to prepare the appropriate patents set.

Moreover, we add, delete or modify the patents fields in order to correct the data (by removing html tags or punctuation characters), change the way they appear or eliminate data inconsistencies. For example, a frequent data inconsistency appears in the Assignee (Inventor or Applicant) field where the same company is recorded with one or more different names (i.e. "ABC Co., Ltd" and "ABC Company Limited" is regarded as two different assignees, although they are identical). We should correct any data inconsistencies prior to the analysis task in order to get accurate results. The results of this phase are automatically saved to an internal representation form suitable for further analysis. Moreover, we are able to export the system database in other well known formats e.g. .xls, .doc, .pdf, etc.

User-defined Linguistic Process

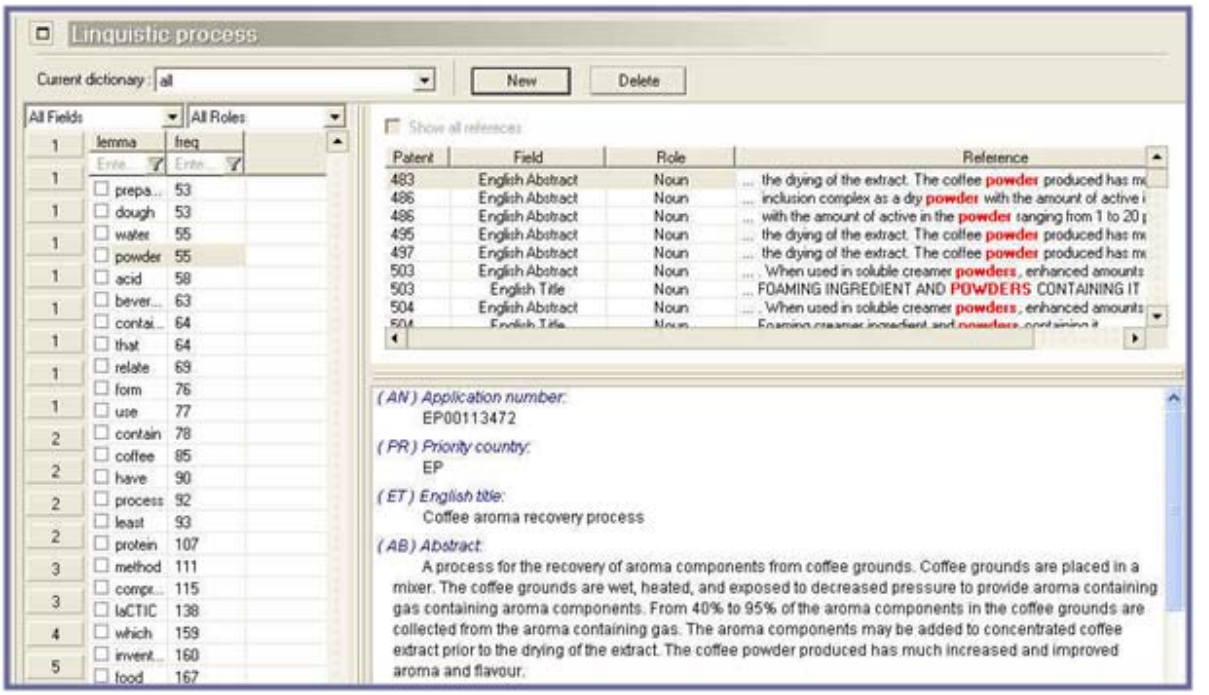
The main aim of the linguistic process (Beaugrande & Dressler, 1981) is to identify the words from specific fields (abstract and title) of each patent, filter out insignificant words (i.e. words like "this", "the") and determine a lexicon of lemmas to support the latter analysis. A parser is used for reading the textual data and restricting the morphologic variation of each word to its unique canonical representation-lemma. We further reduce the vocabulary size, by selecting the word categories, as identified by the assigned parts-of-speech, and restrict the analysis to specific word categories. We can use a number of different dictionaries in the process. Either we select a predefined dictionary or define a new one. We determine the parse fields (title, abstract or both) and specify the word categories to be kept (nouns, verbs, symbols or any combination of them).

In addition, we use stop-lists to eliminate words bearing no content and exclude them from the analysis, such as frequent used words. We utilize synonym lists to collapse semantically similar words and stem variants to their base form. We identify semantically important terms that must remain and involve in the analysis. Moreover, we explore the list of lemmas and the corresponding frequencies by referring back to the original patent data. We can see the list of references for every lemma. A list is automatically created with the number of the patents where the lemma appears, the exact field (English Abstract or English Title), the syntactic category of the lemma (Noun, Verb, etc.) and the reference sentence where the lemma is marked in red color. We export the list of lemmas and the corresponding frequencies in Excel format. Finally, we visualize all the existing words both in order of frequency or in alphabetical order.

Simple Analysis

Simple Analysis based on the original data and more specifically in the supplementary variables involved in the analysis. Therefore, it is applied in a data set that does not need linguistic pre-processing. This procedure gives us the ability to use simple statistical measures for quantifying information stored in patents and representing it in various graphs and tables.

Figure 2. Linguistic processing.



Correspondence Analysis

Correspondence Analysis (Benzecri, 1992) is the first step in order to perform Cluster Analysis on patent data. Previously we should perform linguistic pre-processing. The input data is the contingency table where the rows contain the lemmas, the columns represent the patents, and each cell gives the frequency of the specific word in the corresponding patent. This analysis enables us to explore the non-random dependencies between the variables involved in it and the vocabulary obtained from the title and abstracts of the patents. More precisely, the correspondence analysis produces a new vector space in which similarities between the rows and the columns of the input contingency table (as measured by the x^2-distance) can be visualized as geometric proximities.

- **Words selection.** We can create the contingency table by applying specific criteria and preferences. From the lemmas list, the preferred frequencies (i.e. maximum or minimum) can be selected. The following statistic metric is also available: the frequency of the selected lemmas in normal or logarithmic scale. Moreover, we can change the graphical appearance of the metric.
- **Contingency table.** We can explore the contingency table of the lemmas (rows) involved in the analysis and the corresponding patents (columns). Non-zero frequencies are highlighted, so we can easily focus in those cells.
- **Number of dimensions.** We can define the number of dimensions to be kept as a result of the *Factor Analysis* performed, through an interactive process. In each row the following information is available: 1) the Eigen value for each dimension, 2) the percentage of information, 3) the cumulative percentage of information expressed for the selected dimensions. The cumulative percentage of the information is also graphically visualized through horizontal bars.

Cluster Analysis

Cluster Analysis (Huang, 2006) is the basis for technology indicators derivation and the classification of the technology on-goings in homogeneous classes. It follows linguistic pre-processing of patents and Correspondence Analysis applied to the lemmatized

data. The aim is to identify groups of patents that share common vocabulary and technologies in order to produce conclusions about technological trends and innovation.

The selection of the clustering algorithm based on the number of data and can be either “Hierarchical Clustering” or “k-means Clustering”. In the second case, “Hierarchical Clustering” is performed in the k clusters obtained from the “k-means”. In both cases Cluster Analysis is performed in the factorial axes derived from the Correspondence Analysis. Through the Cluster Analysis the patents are grouped into clus-

27	0.531356	1.465471	49.065377	1.465

ters that share similar characteristics and thus describe similar technologies.

- **Number of clusters – cut-off value.** From the produced dendrogram, by moving the horizontal weighted blue bar up and down we can determine the number of clusters to be kept. The placement of the line on a specific level expresses the cut-off value, i.e. the number of the remaining clusters and visualizes the iterative process of hierarchical clustering. Otherwise we can define the maximum number of clusters by clicking on the value we wish to keep from a predefined series of values. When we cannot compute the optimal cut-off value from the produced dendrogram, the system automatically computes the optimal number of clusters to be kept.
- **Relationship maps.** The clustering results are represented into a map that visualizes the relations between clusters (i.e. technological sectors). Every cluster is a bubble, while its size indicates the volume of patents inside the cluster. By double-clicking a bubble, the list of patents that belong to it appears. We can move the bubbles of the map by left-clicking and dragging them anywhere in the screen and thus explore the relationship between the clusters. Furthermore, the width of the lines connecting the bubbles expresses the relationship (similarity) among clusters.

Indicators

Advanced visualization techniques allow the indicators to be explored from many different perspectives. These views can have many forms including bar graphs, plots, trees, spreadsheets, and summary reports.

A first indicator is the one that gives the number of patents that correspond to each area of technology. This permits to identify the maturity of a specific area of technology, as well as innovations. According to our interests, we can obtain either the top areas of technology or the less active technologies based on the number of patents.

Another indicator relates to the level of continents, countries or designated states. The number of patents taken in a given country, broken down by country of the patentee (the inventor or the applicant) or by priority country (first country where the invention is filed

Figure 6. Interactive selection of number of clusters

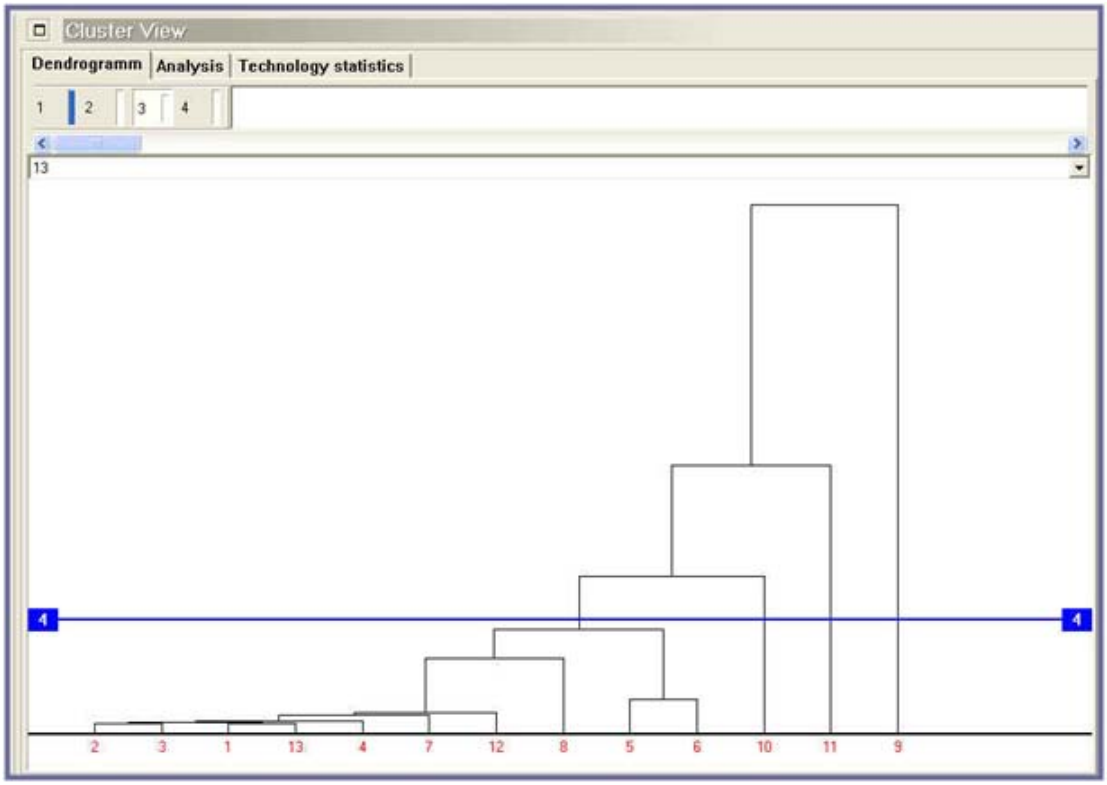

Figure 7. Relationship map of clusters

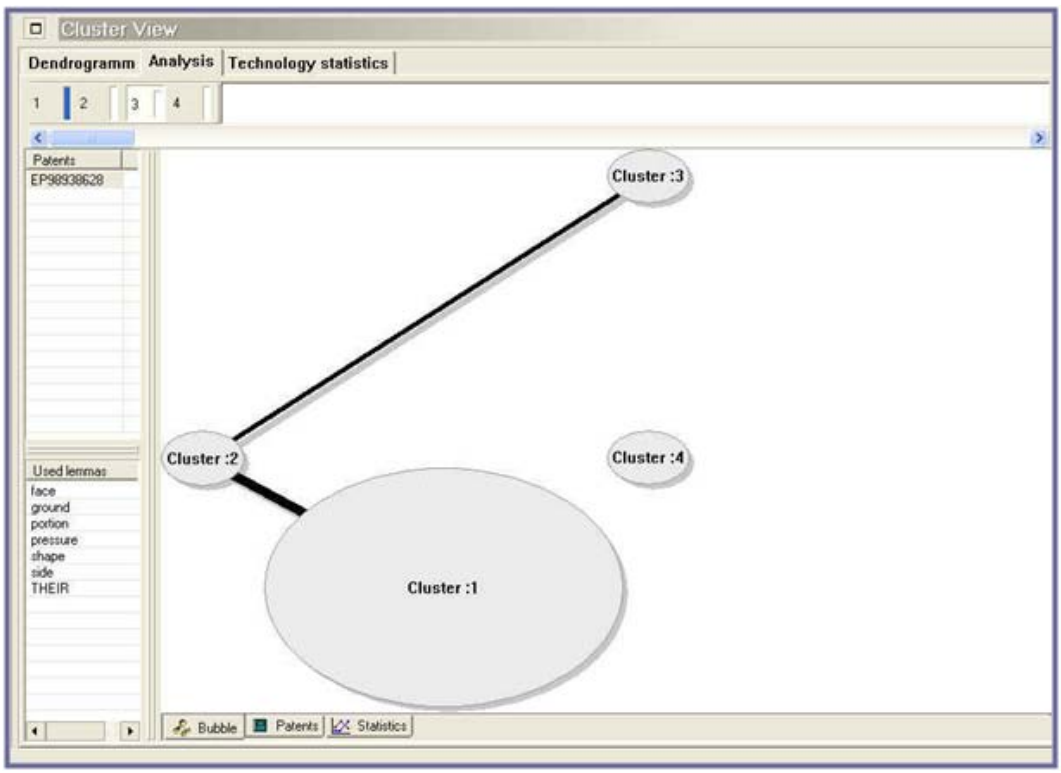


before protection is extended to other countries) can reveal to what extent do countries share their technological output (i.e. protection for smaller inventions is searched on the local market only). In addition, another indicator is this that gives the top areas of technology of each continent or the less active areas of technology for each continent.

The field of assignees can also be used for producing different kind of indicators in order to catch points of interest. Firstly, the top assignees as well as the less active are of great importance in order to identify the leaders in specific areas of technology. We should have in mind that those who apply a patent vary from individuals to companies public or private, universities, etc. Therefore we should be able to define all these categories that will form the basis for different analyses.

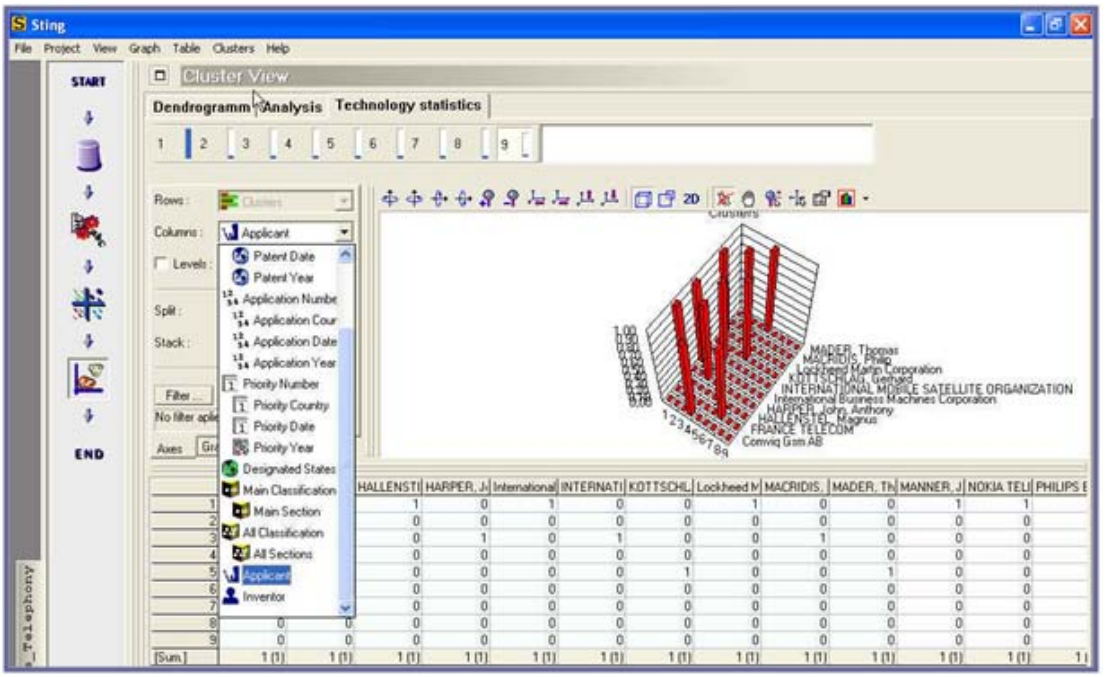
Taking into account the indicators mentioned above, we could derive statistical measures based on the number or percentages of patents for each technology area, as well as for the designated states or inventors. The evolution over time is another feature that helps tracing the technology on-goings and monitoring the novelty of an invention.

FUTURE TRENDS

The previous sections discuss our methodology for patent mining and the tool we have built to experiment with it. Currently, we are exploring the way Semantic Web Mining techniques can be integrated into the model. Especially, ontologies appear as a promising technology since they provide a level of semantics that we do not currently address, allowing improved taxonomies and reasoning about the data and text. The semantic analysis of patents will help in the creation of their richer representation and in the capture of their "hidden" relations and associations. Moreover, it can play significant role in the stage of knowledge discovery so that it can leads to better results. Although these techniques require important calculating time, the investigation of the way that they could be more efficient and scalable particularly for big sets of patents it comprise an important research challenge.

Another area of future research that we believe is promising relates to the problem of multilingualism. The adopted TM techniques were applied in the English texts of patents. It constitutes important question that it requires more study the implementation of algorithms that will process multilingual texts and will produce intermediary forms that do not depend on the language.

Figure 8. Key players in the area of "Mobile Telephony"



The application of mining analysis on these forms will allow the access of new knowledge and will open new possibilities of their exploitation.

Current systems and tools that apply TM techniques address specialized users and experts. Future applications would be useful to incorporate a higher degree of usability so that they concern more users e.g. automatic translation of natural language questions that will execute the suitable operations of mining. Also these tools could have the form of intelligent personal agents which will learn the profile of each user and based on this will execute the TM operations automatically without being necessary the explicit requirement from the user. Besides, the provision of personalized experiences has gained substantial momentum with the rise of Web.

Finally, special interest would present the application of the proposed methodological approach in different types of semi-structured or unstructured data such as documents or web pages. Particularly, its application in Web data e.g. in the problem of web site content classification or the forecast which pages will have the bigger demand we believe that it will lead to useful conclusions.

CONCLUSION

In this article we show that patent data can provide valuable insights for improving the quality of business decisions. The proposed methodological approach analyzes patents based on multidimensional techniques. In this way it facilitates the capture of knowledge not only in the level of a technological sector but also in the level of country or a set of sectors allowing the easy comparison of results and leading to the production of indicators for technological trends. The innovative features of the approach are related mainly to the use and the combination of statistical techniques that allows the more effective analysis of patents.

Firstly, the data used by the tool take into consideration all the information that describes a patent. Compared to the existing approaches (as EUROSTAT), that exploit only the first digits of IPC codes and consequently lose certain information, our tool analyses are based on the exploitation of all fields. At the same time, the use of texts that describes a patent as the title and the abstract allows a more completed description of its technical characteristics. The use of other fields such as countries, businesses, years, etc. helps considerably in the implementation of different types of analyses and in the depiction of information via different ways.

The approach has the possibility to analyze the scientific and technological innovations and the progress in Europe in three different levels. Initially the analysis can be executed in the level of sector. This means that a specific sector can be isolated so that it is analyzed and is determined consequently its technological evolution, which is not obvious. We use for the analysis the code IPC and/or the text that describes the patent so that we create homogeneous clusters from which they can be determined technological tendencies and be drawn useful conclusions. The variables that are not included in the main part of analysis e.g. the businesses that submit the patents, the inventors, the countries in which were submitted the patents, etc. enrich further the result of clustering and they are used as additional variables in the analysis. The same analysis can be executed in the level of all sectors. This allows us to take information on the scientific and technological activity per selected sector with regard to the total of enterprises that submit patents in this particular sector, for a specific year or for few years. Moreover, the analysis in the level of country is available. Through this, homogeneous clusters of countries can be created that present the progress the scientific and technological evolution in the different countries of Europe.

Finally, the innovative feature from the point of used statistical methods is not related so much to the methods themselves but to their combination for the patents' analysis. The incorporation of TM techniques on the processing patents content (titles and abstracts) is one of the most important characteristics of the methodology. The idea is that the vocabulary that is characteristic for the patents categories based on various descriptive variables that are linked with them (as the country or the date of application), it provides additional interesting ideas for the analysis of patents. Competitive indicators with regard to competitive level of each country can be exported, as well as countries that are active in the particular technological region, etc. The combination of correspondence and cluster analysis provides a powerful tool for the efficient exploitation of patents. The production of technology indicators is the most important feature of the proposed methodology.

KEY TERMS

Business Intelligence (BI): BI is the process of gathering high-quality and meaningful information about the subject being researched to answer questions and identify significant trends or patterns, giving key stakeholders the ability to draw conclusions and make strategic and long-term business decisions.

Cluster Analysis: The process of grouping objects into clusters so that objects are similar to one another within a cluster but dissimilar to objects in other clusters.

Correspondence Analysis: A multivariate method for exploring cross-classified data by finding low dimensional geometrical representations and related numerical statistics. It can reveal features in the data without assuming any underlying distributions of the data.

Linguistic Preprocessing: The process of restricting the morphologic variation of the textual data by reducing each of the different inflections of a given word form to a unique canonical representation (or lemma). It requires a disambiguation, involving a morpho-syntactic analysis and some times a pragmatic analysis.

Patent Databases: Databases that include information about patents and can be distinguished to online ones e.g. WPI(L), EPAT, US, CLAIMS, etc. and those that offered in CD-ROM e.g. ESPACE ACCESS, ESPACE-FIRST, ESPACE BULLETIN, etc.

Patent Mining: The process of searching for meaningful trends, patterns, and relationships among patent records contained in patent databases.

Technology Watch: The activity of surveying the development of new technologies, of new products, of tendencies of technology, as well as measuring their impact on actual technologies, organizations or people. Technology Watch is closely related to innovation.

Text Mining (TM): TM constitutes an extension of traditional Data Mining and concerns the extraction of new, previously unknown and useful information from large volumes of text (semi-structured or unstructured).

Text Mining Methods for Hierarchical Document Indexing

Han-Joon Kim
The University of Seoul, Korea

INTRODUCTION

We have recently seen a tremendous growth in the volume of online text documents from networked resources such as the Internet, digital libraries, and company-wide intranets. One of the most common and successful methods of organizing such huge amounts of documents is to hierarchically categorize documents according to topic (Agrawal, Bayardo & Srikant, 2000; Kim & Lee, 2003). The documents indexed according to a hierarchical structure (termed 'topic hierarchy' or 'taxonomy') are kept in internal categories as well as in leaf categories, in the sense that documents at a lower category have increasing specificity. Through the use of a topic hierarchy, users can quickly navigate to any portion of a document collection without being overwhelmed by a large document space. As is evident from the popularity of web directories such as Yahoo (http://www.yahoo.com/) and Open Directory Project (http://www.dmoz.org/), topic hierarchies have increased in importance as a tool for organizing or browsing a large volume of electronic text documents.

Currently, the topic hierarchies maintained by most information systems are manually constructed and maintained by human editors. The topic hierarchy should be continuously subdivided to cope with the high rate of increase in the number of electronic documents. For example, the topic hierarchy of the Open Directory Project has now reached about 590,000 categories. However, manually maintaining the hierarchical structure incurs several problems. First, such a manual task is prohibitively costly as well as time-consuming. Until now, large search portals such as Yahoo have invested significant time and money into maintaining their taxonomy, but obviously they will not be able to keep up with the pace of growth and change in electronic documents through such manual activity. Moreover, for a dynamic networked resource (e.g., World Wide Web) that contains highly heterogeneous documents accompanied by frequent content changes, maintaining a 'good' hierarchy is fraught with difficulty, and oftentimes is beyond the human experts' capabilities. Lastly, since human editors' categorization decision is not only highly subjective but their subjectivity is also variable over time, it is difficult to maintain a reliable and consistent hierarchical structure. The above limitations require information systems that can provide intelligent organization capabilities with topic hierarchies. Related commercial systems include Verity Knowledge Organizer (http://www.verity.com/), Inktomi Directory Engine (http://www.inktomi.com/), and Inxight Categorizer (http://www.inxight.com/), which enable a browsable web directory to be automatically built. However, these systems did not address the (semi-)automatic evolving capabilities of organizational schemes and classification models at all. This is one of the reasons why the commercial taxonomy-based services do not tend to be as popular as their manually constructed counterparts, such as Yahoo.

BACKGROUND

In future systems, it will be necessary for users to be able to easily manipulate the hierarchical structure and the placement of documents within it (Aggarwal, Gates & Yu, 1999; Agrawal, Bayardo & Srikant, 2000). In this regard, this section presents three critical requirements for intelligent taxonomy construction, and taxonomy construction process using text-mining techniques.

Requirements for Intelligent Taxonomy Construction

1. **Automated classification of text documents:** In order to organize a huge number of documents, it is essential to automatically assign incoming documents to an appropriate location on a predefined taxonomy. Recent approaches towards automated classification have used a supervised

machine-learning paradigm to inductively build a classification model of pre-defined categories from a training set of labeled (pre-classified) data. Basically, such machine-learning based classification requires sufficiently large number of labeled training examples to build an accurate classification model. Assigning class labels to unlabeled documents should be performed by human labeler, and the task is a highly time-consuming and expensive. In fact, it is not easy to obtain a large number of good quality labeled documents in real world operational environments. Thus one of important issues is to develop a reasonable classification model only with insufficient training examples. We must assume that rather than trying to prepare a perfect set of training examples at first, new training documents are continuously provided for learning as a data stream; this means that continuous (on-line) update of the current classification model is required whenever a new set of training examples are prepared.

2. **Semiautomatic management of evolving taxonomy:** The taxonomy initially constructed should change and adapt as its document collection continuously grows or users' needs change. When concept drift happens in particular categories, or when the established criterion for classification alters with time as the content of the document collection changes, it should be possible for part of taxonomy to be reorganized; the system is expected to recommend users a number of feasible sub-taxonomies for the reorganized part.
3. **Making use of domain (or human) knowledge in cluster analysis for topic discovery:** In order to refine the taxonomy, it is necessary to discover new topics (or categories) that can precisely describe the currently indexed document collection. In general, topic discovery is achieved by clustering techniques since clusters that are distinct groups of similar documents can be regarded as representing topically coherent topics in the collection. Clustering for topic discovery is a challenging problem with sufficient domain knowledge. This is because taxonomy should reflect the preferences of an individual user or specific requirements of an application. However, clustering is inherently an unsupervised learning process without depending on external knowledge. Therefore, a new type of supervised clustering is required that reflects external knowledge provided by users.

Taxonomy Construction Process using Text-Mining Techniques

Table 1 illustrates a procedure for hierarchically organizing text documents. The system begins with an initial topic hierarchy in which each document is assigned to its appropriate categories by automatic document classifiers. The topic hierarchy is then made to evolve so as to reflect the current contents and usage of indexed documents. The classification process repeats based on the more refined hierarchy.

Table 1: Procedure for hierarchically organizing text documents

Step 1. Initial construction of taxonomy
i. Define an initial (seed) taxonomy
Step 2. Category (Re-) Learning
i. Collect a set of the controlled training data fit for the defined (or refined) taxonomy
ii. Generate (or Update) the current classification model so as to enable a classification task for newly generated categories
iii. Periodically, update the current classification model so as to constantly guarantee high degree of classification accuracy while refining the training data
Step 3. Automatic Classification
i. Retrieve documents of interest from various sources
ii. Assign each of the unknown documents into more than one categories with its maximal membership value according to the established model
Step 4. Evolution of taxonomy
i. If concept drift or a change in the viewpoint occurs within a sub-taxonomy, reorganize the specified sub-taxonomy
ii. If a new concept sprouts in the unclassified area, perform the cluster analysis for the data within the unclassified area into new categories
Step 5. Sub-taxonomy Construction and Integration
i. Integrate the refined sub-taxonomy or new categories into the main taxonomy
Step 6. Go to Step 2

In Table 1, steps 2 and 3 are related to machine-learning based text classification, step 4 semisupervised clustering for topic discovery, and step 5 taxonomy building.

MAIN THRUST OF THE CHAPTER

This section discusses a series of text mining algorithms that can effectively support the taxonomy construction process. Recent text mining algorithms are prompted by machine learning paradigm; in particular, so are classification and clustering algorithms. Another important issue is about feature selection algorithms because textual data includes a huge number of features such as words or phrases. A feature selection module in the system extracts plain text from each of the retrieved documents and automatically determines only more significant features to speed up the learning process and to improve the classification (or clustering) accuracy. However, this chapter does not present the feature selection algorithms because their related issues are not significantly dependent upon the system.

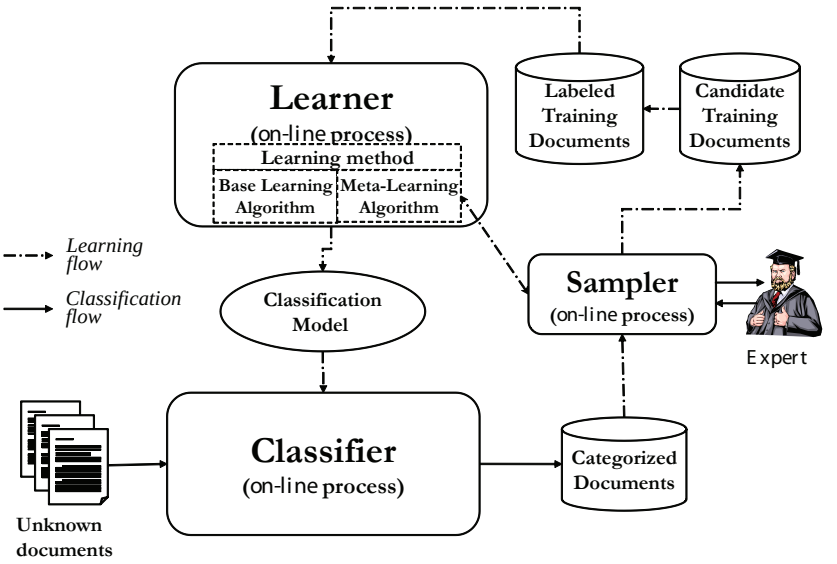
Operational Automated Classification: Combination of Metalearning and On-line Learning

As mentioned before, machine-learning based classification methods require a large number of good quality data for training. However, this requirement is not easily satisfied in real-world operational environments. Recently, many studies on text classification focus on the effective selection of good quality training data that accurately reflect a concept in a given category, rather than algorithm design. How to compose training data has become a very important issue in developing operational classification systems. Recent promising approaches include a combination of 'active learning' and 'semisupervised learning' (Kim & Chang, 2003; Muslea, Minton & Knoblock, 2002) and a combination of 'active learning' and 'boosting' (Kim & Kim, 2004; Liu, Yin, Dong & Ghafoor, 2005)

Firstly, the active learning approach is that the learning module actively chooses the training data from a pool of unlabeled data for humans to give their appropriate class label (Argamon-Engelson & Dagan, 1999). Among different types of active learning, the selective sampling method has been frequently used for learning with text data. It examines a pool of unlabeled data and selects only the most informative ones through a particular measure such as the uncertainty of classification accuracy. Secondly, the semisupervised learning is a variant of supervised learning algorithm in which classifiers can be more precisely learned by augmenting a few labeled training data with many unlabeled data (Demiriz & Bennett, 2000). For semisupervised learning, EM (Expectation-Maximization) algorithm can be used that is an iterative method for finding maximum likelihood in problems with unlabeled data (Dempster, Laird & Rubin, 1977). To develop operational text classifiers, the EM algorithm has been evaluated to be a practical and excellent solution to the problem of lack of training examples in developing classification systems (Nigam, McCallum, Thrun, & Mitchell, 2000). Lastly, boosting is an ensemble learning technique that improves the classification accuracy of supervised learning algorithms by combining a series of base (or weak) classifiers to produce a single powerful classifier (Freund & Schapire, 1996). The Boosting algorithm can significantly improve 'decision tree' learning algorithm (Friedman, Hastie & Tibshirani, 2000) and the 'Naïve Bayes' learning algorithm (Kim HJ, Kim JU & Ra, 2005) with the same amount of training data. Here, the active learning (or selective sampling), EM, and boosting algorithms are included in 'metalearning' algorithms that employ a specific machine learning algorithm (such as Naïve Bayes) as its component.

Figure 1 shows a text classification system architecture, which supports a metalearning process to improve the performance of a text classifier. The system consists of three modules: *Learner*, *Classifier*, and *Sampler*; in contrast, conventional systems do not include the *Sampler* module. The *Learner* module creates a classification model (or function) by examining and analyzing the contents of training documents. The base learning algorithms for text classification can include the Naïve Bayes (Mitchell, 1997b) and Support Vector Machine (Joachims, 2001), and the metalearning algorithms EM and Boosting algorithms. The Naïve Bayes algorithm has been improved by incorporating selective sampling into EM or Boosting algorithm (Kim & Chang, 2003; Kim HJ, Kim JU & Ra, 2005). By using a special measure called 'classification uncertainty' proposed in (Kim & Chang, 2003), new training documents can be automatically selected in the *Sampler* module while interacting with EM or Boosting learning process.

Figure 1: Architecture of an operational classification system



The *Classifier* module uses the classification model built by the *Learner* to determine the categories of each of unknown documents. In the conventional systems, the *Learner* runs only once as an off-line process, but it is desirable to update the current model continuously as an 'on-line' process. To achieve the on-line learning, Naïve Bayes is a good selection. This is because the algorithm can incrementally update the classification model only by adding additional feature estimates to currently learned model instead of re-building the model completely (Yang & Liu, 1999). The learning algorithm has been successfully used for textual data with high dimensional feature space (Agrawal, Bayardo & Srikant, 2000). Moreover, the Naïve Bayes is straightforwardly applied to the EM algorithm due to its probabilistic learning framework (Nigam, McCallum, Thrun, & Mitchell, 2000). Lastly, the *Sampler* module isolates a subset of candidate examples (e.g., through uncertainty-based selective sampling proposed in (Kim & Chang, 2003)) from currently classified data, and returns them to a human expert for class labeling.

The metalearning algorithms assume that a stream of unlabeled documents is provided from some external sources. Practically, rather than acquiring the extra unlabeled data, it is more desirable to use the entire set of data indexed on the current populated taxonomy as a pool of unlabeled documents. As you see in Figure 1, the classified documents are fed into the *Sampler* to augment the current training documents, and then they are used by the *Learner* as a pool of the unlabeled documents for metalearning process. Consequently, in the context of the *Learner* module, not only can we easily obtain the unlabeled data used for metalearning process without extra effort, but also some of the mistakenly classified data are correctly classified.

Semisupervised (User-constrained) Clustering for Topic Discovery

Most clustering algorithms do not allow introducing external knowledge to the clustering process. However, to discover new categories for taxonomy reorganization, it is essential to incorporate external knowledge into cluster analysis. Such a clustering algorithm is called 'semisupervised clustering', which is very helpful in the situation where we should continuously discover new categories from incoming documents. A few strategies for incorporating external human knowledge into cluster analysis have already been proposed in (Talavera & Bejar, 1999; Xing, Ng, Jordan & Russell, 2003). One possible strategy is to vary the distance metrics by weighting dependencies between different components (or features) of feature vectors with the quadratic form distance for similarity scoring. That is, the distance between two document vectors $\mathbf{d}_x$ and $\mathbf{d}_y$ is given by:

$$dist_{\mathbf{W}}(\mathbf{d}_x, \mathbf{d}_y) = \sqrt{(\mathbf{d}_x - \mathbf{d}_y)^{\mathrm{T}} \cdot \mathbf{W} \cdot (\mathbf{d}_x - \mathbf{d}_y)} \qquad (1)$$

where each document is represented as a vector of the form $\mathbf{d}_x = (d_{x1}, d_{x2}, \ldots, d_{xn})$, where n is the total number of index features in the system and $d_{xi} (1 \le i \le n)$ denotes the weighted frequency that feature t_i occurs in document $\mathbf{d}_x$, T denotes the transpose of vectors, and $\mathbf{W}$ is an $n \times n$ symmetrical weight matrix whose entry w_{ij} denotes the interrelationship between the components t_i and t_j of the vectors. Each entry w_{ij} in $\mathbf{W}$ reveals how closely features t_i is associated with feature t_j. If the clustering algorithm uses this type of distance functions, then the clusters reflecting users' viewpoints will be identified more precisely.

To represent user knowledge for topic discovery, one can introduce one or more groups of relevant (or irrelevant) examples to the clustering system, depending on the user's judgment of the selected examples from a given document collection (Kim & Lee, 2002). Each of these document groups is referred to as a 'document bundle', which is divided into two types of bundles: positive and negative ones. Documents within positive bundles (i.e., documents judged jointly 'relevant' by users) must be placed in the same cluster while documents within negative bundles (i.e., documents judged 'irrelevant' by users) must be located in different clusters. Then, when document bundles are given, the clustering process induces the distance metric parameters to satisfy the given bundle constraints. The problem is how to find the weights that best fit the human knowledge represented as document bundles. The distance metric must be adjusted by minimizing the distance between documents within positive bundles that belong to the same cluster while maximizing the distance between documents within negative bundles. This dual optimization problem can be solved using the following objective function $Q(\mathbf{W})$: (see equation (2)).

The above formula is a function of weight matrix $\mathbf{W}$ since the distance value depends on the weight matrix. In the above formula, document bundle set B^+ (or B^-) is defined to be a collection of positive (or negative) bundles, and $\langle \mathbf{d}_x, \mathbf{d}_y \rangle \in R_B+$ or $\langle \mathbf{d}_x, \mathbf{d}_y \rangle \in R_B-$ denotes that a pair of documents $\mathbf{d}_x$ and $\mathbf{d}_y$ is found in positive bundles or negative bundles, respectively. Each pair within the bundles is processed as a training example for learning the weighted distance measure, and we should find a weight matrix that minimizes the objective function. The reasons why the real distance value is squashed by θ is that the sum of the distance values of documents within R_{B^-} during the learning process can dominate the total sum of the distance values of documents within $R_{B^+} \cup R_{B^-}$. A squashing function θ is used that converges to $k/2$ and its steepness is determined by σ. To search for an optimal matrix, we can use a gradient descent search method that is used for tuning weights among neurons in artificial neural networks (Mitchell, 1997a).

Each entry w_{ij} in the weight matrix is iteratively updated according to the following training rule:

$$w_{ij} \leftarrow w_{ij} + \Delta w_{ij} = w_{ij} + \left(-\eta \cdot \frac{\partial Q}{\partial w_{ij}} \right) \qquad (3)$$

Equation (2).

$$Q(\mathbf{W}) = \sum_{(\mathbf{d}_x, \mathbf{d}_y) \in R_{B^+} \cup R_{B^-}} I(\mathbf{d}_x, \mathbf{d}_y) \cdot \theta\left(dist_{\mathbf{W}}(\mathbf{d}_x, \mathbf{d}_y)\right)$$

$$I(\mathbf{d}_x, \mathbf{d}_y) = \begin{cases} +1 \ if < \mathbf{d}_x, \mathbf{d}_y > \in R_{B^+} \\ -1 \ if < \mathbf{d}_x, \mathbf{d}_y > \in R_{B^-} \end{cases}$$

$$\theta(z) = \frac{k}{1 + e^{\frac{\sigma}{z}}}$$

where

$$R_{B^+} = \left\{ \left\langle \mathbf{d}_x, \mathbf{d}_y \right\rangle | \, \mathbf{d}_x \in B^+ \ and \ \mathbf{d}_y \in B^+ \ for \ any \ positive \ bundle \ set \ B^+ \right\}$$

$$R_{B^-} = \left\{ \left\langle \mathbf{d}_x, \mathbf{d}_y \right\rangle | \, \mathbf{d}_x \in B^- \ and \ \mathbf{d}_y \in B^- \ for \ any \ negative \ bundle \ set \ B^- \right\}$$

$$\frac{\partial Q}{\partial w_{ij}} = \sum_{\langle \mathbf{d}_x, \mathbf{d}_y \rangle \in R_{B^+} \cup R_{B^-}} I(\mathbf{d}_x, \mathbf{d}_y) \cdot \frac{k\sigma e^{\frac{\sigma}{z}} (d_{xi} - d_{yi})(d_{xj} - d_{yj})}{2z^3 (1 + e^{\frac{\sigma}{z}})^2} \quad (4)$$

where $z - dist_w(\mathbf{d}_x, \mathbf{d}_y)$, η is a positive constant called the 'learning rate', which controls the amount of weight adjustment at each step of training.

When concept drift or a change in a user's viewpoint occurs within a particular area of taxonomy, the user should prepare a set of document bundles as external knowledge reflecting the concept drift or the change in viewpoint. Then, based on the prepared user constraint, the clustering process discovers categories resolving the concept drift or reflecting changes in user's viewpoint, and then the isolated categories are incorporated into the main taxonomy.

Automatic Taxonomy Construction

For building hierarchical relationships among categories, we need to note that a category is represented by topical terms reflecting its concept (Sanderson & Croft, 1999). This suggests that the relations between categories can be determined by describing the relations between their significant terms. In this regard, we find that it is difficult to dichotomize the relations between categories into groups representing the presence or absence of association, because term associations are generally represented not as crisp relations, but as probabilistic equations. Thus, degrees of association between two categories can be represented by membership grade in a fuzzy (binary) relation. That is, the generality and specificity of categories can be expressed by aggregating the relations among their terms. In (Kim & Lee, 2003), a hierarchical relationship between two categories is represented by membership grade in a fuzzy (binary) relation. The fuzzy relation $CSR(c_i, c_j)$ (which represents the relational concept "c_i *subsumes* c_j"), called 'category subsumption relation' (*CSR*), between two categories c_i and c_j is defined as follows:

$$\mu_{CSR}(c_i, c_j) = \frac{\sum_{t_i \in V_{c_i}, t_j \in V_{c_j}, \Pr(t_i|t_j) > \Pr(t_j|t_i)} \tau_{c_i}(t_i) \times \tau_{c_j}(t_j) \times \Pr(t_i \mid t_j)}{\sum_{t_i \in V_{c_i}, t_j \in V_{c_j}} \tau_{c_i}(t_i) \times \tau_{c_j}(t_j)} \quad (5)$$

where $\tau_c(t)$ denotes the degree to which the term t represents the concept corresponding to the category c, which can be estimated by calculating the χ^2 statistic value of term t in category c since the χ^2 value represents the degree of term importance (Yang & Pedersen, 1997). $\Pr(t_i|t_j)$ should be weighted by the degree of significance of the terms t_i and t_j in their categories, and thus the membership function $\mu_{CSR}(\cdot)$ for categories is calculated as the weighted average of the values of $\Pr(t_i|t_j)$ for terms. The function value of $\mu_{CSR}(\cdot)$ is represented by a real number in the closed interval [0,1], and indicates the strength of the relationship present between two categories. By using the above fuzzy relation, we can build a sub-taxonomy of categories discovered by cluster analysis. A procedure for building a topic hierarchy is the following:

- **Step 1:** Calculate the *CSR* matrix with entries representing the degree of membership in a fuzzy relation *CSR* for a given set of categories (see Eq. (5)).
- **Step 2:** Generate the α-cut matrix of the *CSR* matrix (denoted by CSR_α) by determining an appropriate value of α.
- **Step 3:** Create a hierarchy of the partitioned categories from the CSR_α matrix representing partial ordering.

FUTURE TRENDS

In applying text-mining techniques to hierarchically organizing large textual data, a number of issues remain to be explored in the future. A practical issue in machine-learning based text classification is how to continuously update the current classification model with insufficient training data while achieving its high accuracy. A good approach to this issue is to use metalearning algorithms such as EM and Boosting. Additionally, an important issue related to topic discovery is how to seamlessly reflect human knowledge to text mining algorithms. Recent studies show that the semisupervised clustering technique that employs document bundle constraint can effectively enhance the cluster quality. As an example, for semisupervised clustering, (Kim & Lee, 2002) attempted to generate external human knowledge of bundle constraints through user-relevance feedback. And (Basu, Bilenko, & Mooney, 2004) proposed a probabilistic framework for semisupervised clustering. In other different aspects, the problem will continue to be intensively tackled.

In terms of automatic taxonomy construction, semantically richer information needs to be automatically built beyond the subsumption hierarchy information of categories; for example, relevance relationship among categories needs to be extracted for cross-referencing of categories. Another challenging issue is that for extracting more precise document context, it is necessary to utilize structural and contextual features (e.g., tree-like structures and diverse tag information of XML documents) of the original textual data, if any, as well as the simple features of 'a bag of words'. In fact, such feature engineering is more profitable and effective than algorithm design, particularly in building commercial applications.

On a practical level, an open challenge is automatic taxonomy engineering for manually constructed topic hierarchies such as Yahoo directory (http://www.yahoo.com/), ODP directory (http://www.dmoz.org/) and UNSPSC classification system (http://www.unspsc.org/). Since these topic hierarchies are popular and huge in size, they are expected to be good exemplars to evaluate practical value of text-mining techniques for taxonomy building.

CONCLUSION

Towards intelligent taxonomy engineering for large textual data, text-mining techniques are of great importance. In this chapter, for developing operational classification systems, a employment of metalearning algorithms such as selective sampling, EM, and boosting algorithms has been introduced together with the classification system architecture that has the on-line learning framework. In terms of category discovery, a simple representation, called document bundles, of human knowledge has been discussed as a way of incorporating human knowledge into cluster analysis for semisupervised clustering. As for taxonomy building, the simple fuzzy-relation based algorithm is described without any complicated linguistic analysis.

The current research on building hierarchical structure automatically is still in an early stage. Basically, current techniques consider only subsumption hierarchy, but future studies should try to extract other useful semantics of discovered categories. More importantly, how to incorporate human knowledge into text-mining algorithm should be further studied with user interaction design. In this regard, semisupervised clustering, semisupervised learning, and metalearning are challenging issues with both academic and practical values.

KEY TERMS

Active Learning: Learning modules that support active learning select the best examples for class labeling and training without depending on a teacher's decision or random sampling.

Boosting: A machine learning metaalgorithm for performing supervised learning in which a set of weak learners create a single strong learner.

Concept Drift: A temporal phenomenon in which the general subject matter of information within a category may no longer suit the subject that best explained that information when it was originally created.

Document Clustering: An unsupervised learning technique that partitions a given set of documents into distinct groups of similar documents based on similarity or distance measures.

EM Algorithm: An iterative method for estimating maximum likelihood in problems with incomplete (or unlabeled) data. EM algorithm can be used for semi-supervised learning (see below) since it is a form of clustering algorithm that clusters the unlabeled data around the labeled data.

Fuzzy Relation: In fuzzy relations, degrees of association between objects are represented not as crisp relations but membership grade in the same manner as degrees of set membership are represented in a fuzzy set.

Metalearning Algorithm: a subfield of machine learning where machine learning algorithms are applied on metadata such as properties of the learning problem,

performance measures, or patterns previously derived from the data in order to improve the performance of existing machine learning algorithms.

Supervised Learning: A machine learning technique for inductively building a classification model (or function) of a given set of classes from a set of training (pre-labeled) examples

Semisupervised Clustering: A variant of unsupervised clustering techniques without requiring external knowledge. Semi-supervised clustering performs clustering process under various kinds of user constraints or domain knowledge.

Semisupervised Learning: A variant of supervised learning that uses both labeled data and unlabeled data for training. Semi-supervised learning attempts to provide more precisely learned classification model by augmenting labeled training examples with information exploited from unlabeled data.

Text Classification: The task of automatically assigning a set of text documents to a set of predefined classes. Recent text classification methods adopt supervised learning algorithms such as Naïve Bayes and support vector machine.

Topic Hierarchy (Taxonomy): Topic hierarchy in this chapter is a formal hierarchical structure for orderly classification of textual information. It hierarchically categorizes incoming documents according to topic in the sense that documents at a lower category have increasing specificity.

Theory and Practice of Expectation Maximization (EM) Algorithm

Bala Rajaratnam
Stanford University, USA

INTRODUCTION

In the field of statistical data mining, the Expectation Maximization (EM) algorithm is one of the most popular methods used for solving parameter estimation problems in the maximum likelihood (ML) framework. Compared to traditional methods such as steepest descent, conjugate gradient, or Newton-Raphson, which are often too complicated to use in solving these problems, EM has become a popular method because it takes advantage of some problem specific properties (Xu et al., 1996). The EM algorithm converges to the local maximum of the log-likelihood function under very general conditions (Demspter et al., 1977; Redner et al., 1984). Efficiently maximizing the likelihood by augmenting it with latent variables and guarantees of convergence are some of the important hallmarks of the EM algorithm.

EM based methods have been applied successfully to solve a wide range of problems that arise in fields of pattern recognition, clustering, information retrieval, computer vision, bioinformatics (Reddy et al., 2006; Carson et al., 2002; Nigam et al., 2000), etc. Given an initial set of parameters, the EM algorithm can be implemented to compute parameter estimates that locally maximize the likelihood function of the data. In spite of its strong theoretical foundations, its wide applicability and important usage in solving some real-world problems, the standard EM algorithm suffers from certain fundamental drawbacks when used in practical settings. Some of the main difficulties of using the EM algorithm on a general log-likelihood surface are as follows (Reddy et al., 2008):

- EM algorithm for mixture modeling converges to a local maximum of the log-likelihood function very quickly.
- There are many other promising local optimal solutions in the close vicinity of the solutions obtained from the methods that provide good initial guesses of the solution.
- Model selection criterion usually assumes that the global optimal solution of the log-likelihood function can be obtained. However, achieving this is computationally intractable.
- Some regions in the search space do not contain any promising solutions. The promising and non-promising regions co-exist and it becomes challenging to avoid wasting computational resources to search in non-promising regions.

Of all the concerns mentioned above, the fact that most of the local maxima are not distributed uniformly makes it important to develop algorithms that not only help in avoiding some inefficient search over the low-likelihood regions but also emphasize the importance of exploring promising subspaces more thoroughly (Zhang et al, 2004). This subspace search will also be useful for making the solution less sensitive to the initial set of parameters. In this chapter, we will discuss the theoretical aspects of the EM algorithm and demonstrate its use in obtaining the optimal estimates of the parameters for mixture models. We will also discuss some of the practical concerns of using the EM algorithm and present a few results on the performance of various algorithms that try to address these problems.

BACKGROUND

Because of its greedy nature, the EM algorithm converges to a local maximum on the log-likelihood surface. Hence, the final solution will be very sensitive to the given initial set of parameters. This local maxima problem (popularly known as the initializa-

tion problem) is one of the well studied issues in the context of the EM algorithm. Several algorithms have been proposed in the literature to try and solve this issue (Reddy, 2007).

Although EM and its variants have been extensively used in the literature, several researchers have approached the problem by identifying new techniques that give good initialization. More generic techniques like deterministic annealing (Ueda et al., 1998), genetic algorithms (Pernkopf et al., 2005) have been successfully applied to obtain good parameter estimates. Though, these techniques have asymptotic guarantees, they are very time consuming and hence cannot be used in most practical applications. Some problem specific algorithms like split and merge EM (Ueda et al., 2000), component-wise EM (Figueiredo et al., 2002), greedy learning (Verbeek et al., 2003), parameter space grid (Li, 1999) have also been proposed in the literature. Some of these algorithms are either computationally very expensive or infeasible when learning mixture models in high dimensional spaces (Li, 1999). In spite of the high computational cost associated with these methods, very little effort has been taken to explore promising subspaces within the larger parameter space. Most of the above mentioned algorithms eventually apply the EM algorithm to move to a locally maximal set of parameters on the log-likelihood surface. Simpler practical approaches like running EM from several random initializations, and then choosing the final estimate that leads to the local maximum with the highest log-likelihood value to a certain extent have also been successful.

For a problem with a non-uniform distribution of local maxima, it is difficult for most methods to search neighboring subspaces (Zhang et al, 2004). Though some of these methods apply other additional mechanisms (like perturbations) to escape out of local optimal solutions, systematic methods for searching the subspace have not been thoroughly studied. More recently, TRUST-TECH based Expectation Maximization (TRUST-TECH-EM) algorithm has been developed by Reddy et al (2008), which applies some properties of the dynamical system of the log-likelihood surface to identify promising initial starts for the EM algorithm. This dynamical system approach will reveal more information about the neighborhood regions and helps in moving to different basins of attraction in the neighborhood of the current local maximum.

MAIN FOCUS

In this section, we will first discuss the theoretical aspects of the EM algorithm and prove some of its basic properties. We will then demonstrate the use of the EM algorithm in the context of mixture models and give some comparative results on multiple datasets.

THEORY OF THE EM ALGORITHM

Formally consider the problem of maximizing the likelihood function $L(\theta;x)$ arising from a density $f(x;\theta)$, with x denoting the data or sample, and θ the parameter of interest. As noted above, in both theoretical and applied problems maximizing $L(\theta;x)$ can often be a difficult task. Let us assume that we can identify another random variable y such that

$$f(x;\theta) = \int f(x,y;\theta)dy \qquad (1)$$

and where the likelihood function arising from $f(x,y;\theta)$ is relatively easier to maximize. The variable y is often called the "hidden", "latent" or "missing" data and together (x,y) is often referred to as the "complete" data.

The EM algorithm maximizes the original likelihood function by working with the complete or augmented likelihood. The expectation or E-step takes the expected value of the complete likelihood over the missing data given the original data y and a starting parameter value. This process gives rise to an expected (rather conditional expectation) version of the complete likelihood which is easier to maximize. The E-step essentially has the effect of "substituting" values for the hidden variable y. The maximization or M-step optimizes the resulting conditional expectation of the complete likelihood leading to a new parameter estimate. Based on the new parameter estimate, the E-step and the M-step are repeated back and forth in an iterative manner (McLachlan et al., 1997).

We shall prove below that every EM-step gives an improvement in the likelihood in the original problem but let us first formally state the EM algorithm.

The EM Algorithm

Consider the likelihood function $L(\theta;x)$ and the corresponding log-likelihood $\lambda(\theta;x)$ based on the density $f(x;\theta)$ of the observed data and let $f(x,y;\theta)$ be the density of the augmented data as defined in eqn(1).

Start with an initial value of the parameter estimates given by θ_0 and for a given θ_t $t = 0,1,2,\ldots$ obtain θ_{t+1} by iterating between the following two steps:

E-step - Compute the function $Q(\theta;\theta_t)$ where

$$Q(\theta;\theta_t) = E_{\theta_t}\left[\log \frac{f(x,y;\theta)}{f(x,y;\theta_t)} \middle| X=x\right]$$

Note 1: The quantities θ, θ_t, and x are considered as fixed and the expectation is taken over the hidden variable y.

M-step - Maximize $Q(\theta;\theta_t)$ to obtain the new parameter estimate θ_{t+1} i.e.

$$\theta_{t+1} = \arg\max_{\theta} Q(\theta\ ;\theta_t)$$

Note 2: Here the function $Q(\theta;\theta_t)$ is maximized with respect to θ yielding the updated parameter value θ_{t+1}.

Note 3: Since the denominator in the definition of $Q(\theta;\theta_t)$ does not depend on θ, one could as well maximize the conditional expectation of the log of $f(x,y;\theta)$, i.e. the numerator, w.r.t θ and obtain θ_{t+1}. This is often done in practice as we will see when we apply the EM algorithm to maximum likelihood estimation in Gaussian mixture models.

Basic Properties of EM Algorithm

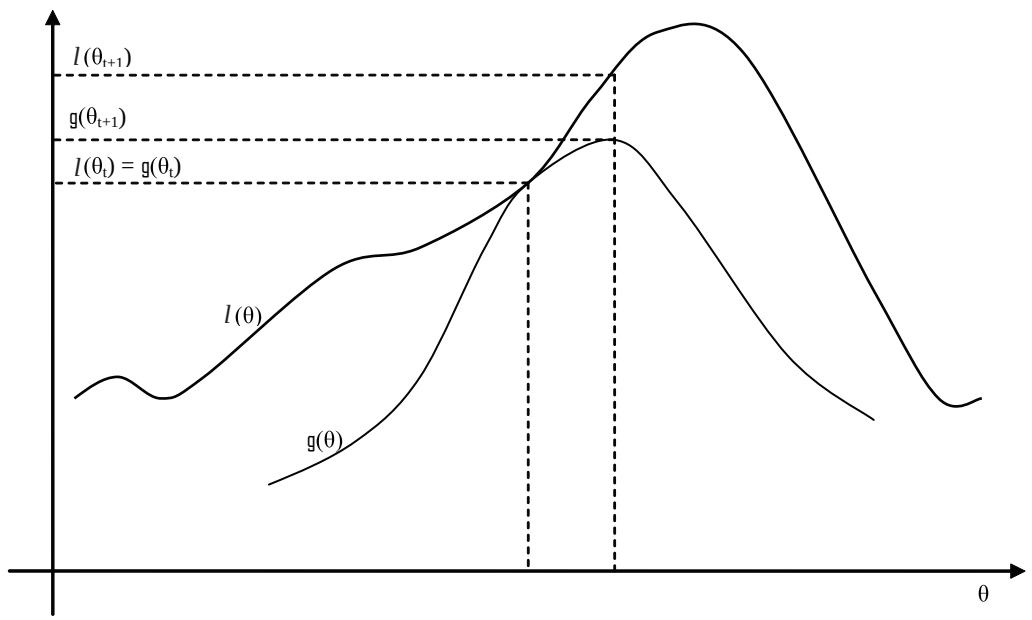
We now proceed to demonstrate that at every EM iteration the likelihood value does not decrease.

Theorem 1: $L(\theta_{t+1}) \geq L(\theta_t)$ for all t [or equivalently, $l(\theta_{t+1}) - l(\theta_t) \geq 0$]

The proof is found in the appendix.

An intuitive interpretation of the working of the EM algorithm stems from noting the following: The E-step introduces a function $g(\theta)$ which is always bounded above by the log likelihood function $l(\theta)$. Moreover, at the current value $\theta = \theta_t$, the original log-likelihood

Figure 1.Illustration of a single EM step. Note that the two functions l(θ) and g(θ) are equal at θ = θ t and that g(θ) is always bounded above by the log likelihood function l(θ). Hence maximizing g(θ) cannot lead to a decrease in the value of l(θ).



function $l(\theta)$ and $g(\theta)$ are equal, i.e. $l(\theta_t) = g(\theta_t)$. The M-step maximizes $g(\theta)$. So at each EM cycle the two functions start off at the same value and since $l(\theta) \geq g(\theta)$, increasing $g(\theta)$ guarantees that the value of $l(\theta)$ also increases. Figure 1 gives a graphical illustration of a single EM step.

CASE STUDY: MIXTURE MODELS

One of the most well-known applications of the EM algorithm is its use in finite mixture models. In this section, we shall give a concrete example where using the EM algorithm can significantly facilitate the task of finding maxima of the likelihood of a finite Gaussian mixture model (GMM) (McLachlan et al., 2000).

Let us assume that there are k components in the mixture model with probability density function given as follows:

$$p(x \mid \Theta) = \sum_{i=1}^{k} \alpha_i \, p(x \mid \theta_i) \tag{4}$$

Where $x=[x_1, x_2,\ldots, x_d]'$ is the feature vector of d dimensions. The α's represent the mixing weights and the Θ represents the parameter set $[\alpha_1, \alpha_2, .., \alpha_k, \theta_1, \theta_2,\ldots,\theta_k]$. Also it should be noted that being probabilities the α_i (with $0 \leq \alpha_i \leq 1$) should sum to 1.

One of the goals of learning in mixture models is to obtain parameter estimates for Θ from a sample of n data points, denoted by $X = \{x^{(1)},x^{(2)},\ldots, x^{(n)}\}$, drawn from a distribution with density given by eqn(4). The maximum likelihood estimate (MLE) is given as follows:

$$\hat{\Theta}_{MLE} = \arg\max_{\Theta}[\log \; p(x \mid \Theta)] \tag{5}$$

Since in general this MLE cannot be found analytically for Gaussian mixture models, one has to rely on iterative procedures that can find the global maximum of the likelihood function. The EM algorithm has been used successfully to find the local maxima of such a function.

The EM Algorithm for Mixture Models

The EM algorithm takes X to be the observed data and the missing part, termed as "hidden data" is a set of n labels $Y = \{y^{(1)},y^{(2)},\ldots, y^{(n)}\}$ associated with each of the n sample points, indicating which component produced each sample (McLachlan et al., 1997). Each label $y^{(j)} = [y_1^{(j)},y_2^{(j)},\ldots, y_k^{(j)}]$ is a binary vector where $y_i^{(j)} = 1$ and $y_m^{(j)} = 0$ for all $m \neq i$, indicating that sample $x^{(j)}$ was produced by the i^{th} component. Now, the complete log-likelihood (i.e. the one from which we would estimate Θ for the complete data $U = \{X, Y\}$) is:

$$\log p(U \mid \Theta) = \sum_{j=1}^{n} \log \prod_{i=1}^{k} [\alpha_i \, p(x^{(j)} \mid \theta_i)]^{y_i^{(j)}} \tag{6}$$

$$\log p(U \mid \Theta) = \sum_{j=1}^{n} \sum_{i=1}^{k} y_i^{(j)} \log \; [\alpha_i \, p(x^{(j)} \mid \theta_i)] \tag{7}$$

The EM algorithm produces a sequence of estimates $\{\hat{\Theta}(t), \;\; t = 0,1,2,\ldots\}$ by alternating between the following two steps until convergence:

- **E-Step:** Compute the conditional expectation of the hidden data, given X and the current estimate $\hat{\Theta}(t)$. Since $\log p\,(X, Y \mid \Theta)$ from eqn(7) is linear with respect to the missing data Y, we simply have to compute the conditional expectation $W = E\,[Y \mid X, \Theta(t)]$ in $\log p\,(X, Y \mid \Theta)$. We can therefore define the Q-function as follows:

$$Q(\Theta \mid \hat{\Theta}(t)) \equiv E_Y[\log \;\; p(X,Y) \mid X, \hat{\Theta}(t)] \tag{8}$$

As Y is a binary vector, its conditional expectation is given by :

$$\begin{aligned} w_i^{(j)} &\equiv E \;\; [y_i^{(j)} \mid X, \hat{\Theta}(t)] \\ &= \Pr \; [y_i^{(j)} = 1 \mid x^{(j)}, \hat{\Theta}(t)] \\ &= \frac{\hat{\alpha}_i(t) \, p(x^{(j)} \mid \hat{\theta}_i(t))}{\sum_{i=1}^{k} \hat{\alpha}_i(t) \, p(x^{(j)} \mid \hat{\theta}_i(t))} \end{aligned} \tag{9}$$

where the last equality follows from Bayes law (α_i is the a priori probability that $y_i^{(j)} = 1$), while $w_i^{(j)}$ is the a posteriori probability that $y_i^{(j)} = 1$ given the observation $x^{(j)}$.

- **M-Step:** The parameter estimates are updated using the following equation:

$$\hat{\Theta}(t+1) = \arg\max_{\Theta}\{Q(\Theta, \hat{\Theta}(t))\} \quad (10)$$

EM for Gaussian Mixture Models

We now proceed to illustrate the workings of the EM algorithm in the context of Gaussian Mixture Models. The convergence properties of the EM algorithm for Gaussian mixtures are thoroughly discussed in (Xu et al., 1996). The function $p(x|\theta_i)$ is a multivariate Gaussian density parameterized by θ_i (i.e. μ_i and Σ_i):

$$p(x|\theta_i) = \frac{|\Sigma_i|^{-1/2}}{(2\pi)^{d/2}} e^{-\frac{1}{2}(x-\mu_i)'\Sigma_i^{-1}(x-\mu_i)}$$

The *Q*-function for Gaussian mixture models (GMMs) is given by:

$$Q(\Theta|\hat{\Theta}(t)) = \sum_{j=1}^{n}\sum_{i=1}^{k} w_i^{(j)}[\log\frac{|\Sigma|^{-\frac{1}{2}}}{(2\pi)^{\frac{d}{2}}} - \frac{1}{2}(x^{(j)}-\mu_i)^T\Sigma_i^{-1}(x^{(j)}-\mu_i) + \log\alpha_i] \quad (11)$$

Where

$$w_i^{(j)} = \frac{\hat{\alpha}_i(t)|\hat{\Sigma}_i(t)|^{-\frac{1}{2}} e^{-\frac{1}{2}(x^{(j)}-\hat{\mu}_i(t))^T|\hat{\Sigma}_i(t)|^{-1}(x^{(j)}-\hat{\mu}_i(t))}}{\sum_{i=1}^{k}\hat{\alpha}_i(t)|\hat{\Sigma}_i(t)|^{-\frac{1}{2}} e^{-\frac{1}{2}(x^{(j)}-\hat{\mu}_i(t))^T|\hat{\Sigma}_i(t)|^{-1}(x^{(j)}-\hat{\mu}_i(t))}} \quad (12)$$

The maximization step is given by the following equation:

$$\frac{\partial}{\partial\Theta_k} Q(\Theta|\hat{\Theta}(t)) = 0 \quad (13)$$

where Θ_k denotes the parameters for the k^{th} component. As the posterior probabilities in the E-step now appear in the *Q*-function as constants, the *Q*-function resembles the Gaussian likelihood when the components are pre-specified (Wasserman, 2004). Maximizing this function in the M-step now becomes trivial as the problem essentially reduces to finding MLEs in a (single-component) Gaussian model, the solution to which is well known and is available in closed form expressions. One can easily verify that the updates for the maximization step in the case of GMMs are given as follows:

$$\mu_i(t+1) = \frac{\sum_{j=1}^{n} w_i^{(j)} x^{(j)}}{\sum_{j=1}^{n} w_i^{(j)}}$$

$$\Sigma_i(t+1) = \frac{\sum_{j=1}^{n} w_i^{(j)}(x^{(j)}-\mu_i(t+1))(x^{(j)}-\mu_i(t+1))^T}{\sum_{j=1}^{n} w_i^{(j)}} \quad (14)$$

$$\alpha_i(t+1) = \frac{1}{n}\sum_{j=1}^{n} w_i^{(j)}$$

Results of Various Global Optimization Methods

Table 1 compares the performance of different methods proposed in the literature such as k-means+EM , split and merge EM (SMEM) and TRUST-TECH-EM for two datasets. RS+EM corresponds to just a single random start and is shown here to illustrate the empirical lower bound on the performance of all these methods. The mean and the standard deviations of the log-likelihood values are reported. Higher log-likelihood values correspond to better parameter estimates of the mixture model. Two datasets were used for this performance comparison: (i) Elliptical dataset which is an artificially created dataset containing three well-separated Gauss-

Table 1. Comparison results for different initialization methods for EM algorithm on two datasets

Method	Elliptical	Iris
RS+EM	-3235 ± 14.2	-198 ± 27
K-Means+EM	-3195 ± 54	-186 ± 10
SMEM	-3123 ± 54	-178.5 ± 6
TRUST-TECH-EM	-3079 ± 0.03	-173.6 ± 11

ian clusters with 900 datapoints. The data generated from a two-dimensional, three-component Gaussian mixture distribution with mean vectors at $[0\ -2]^T$, $[0\ 0]^T$, $[0\ 2]^T$ and same diagonal covariance matrix with values 2 and 0.2 along the diagonal. All the three mixtures have uniform priors. (ii) Iris dataset which contains 150 samples, 3 classes and 4 features. For this dataset, the class labels were deleted allowing it to be treated as an unsupervised learning problem.

One can see that the TRUST-TECH-EM method not only gives better results, but it also performs consistently well compared to other popular methods proposed in the literature. More details on the experiments and the algorithmic performance are presented in Reddy et al., 2008. One other problem with the standard EM algorithm is that it might sometimes converge to the boundary of the parameter space. The boundary space problem (popularly known as the singularity problem) occurs when one of the unconstrained covariance matrices approaches zero. This can be solved by using soft constraints on the covariance matrices.

FUTURE TRENDS

The EM algorithm has been successfully used in various contexts other than GMMs. Real-world applications that arise in some popular areas (such as finance) demand the use of mixture models for Poisson and various heavy-tailed distributions. The EM algorithm has been effectively used in these contexts.

In the field of data mining, EM has been very successful in solving the parameter estimation problems for probabilistic graphical models such as Hidden Markov Models, Mixtures of Factor Analyzers, Bayesian Networks etc. For example, one of the most popular EM variant used in training hidden Markov models is the Baum-Welch algorithm. Many variants of the EM algorithm are heavily used in the context of soft-clustering and hard clustering in a wide variety of real-world applications.

There is also ongoing work on effectively combining various model selection criteria and parameter estimation in the context of the EM algorithm. This topic is one of the most active areas of research in recent times. Constrained clustering is also generating much interest from different application areas. Constrained versions of the EM algorithm are also being investigated (Shental et al., 2003).

CONCLUSION

This chapter gives an overview of the EM algorithm. The theoretical properties of the EM algorithm were derived and some of the popularly used global optimization methods in the context of the EM algorithm are discussed. The details of using the EM algorithm in the context of the finite mixture models are thoroughly investigated. A comprehensive set of derivations are also provided in the context of Gaussian mixture models. Some comparative results on the performance of the EM algorithm when used along with popular global optimization methods for obtaining maximum likelihood estimates are shown. Finally, the future research trends in the EM literature are discussed.

KEY TERMS

EM Algorithm: The expectation maximization (EM) algorithm is an iterative method for finding maximum likelihood estimates.

Global Optimization: Global optimization is the task of obtaining the absolutely best set of parameters that attain the highest (or lowest) value of an objective function.

Jensen's Inequality: Jensen's inequality relates the expected value of a convex(concave) function of a random variable to the convex(concave) function of the expected value of the random variable. It emphasizes the fact that in general the expected value of a function of a random variable is not equal to the function of the expected value.

KL-Divergence: The Kullback–Leibler divergence or relative entropy is a measure of the difference between two probability distributions. It is not a metric on the space of probability distributions.

Local Maximum: A local maximum is a point which yields the highest value of a given objective function within a neighborhood region. A function has a local maximum point at x^*, if $f(x^*) \geq f(x)$ when $|x - x^*| < \varepsilon$, for some $\varepsilon > 0$. The value of the function at this point is called the local maximum of the function.

Log-Likelihood Surface: The log-likelihood surface is the log of the likelihood function which is defined as the probability density or mass function for a given data set viewed as a function of the parameters.

Maximum Likelihood: Maximum likelihood is a commonly used parameter estimation method in statistics (and allied fields) which for given data and underlying probability model chooses the parameter value under which the given data has the highest probability of occurring. The maximum likelihood estimate is not always uniquely defined.

Mixture Models: In probability and statistics, a mixture model is a probabilistic model with a distribution that is a convex combination (or weighted sum) of other distributions.

APPENDIX: PROOF OF THEOREM 1

In this appendix, we proceed to demonstrate that at every EM iteration the likelihood value does not decrease.

Theorem 1: $L(\theta_{t+1}) \geq L(\theta_t)$ for all t [or equivalently, $l(\theta_{t+1}) - l(\theta_t) \geq 0$]

We first state three simple lemmas which we shall use in the proof.

Lemma 1:

$$Q(\theta_t;\theta_t) = E_{\theta_t}\left[\log\frac{f(x,y;\theta_t)}{f(x,y;\theta_t)}\middle|X=x\right] = E_{\theta_t}[\log 1 \ \middle|X=x] = 0$$

Lemma 2: (Jensen's inequality):

Given a random variable Z and a concave function $g(.)$ defined on the support of Z, then $g(E[Z]) \geq E[g(Z)]$ (see Wasserman, 2004).

Lemma 3:

$$E_{\theta_t}\left[\log\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right] \leq 0$$

Proof of Lemma 3:

$$\begin{aligned} E_{\theta_t}\left[\log\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right] &\leq \log E_{\theta_t}\left[\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right], \quad \textit{by Jensen's inequality} \\ &= \log\left[\int \frac{f(y|x,\theta)}{f(y|x,\theta_t)} f(y|x,\theta_t)dy\right] \\ &= \log\left[\int f(y|x,\theta)dy\right] \\ &= \log 1, \ \textit{since } f(y|x,\theta) \textit{ is a density function} \\ &= 0 \end{aligned}$$

Note: The above lemma proves that the Kullback-Leibler divergence is always non-negative.

We now have all the ingredients to prove theorem 1.

Proof of Theorem 1

First note that

$$\begin{aligned} Q(\theta;\theta_t) &= E_{\theta_t}\left[\log\frac{f(x,y;\theta)}{f(x,y;\theta_t)}\middle|X=x\right] \\ &= E_{\theta_t}\left[\log\frac{f(x,\theta)f(y|x,\theta)}{f(x,\theta_t)f(y|x,\theta_t)}\middle|X=x\right] \\ &\quad \textit{by the definition of conditional distributions} \\ &= \log\left[\frac{f(x;\theta)}{f(x;\theta_t)}\right] + E_{\theta_t}\left[\log\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right] \end{aligned}$$

Therefore,

(2)

$$l(\theta) - l(\theta_t) = \log\left[\frac{f(x;\theta)}{f(x;\theta_t)}\right] = Q(\theta;\theta_t) - E_{\theta_t}\left[\log\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right]$$

Now consider the term $l(\theta_{t+1})$ - $l(\theta_t)$ in eqn(2) above with θ_{t+1} substituted for θ. First we know from lemma 3 that the expectation term on the RHS of eqn(2) is always non-positive – thus subtracting this term from $Q(\theta;\theta_t)$ amounts to adding a non-negative quantity to $Q(\theta;\theta_t)$. Note from the M-step in the EM algorithm that we obtain θ_{t+1} by maximizing $Q(\theta;\theta_t)$ w.r.t θ. Since from lemma 1, $Q(\theta_t;\theta_t) = 0$ the maximum value of $Q(\theta;\theta_t)$ w.r.t θ given by $Q(\theta_{t+1};\theta_t) \geq Q(\theta_t;\theta_t) = 0$. So both terms on the RHS of eqn(2) give rise to non-negative quantities. Hence $l(\theta_{t+1}) - l(\theta_t) \geq 0$, thus proving that at each iteration the EM step can only increase the likelihood value.

A more intuitive interpretation of the working of the EM algorithm stems from the following argument. Note from eqn(2) we can write

$$\begin{aligned} l(\theta) &= l(\theta_t) + Q(\theta;\theta_t) - E_{\theta_t}\left[\log\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right] \\ &\geq l(\theta_t) + Q(\theta;\theta_t) \quad \textit{since } E_{\theta_t}\left[\log\frac{f(y|x,\theta)}{f(y|x,\theta_t)}\right] \leq 0 \\ &\equiv g(\theta) \end{aligned}$$

Now maximizing $Q(\theta;\theta_t)$ w.r.t θ in the M-step is equivalent to maximizing $g(\theta)$ since the additional terms $l(\theta_t)$ is a constant function of θ. Examining the function $g(\theta)$ can yield insights into the workings of the EM algorithm. First note that the function $g(\theta)$ is always bounded above by the log likelihood function $l(\theta)$. Second note that at the current value $\theta = \theta_t$ the original log likelihood function $l(\theta)$ and $g(\theta)$ are equal, i.e. $l(\theta_t) = g(\theta_t)$, since $g(\theta_t) = l(\theta_t) + Q(\theta_t;\theta_t) = l(\theta_t)$ because $Q(\theta_t;\theta_t) = 0$ (see lemma 1). So at each EM cycle the two functions start off at the same value and since $l(\theta) \geq g(\theta)$, increasing $g(\theta)$ guarantees that the value of $l(\theta)$ also increases. Figure 1 in the main text gives a graphical illustration of a single EM step.

Time-Constrained Sequential Pattern Mining

Ming-Yen Lin
Feng Chia University, Taiwan

INTRODUCTION

Sequential pattern mining is one of the important issues in the research of data mining (Agrawal & Srikant, 1995; Ayres, Gehrke, & Yiu, 2002; Han, Pei, & Yan, 2004; Lin & Lee, 2004; Lin & Lee, 2005b; Roddick & Spiliopoulou, 2002). A typical example is a retail database where each record corresponds to a customer's purchasing sequence, called data sequence. A data sequence is composed of all the customer's transactions ordered by transaction time. Each transaction is represented by a set of literals indicating the set of items (called itemset) purchased in the transaction. The objective is to find all the frequent sub-sequences (called sequential patterns) in the sequence database. Whether a sub-sequence is frequent or not is determined by its frequency, named support, in the sequence database.

An example sequential pattern might be that 40% customers bought PC and printer, followed by the purchase of scanner and graphics-software, and then digital camera. Such a pattern, denoted by <(PC, printer)(scanner, graphics-software)(digital camera)>, has three elements where each element is an itemset. Although the issue is motivated by the retail industry, the mining technique is applicable to domains bearing sequence characteristics, including the analysis of Web traversal patterns, medical treatments, natural disasters, DNA sequences, and so forth.

In order to have more accurate results, constraints in addition to the support threshold need to be specified in the mining (Pei, Han, & Wang, 2007; Chen & Yu, 2006; Garofalakis, Rastogi, & Shim, 2002; Lin & Lee, 2005a; Masseglia, Poncelet, & Teisseire, 2004). Most time-independent constraints can be handled, without modifying the fundamental mining algorithm, by a post-processing on the result of sequential pattern mining without constraints. Time-constraints, however, cannot be managed by retrieving patterns because the support computation of patterns must validate the time attributes for every data sequence in the mining process. Therefore, time-constrained sequential pattern mining (Lin & Lee, 2005a; Lin, Hsueh, & Chang, 2006; Masseglia, Poncelet, & Teisseire, 2004;) is more challenging, and more important in the aspect of temporal relationship discovery, than conventional pattern mining.

BACKGROUND

The issue of mining sequential patterns with time constraints was first addressed by Srikant and Agrawal in 1996 (Srikant & Agrawal 1996). Three time constraints including minimum gap, maximum gap and sliding time-window are specified to enhance conventional sequence discovery. For example, without time constraints, one may find a pattern <(b, d, f)(a, e)>. However, the pattern could be insignificant if the time interval between (b, d, f) and (a, e) is too long. Such patterns could be filtered out if the maximum gap constraint is specified.

Analogously, one might discover the pattern <(b, c, e)(d, g)> from many data sequences consisting of itemset (d, g) occurring one day after the occurrence of itemset (b, c, e). Nonetheless, such a pattern is a false pattern in discovering weekly patterns, i.e. the minimum gap of 7 days. In other words, the sale of (b, c, e) might not trigger the sale of (d, g) in next week. Therefore, time constraints including maximum gap and minimum gap should be incorporated in the mining to reinforce the accuracy and significance of mining results.

Moreover, conventional definition of an element of a sequential pattern is too rigid for some applications. Essentially, a data sequence is defined to support a pattern if each element of the pattern is contained in an individual transaction of the data sequence. However, the user may not care whether the items in an element (of the pattern) come from a single transaction or from adjoining transactions of a data sequence if the adjoining transactions occur close in time (within a specified time interval). The specified interval is named sliding time-

window. For instance, given a sliding time-window of 6, a data sequence $< {}_{t1}(a, e)\ {}_{t2}(b)\ {}_{t3}(f)>$ can support the pattern <(a, b, e)(f)> if the difference between time t1 and time t2 is no greater than 6. Adding sliding time-window constraint to relax the definition of an element will broaden the applications of sequential patterns.

In addition to the three time constraints, duration and exact gap constraints are usually specified for finding actionable patterns (Lin, Hsueh, & Chang, 2006; Zaki, 2000). Duration specifies the maximum total time-span allowed for a pattern. A pattern having transactions conducted over one year will be filter out if the duration of 365 days is given. Exact gap can be used to find patterns, within which adjacent transactions occur exactly the specified time difference. The discovery of sequential patterns with additionally specified time constraints is referred to as mining time-constrained sequential patterns.

A typical example of mining time-constrained sequential patterns might be that finding out frequent sub-sequences having minimum support of 40%, minimum gap of 7 days, maximum gap of 30 days, sliding time-window of 2 days, and duration of 90 days.

MAIN FOCUS

Sequential pattern mining is more complex than association rule mining because the patterns are formed not only by combinations of items but also by permutations of itemsets. The number of potential sequences is by far larger than that of potential itemsets. Given 100 possible items in the database, the total number of possible itemsets is

$$\sum_{i=0}^{100}\binom{100}{i} = 2100.$$

Let the size of a sequence (sequence size) be the total number of items in that sequence. The number of potential sequences of size k is

$$\sum_{i_1=1}^{k}\binom{100}{i_1}\sum_{i_2=1}^{k-i_1}\binom{100}{i_2}\sum_{i_3=1}^{k-i_1-i_2}\binom{100}{i_3}\cdots\sum_{i_k=1}^{k-i_1-\cdots-i_{k-1}}\binom{100}{i_k}.$$

The total number of potential sequences, accumulating from size one to size 100 and more, could be enormous. Adding time constraints complicates the mining much more so that the focus of time-constrained sequential pattern mining is to design efficient algorithms for mining large sequence databases. In general, these algorithms can be categorized into Apriori based and pattern-growth based approaches, as well as vertical mining approaches.

Apriori-Based Approaches

Although there are many algorithms dealing with sequential pattern mining, few handle the mining with the addition of time constraints. The GSP (Generalized Sequential Pattern) algorithm (Srikant & Agrawal 1996) is the first algorithm that discovers sequential patterns with time constraints (including minimum gap, maximum gap, and sliding time-window) within Apriori framework. GSP solves the problem by generating and testing candidate patterns in multiple database scans and it scans the database k times to discover patterns having k items. Candidate patterns having any non-frequent sub-sequence are pruned before testing to reduce the search space. In a database scan, each data sequence is transformed into items' transaction-time lists for fast finding of certain element with a time tag. Since the start-time and end-time of an element (may comprise several transactions) must be considered, GSP defines 'contiguous sub-sequence' for candidate generation, and move between 'forward phase' and 'backward phase' for checking whether a data sequence contains a certain candidate.

Pattern-Growth Based Approaches

A general pattern-growth framework was presented for constraint-based sequential pattern mining (Pei, Han, & Wang, 2007). From the application point of view, seven categories of constrains including item, length, super-pattern, aggregate, regular expression, duration, and gap constraints were covered. Among these constraints, duration and gap constraints are tightly coupled with the support counting process because they confine how a data sequence contains a pattern. Orthogonally classifying constraints by their roles in mining, monotonic, anti-monotonic, and succinct constraints were characterized and the prefix-monotone constraint was introduced. The prefix-growth framework which pushes prefix-monotone constraints into PrefixSpan (Pei, Han, Mortazavi-Asl, Wang, Pinto,

Chen, Dayal, & Hsu, 2004) was also proposed in (Pei, Han, & Wang, 2007). However, with respect to time constraints, prefix-growth mentioned only minimum gap and maximum gap time constraints (though duration constraint was addressed). The sliding time-window was not considered at all since the constraint is neither monotonic nor anti-monotonic.

The DELISP (DELImited Sequential Pattern mining) algorithm (Lin & Lee, 2005a), fully functionally equivalent to GSP on time constraint issues, solves the problem within the pattern-growth framework. DELISP solves the problem by recursively growing valid patterns in projected sub-databases generated by sub-sequence projection. To accelerate mining by reducing the size of sub-sequences, the constraints are integrated in the projection to delimit the counting and growing of sequences. The main idea of DELISP is efficiently 'finding' the frequent items, and then effectively 'growing' potential patterns in the sub-databases constructed by projecting sub-sequences corresponding to the frequent items. The time-tags are also projected into the sub-databases to generate patterns satisfying the time constraints. DELISP decomposes the mining problem by recursively growing patterns, one item longer than the current patterns, in the projected sub-databases. However, the potential items used to grow are subjected to minimum gap and maximum gap constraints, called de-limited growth. On projecting sub-databases, bi-directional growth is avoided by imposing the item-order in the growth. Only items having order lexicographically larger than the order of the existing items need to be projected to grow the itemset-typed patterns. Such a projection is referred to as windowed-projection. In DELISP, the bounded projection technique eliminates invalid sub-sequence projections caused by unqualified maximum/minimum gaps, the windowed projection technique reduces redundant projections for adjacent elements satisfying the sliding time-window constraint, and the delimited growth technique grows only the patterns satisfying constraints.

The METISP (MEmory Time-Indexing for Sequential Pattern mining) algorithm (Lin, Hsueh, & Chang, 2006) also finds out time-constrained sequential patterns. METISP uses the pattern-growth strategy similar to PrefixSpan and DELISP algorithms. METISP algorithm solves time constraints including minimum/maximum/exact gap, sliding time-window and duration constraints at the same time. The technique of memory indexing is used to mark the timestamps (called time-index) for fast growth of patterns in memory. Hence, the inherent properties of time constraints can be applied to reduce the search space and improve the efficiency of mining. METISP first loads DB into memory and scans the in-memory database once to find all frequent items. With respect to each frequent item, METISP then constructs a time index-set for the sequences of single items and recursively forms time-constrained sequential patterns of longer length. The time index-set is a set of (data-sequence pointer, time index) pairs. Only those data sequences containing that item would be included. The time index indicates the list of *it:lst:let* triplets, where *it* represents the initial time, *lst* the last start-time, and *let* the last end-time of a pattern. For extra-large database, the algorithm applies a partition-and-verification technique for mining databases that cannot fit into the memory. The extra-large database is partitioned so that each partition can be handled, in memory, by the METISP algorithm. The potential time-constrained sequential patterns in each partition are collected and served as candidates to be validated in the second pass of the entire database scanning. The memory time index sets are effective to handle these time constraints within the pattern-growth framework without generating any candidates or sub-databases in disk.

Vertical Mining Approaches

The cSPADE (constrained SPADE) algorithm (Zaki 2001) extends the vertical mining algorithm SPADE (Sequential PAttern Discovery using Equivalence classes) (Zaki 2000) to deal with time constraints. Vertical mining approaches discover sequential patterns using join-operations and vertical database layout, where data sequences are transformed into items' (sequence-id, time-id) lists. The cSPADE algorithm checks minimum and maximum gaps while doing temporal joins. The huge sets of frequent 2-sequences must be preserved to generate the required classes for the maximum gap constraint. However, it does not appear feasible for cSPADE to incorporate the sliding time-window by expanding the id-lists and augmenting the join-operations with temporal information. The sliding time-window constraint was not mentioned in cSPADE.

FUTURE TRENDS

Time-constrained sequential pattern mining will become one of the essential components of any sequential pattern mining mechanism. More constraints, theories, and techniques of time-constrained sequential pattern mining will be developed in the near future, followed by comprehensive comparisons of these theories and techniques. Efficient and effective mining algorithms will also be developed not only for conventional databases but also for data stream applications (Jiang & Gruenwald, 2006). Queries involving time constraints will also be expanded for practical systems.

CONCLUSION

In order to provide users with more flexibility and more accurate results on the discovery of sequential patterns, time constraints should be incorporated into the mining. Given that time-constrained sequential pattern mining is more complicated than traditional sequential pattern mining, some algorithms were developed. In general, mining sequence databases could be solved under the Apriori or pattern-growth framework. Apriori based approaches generate candidates and have to check the time constraints for every data sequence. Pattern-growth based approaches recursively mine patterns either in the disk-projected databases or in memory using the memory index. Pattern-growth based algorithms generally perform better than Apriori ones. Still, more efforts are desirable to solve the complicated mining problem, in conventional static databases or in the evolving data streams.

KEY TERMS

Duration: The maximum allowed time difference between the first and the latest occurrences of elements in the entire sequence.

Exact Gap: The time difference between the occurrences of any two adjacent elements.

Maximum Gap: The maximum allowed time difference between the earliest occurrence of an item in an element and the latest occurrence of an item in the immediately succeeding element.

Minimum Gap: The minimum allowed time difference between the latest occurrence of an item in an element and the earliest occurrence of an item in the immediately succeeding element.

Sequential Pattern: A sequence whose occurrence frequency in a sequence database is no less than a user-specified frequency threshold.

Sliding Time-Window: The maximum allowed time difference between the first and the latest occurrences of elements to be considered as a single element.

Time-Constrained Sequential Pattern: The sequential pattern that additionally satisfies the user-specified time constraints.

Time-Index: An index that indicates the occurrences of a pattern for a data sequence.

Topic Maps Generation by Text Mining

Hsin-Chang Yang
Chang Jung University, Taiwan

Chung-Hong Lee
National Kaohsiung University of Applied Sciences, Taiwan

INTRODUCTION

Topic maps provide a general, powerful, and user-oriented way to navigate the information resources under consideration in any specific domain. A topic map provides a uniform framework that not only identifies important subjects from an entity of information resources and specifies the resources that are semantically related to a subject, but also explores the relations among these subjects. When a user needs to find some specific information on a pool of information resources, he or she only needs to examine the topic maps of this pool, select the topic that seems interesting, and the topic maps will display the information resources that are related to this topic, as well as its related topics. The user will also recognize the relationships among these topics and the roles they play in such relationships. With the help of the topic maps, you no longer have to browse through a set of hyperlinked documents and hope that you may eventually reach the information you need in a finite amount of time, while knowing nothing about where to start. You also don't have to gather some words and hope that they may perfectly symbolize the idea you're interested in, and be well-conceived by a search engine to obtain reasonable result. Topic maps provide a way to navigate and organize information, as well as create and maintain knowledge in an infoglut.

To construct a topic map for a set of information resources, human intervention is unavoidable at the present time. Human effort is needed in tasks such as selecting topics, identifying their occurrences, and revealing their associations. Such a need is acceptable only when the topic maps are used merely for navigation purposes and when the volume of the information resource is considerably small. However, a topic map should not only be a topic navigation map. The volume of the information resource under consideration is generally large enough to prevent the manual construction of topic maps. To expand the applicability of topic maps, some kind of automatic process should be involved during the construction of the maps. The degree of automation in such a construction process may vary for different users with different needs. One person may need only a friendly interface to automate the topic map authoring process, while another may try to automatically identify every component of a topic map for a set of information resources from the ground up. In this article, we recognize the importance of topic maps not only as a navigation tool but also as a desirable scheme for knowledge acquisition and representation. According to such recognition, we try to develop a scheme based on a proposed text-mining approach to automatically construct topic maps for a set of information resources. Our approach is the opposite of the navigation task performed by a topic map to obtain information. We extract knowledge from a corpus of documents to construct a topic map. Although currently the proposed approach cannot fully construct the topic maps automatically, our approach still seems promising in developing a fully automatic scheme for topic map construction.

BACKGROUND

Topic map standard (ISO, 2000) is an emerging standard, so few works are available about the subject. Most of the early works about topic maps focus on providing introductory materials (Ahmed, 2002; Pepper, 1999; Beird, 2000; Park & Hunting, 2002). Few of them are devoted to the automatic construction of topic maps. Two works that address this issue were reported in Rath (1999) and Moore (2000). Rath discussed a framework for automatic generation of topic maps according to a so-called topic map template and a set of generation rules. The structural information of topics is maintained in the template. To create the topic map, they used a generator to interpret the generation rules and

extract necessary information that fulfills the template. However, both the rules and the template are to be constructed explicitly and probably manually. Moore discussed topic map authoring and how software may support it. He argued that the automatic generation of topic maps is a useful first step in the construction of a production topic map. However, the real value of such a map comes through the involvement of people in the process. This argument is true if the knowledge that contained in the topic maps can only be obtained by human efforts. A fully automatic generation process is possible only when such knowledge may be discovered from the underlying set of information resources through an automated process, which is generally known as knowledge discovery from texts, or *text mining* (Hearst, 1999; Lee & Yang, 1999; Wang, 2003; Yang & Lee, 2000).

MAIN THRUST

We briefly describe the text-mining process and the generation process of topic maps in this section.

The Text-Mining Process

Before we can create topic maps, we first perform a text-mining process on the set of information resources to reveal the relationships among the information resources. Here, we only consider those information resources that can be represented in regular texts. Examples of such resources are Web pages, ordinary books, technical specifications, manuals, and so forth. The set of information resources is collectively known as *the corpus*, and individual resource is referred to as a *document* in the following text. To reveal the relationships between documents, the popular *self-organizing map (SOM)* algorithm (Kohonen, Kaski, Lagus, Salojärvi, Honkela, Paatero, & Saarela, 2000) is applied to the corpus to cluster documents. We adopt the vector space model (Baeza-Yates and Ribiero-Neto, 1999) to transform each document in the corpus into a binary vector. These document vectors are used as input to train the map. We then apply two kinds of labeling processes to the trained map and obtain two feature maps, namely the *document cluster map (DCM)* and the *word cluster map (WCM)*. In the document cluster map, each neuron represents a document cluster that contains several similar documents with high word co-occurrence. In the word cluster map, each neuron represents a cluster of words revealing the general concept of the corresponding document cluster that is associated with the same neuron in the document cluster map.

The text-mining process described in the preceding paragraph provides a way for us to reveal the relationships between the topics of the documents. Here, we introduce a method to identify topics and the relationships between them. The method also arranges these topics in a hierarchical manner according to their relationships. As we mention earlier in this article, a neuron in the DCM represents a cluster of documents containing words that often co-occurred in these documents. Besides, documents that associate with neighboring neurons contain similar sets of words. Thus, we may construct a supercluster by combining neighboring neurons. To form a supercluster, we first define the distance between two clusters:

$$D(i,j) = H\left(\left\|\mathbf{G}_i - \mathbf{G}_j\right\|\right), \tag{1}$$

where i and j are the neuron indices of the two clusters, and $\mathbf{G}_i$ is the two-dimensional grid location of neuron i. $\|\mathbf{G}_i - \mathbf{G}_j\|$ measures the Euclidean distance between the two coordinates $\mathbf{G}_i$ and $\mathbf{G}_j$. $H(x)$ is a bell-shaped function that has a maximum value when x=0. We also define the dissimilarity between two clusters:

$$\delta(i,j) = \left\|\mathbf{w}_i - \mathbf{w}_j\right\|, \tag{2}$$

where $\mathbf{w}_i$ denotes the synaptic weight vector of neuron i. We may then compute the *supporting cluster similarity*, S_i, for a neuron i from its neighboring neurons by the equations

$$s(i,j) = \frac{\mathrm{doc}(i)\mathrm{doc}(j)}{F\left(D(i,j)\delta(i,j)\right)}$$
$$S_i = \sum_{j \in B_i} s(i,j) \tag{3}$$

where doc(i) is the number of documents associated with neuron i in the document cluster map, and B_i is the set of neuron indices in the neighborhood of neuron i. The function F: $\mathbf{R}^+ \rightarrow \mathbf{R}^+$ is a monotonically increasing function. A *dominating neuron* is the neuron that has locally maximal supporting cluster similarity.

We may select dominating neurons by the following algorithm:

- **Step 1:** Find the neuron with the largest supporting cluster similarity. Select this neuron as the dominating neuron.
- **Step 2:** Eliminate its neighbor neurons so they will not be considered as dominating neurons.
- **Step 3:** If no neuron is left, or the number of dominating neurons exceeds a predetermined value, stop. Otherwise, go to Step 1.

A dominating neuron may be considered as the centroid of a supercluster, which contains several clusters. We assign every cluster to some supercluster by the following method. The *i*th cluster (neuron) is assigned to the *k*th supercluster if:

$$\delta(i,k) = \min_{l} \delta(i,l),\ l \text{ is a super-cluster.} \quad (4)$$

A supercluster may be thought of as a category that contains several subcategories. Let C_k denote the set of neurons that belong to the *k*th supercluster, or category. The category topics are selected from those words that associate with these neurons in the WCM. For all neurons $j \in C_k$, we select the n^*th word as the category topic if:

$$\sum_{j \in C_k} w_{j_{n^*}} = \max_{1 \le n \le N} \sum_{j \in C_k} w_{j_n} \quad (5)$$

Equation 5 selects the word that is the most important to a supercluster, because the components of the synaptic weight vector of a neuron reflect the willingness that the neuron wants to learn the corresponding input data, that is, words.

The topics that are selected by Equation 5 form the top layer of the category hierarchy. To find the descendants of these topics in the hierarchy, we may apply the above process to each supercluster and obtain a set of subcategories. These subcategories form the new superclusters that are on the second layer of the hierarchy. The category structure can then be revealed by recursively applying the same category generation process to each newfound supercluster. We decrease the size of the neighborhood in selecting dominating neurons when we try to find the subcategories.

Automatic Topic Maps Construction

The text-mining process described in the preceding section reveals the relationships between documents and words. Furthermore, it may identify the topics in a set of documents, reveals the relationships among the topics, and arranges the topics in a hierarchical manner. The result of such a text-mining process can be used to construct topic maps. We discuss the steps in topic map construction in the following subsections.

Identifying Topics and Topic Types

The topics in the constructed topic map can be selected as the topics identified by Equation 5. All the identified topics in every layer of the hierarchy can be used as topics. Because topics in different layers of the hierarchy represent different levels of significance, we may constrain the significance of topics in the map by limiting the depth of hierarchy from which we select topics. If we only used topics in higher layers, the number of topics is small, but those topics represent more important topics. The significance level can be set explicitly in the beginning of the construction process or determined dynamically during the construction process. One way to determine the number of topics is by considering the size of the self-organizing map.

The topic types can also be determined by the constructed hierarchy. As we mention earlier in this paper, a topic on higher layers of the hierarchy represents a more important concept than those on lower layers. For a parent-child relationship between two concepts on two adjacent layers, the parent topic should represent an important concept of its child topic. Therefore, we may use the parent topic as the type of its child topics. Such usage also fulfills the requirement of the topic map standard (that a topic type is also a topic).

Identifying Topic Occurrences

The occurrences of an identified topic are easy to obtain after the text-mining process. Because a topic is a word labeled to a neuron in the WCM, its occurrences can be assigned as the documents labeled to the same neuron in the DCM. That is, let a topic t be labeled to neuron *A* in the WCM, and the occurrences of t should be those documents labeled to the same neuron *A* in the DCM. For example, if the topic 'text mining' was labeled to the 20th neuron in the WCM, all the docu-

ments labeled to the 20th neuron in the DCM should be the occurrences of this topic. Furthermore, we may create more occurrences of this topic by allowing the documents labeled to lower levels of the hierarchy to also be included. For example, if neuron 20 in the preceding example were located on the second level of a topic hierarchy, we could also allow the clusters of documents associated with topics below this level to be occurrences of this topic. Another approach is to use the DCM directly, such that we also include the documents associated with the neighboring neurons as its occurrences.

Identifying Topic Associations

The associations among topics can be identified in two ways with our method. The first is to use the developed hierarchy structure among topics. A topic is associated with the other if a path exists between them. We should limit the lengths of such paths to avoid establishing associations between pairs of unrelated topics. For example, if we limited the length to 1, only topics that are direct parents and children are associated with the topic under consideration. The type of such associations is essentially an instance-class association. The second way to identify topic associations simply examines the WCM and finds the associations. To establish associations to a topic t, we first find the neuron *A* to which t is labeled. We then establish associations between t and every topic associated with some neighboring neuron of *A*. The neighboring neurons are selected from a neighborhood of *A* that is arbitrarily set by the creator. Obviously, a large neighborhood will create many associations. We should at least create associations between t and other topics associated with the same neuron *A*, because they are considered closely related topics in the text-mining process. The association types are not easy to reveal by this method, because we do not fully reveal the semantic relations among neurons after the text-mining process. An alternative method to determine the association type between two topics is to use the semantic relation defined in a well-developed ontology, such as WordNet (Fellbaum, 1998).

FUTURE TRENDS

Topic maps will be an emergent standard for information navigation in the near future. Its topic-driven navigation scheme allows the users to retrieve their documents without tedious browsing of the whole infoglut. However, the generation of topic maps still dominates their spread. An editor will help, provided it can generate the necessary ingradients of a topic map automatically, or at least semiautomatically. However, such a generation process is difficult, because we need to reveal the semantics of the documents. In this aspect, the data-mining techniques will help. Therefore, the future trends of topic map generation should be as follows:

- Applying knowledge discovery techniques to discover topics and their associations without the intervention of human beings
- Incorporating topic map standard and Web representation languages, such as XML, to promote the usage of topic maps
- Developing a user interface that allows users to create and edit the topic maps with the aid of automatic generated ingredients
- Developing a tool to integrate or migrate existing topic maps
- Constructing metadata in topic maps for applications on the semantic Web (Daconta, Obrst, & Smith, 2003)
- Mining the existing topic maps from their structures and ingredients

CONCLUSION

In this paper, we present a novel approach for semiautomatic topic map construction. The approach starts from applying a text-mining process to a set of information resources. Two feature maps, namely the document cluster map and the word cluster map, are created after the text-mining process. We then apply a category hierarchy development process to reveal the hierarchical structure of the document clusters. Some topics are also identified by such a process to indicate the general subjects of those clusters located in the hierarchy. We may then automatically create topic maps according to the two maps and the developed hierarchy. Although our method may not identify all the kinds of components that should construct a topic map, our approach seems promising because the text-mining process achieves satisfactory results in revealing implicit topics and their relationships.

KEY TERMS

Neural Networks: Learning systems, designed by analogy with a simplified model of the neural connections in the brain, that can be trained to find nonlinear relationships in data.

Self-Organizing Maps: A neural network model developed by Teuvo Kohonen that has been recognized as one of the most successful models. The model uses an unsupervised learning process to cluster high-dimensional data and map them into a one- or two-dimensional feature map. The relationships among data can be reflected by the geometrical distance between their mapped neurons.

Text Mining: The application of analytical methods and tools to usually unstructured textual data for the purpose of identifying patterns and relationships such as classification, prediction, estimation, or affinity grouping.

Topic Associations: The relationships between two or more topics in a topic map.

Topic Maps: A navigation scheme for exploring information resources in a topic-driven manner. When a set of information resources are provided, their topics as well as the associations among topics are identified and are used to form a map that guides the user through the topics.

Topic Occurrences: A topic may be linked to one or more information resources that are deemed to be relevant to the topic in some way. Such resources are called occurrences of the topic.

Topics: The object or node in the topic map that represents the subject being referred to. However, the relationship between topics and subjects is (or should be) one to one, with every topic representing a single subject, and every subject being represented by just one topic.

Topic Types: Topics can be categorized according to their kind. In a topic map, any given topic is an instance of zero or more topic types. This corresponds to the categorization inherent in the use of multiple indexes in a book (index of names, index of works, index of places, etc.), and to the use of typographic and other conventions to distinguish different types of topics.

Transferable Belief Model

Philippe Smets
Université Libre de Bruxelle, Belgium

INTRODUCTION

This note is a very short presentation of the transferable belief model (TBM), a model for the representation of quantified beliefs based on belief functions. Details must be found in the recent literature.

The TBM covers the same domain as the subjective probabilities except probability functions are replaced by belief functions which are much more general. The model is much more flexible than the Bayesian one and allows the representation of states of beliefs not adequately represented with probability functions. The theory of belief functions is often called the Dempster-Shafer's theory, but this term is unfortunately confusing.

The Various Dempster-Shafer's Theories

Dempster-Shafer's theory covers several models that use belief functions. Usually their aim is in the modeling of someone's degrees of belief, where a degree of belief is understood as strength of opinion. They do not cover the problems of vagueness and ambiguity for which fuzzy sets theory and possibility theory are more appropriate.

Beliefs result from uncertainty. Uncertainty can result from a random process (the objective probability case), or from a lack of information (the subjective case). These two forms of uncertainty are usually quantified by probability functions.

Dempster-Shafer's theory is an ambiguous term as it covers several models. One of them, the "transferable belief model" is a model for the representation of quantified beliefs developed independently of any underlying probability model. Based on Shafer's initial work (Shafer, 1976) it has been largely extended since (Smets,1998; Smets & Kennes, 1994; Smets & Kruse, 1997).

The Representation of Quantified Beliefs

Suppose a finite set of worlds Ω called the frame of discernment. The term "world" covers concepts like state of affairs, state of nature, situation, context, value of a variable... One world corresponds to the actual world. An agent, denoted You (but it might be a sensor, a robot, a piece of software), does not know which world corresponds to the actual world because the available data are imperfect. Nevertheless, You have some idea, some opinion, about which world might be the actual one. So for every subset A of Ω, You can express Your beliefs, i.e., the strength of Your opinion that the actual world belongs to A. This strength is denoted bel(A). The larger bel(A), the stronger You believe that the actual world belongs to A.

Credal vs. Pignistic Levels

Intrinsically beliefs are not directly observable properties. Once a decision must be made, their impact can be observed.

In the TBM, we have described a two level mental model in order to distinguish between two aspects of beliefs, belief as weighted opinions, and belief for decision making (Smets, 2002a). The two levels are: the credal level, where beliefs are held, and the pignistic level, where beliefs are used to make decisions (credal and pignistic derive from the Latin words "credo", I believe and "pignus", a wage, a bet).

Usually these two levels are not distinguished and probability functions are used to quantify beliefs at both levels. Once these two levels are distinguished, as done in the TBM, the classical arguments used to justify the use of probability functions do not apply anymore at the credal level, where beliefs will be represented by belief functions. At the pignistic level, the probability function needed to compute expected utilities are called pignistic probabilities to enhance they do not represent beliefs, but are just induced by them.

BACKGROUND

Belief Function Inequalities

The TBM is a model developed to represent quantified beliefs. The TBM departs from the Bayesian approach

in that we do not assume that bel satisfies the additivity encountered in probability theory. We get inequalities like : bel(A∪B) ≥bel(A) + bel(B) - bel(A∩B).

Basic Belief Assignment

Definition 2.2

Let Ω be a frame of discernment. A basic belief assignment (bba) is a function $m : 2^{\Omega} \rightarrow [0, 1]$ that satisfies $\Sigma_{A \subseteq \Omega} m(A) = 1$.

The term m(A) is called the basic belief mass (bbm) given to A. The bbm m(A) represents that part of Your belief that supports A, i.e., the fact that the actual world belongs to A, without supporting any more specific subset, by lack of adequate information.

As an example, consider that You learn that the actual world belongs to A, and You know nothing else about its value. Then some part of Your beliefs will be given to A, but no subset of A will get any positive support. In that case, You would have m(A) > 0 and m(B) = 0 for all B≠A, B≠Ω, and m(Ω) = 1-m(A).

Belief Functions

The bba m does not in itself quantify your belief that the actual world belongs to A. Indeed, the bbm m(B) given to any non empty subset B of A also supports that the actual world belongs to A. Hence, the degree of belief bel(A) is obtained by summing all the bbms m(B) for all B non empty subset of A. The degree of belief bel(A) quantifies the total amount of justified specific support given to the fact that the actual world belongs to A. We say justified because we include in bel(A) only the bbms given to subsets of A. For instance, consider two distinct elements x and y of Ω. The bbm m({x, y}) given to {x, y} could support x if further information indicates this. However given the available information the bbm can only be given to {x, y}. We say specific because the bbm m(Ø) is not included in bel(A) as it is given to the subsets that supports not only A but also not A.

The originality of the TBM comes from the non-null masses that may be given to non-singletons of ‡. In the special case where only singletons get positive bbms, the function bel is a probability function. In that last case, the TBM reduces itself to the Bayesian theory.

Shafer assumed m(Ø) = 0. In the TBM, such a requirement is not assumed. That mass m(Ø) reflects both the non-exhaustivity of the frame and the existence of some conflict between the beliefs produced by the various belief sources.

Expressiveness of the TBM

The advantage of the TBM over the classical Bayesian approach resides in its large flexibility, its ability to represent every state of partial beliefs, up to the state of total ignorance. In the TBM, total ignorance is represented by the vacuous belief function, i.e., a belief function such that m(Ω) = 1, m(A) = 0 for all A with A≠Ω. Hence bel(Ω) = 1 and bel(A) = 0 for all A strict subset of Ω. It expresses that all You know is that the actual world belongs to Ω. The representation of total ignorance in probability theory is hard to achieve adequately, most proposed solutions being doomed to contradictions. With the TBM, we can of course represent every state of belief, full ignorance, partial ignorance, probabilistic beliefs, or even certainty (m(A) = 1 corresponds to A is certain).

Example

Let us consider a somehow reliable witness in a murder case who testifies to You that the killer is a male. Let 0.7 be the reliability You give to the testimony (0.7 is the probability, the belief that the witness is reliable). Suppose furthermore that a priori You have an equal belief that the killer is a male or a female.

A classical probability analysis would compute the probability P(M) of M= “the killer is a male” given the witness testimony as: P(M) = P(M|Reliable)P(Reliable) + P(M|Not Reliable)P(Not Reliable)= 1.0x0.7 + 0.5x0.3 = 0.85, where “Reliable and Not Reliable refer to the witness” reliability. The value 0.85 is the sum of the probability of M given the witness is reliable (1.) weighted by the probability that the witness is reliable (0.7) plus the probability of M given the witness is not reliable (0.5, the proportion of males among the killers) weighted by the probability that the witness is not reliable (0.3).

The TBM analysis is different. You have some reason to believe that the killer is a male, as so said the witness. But this belief is not total (maximal) as the witness might be wrong. The 0.7 is the belief You give to the fact that the witness tells the truth (is reliable), in which case the killer is male. The remaining 0.3 mass is given to the fact that the witness is not really telling

the truth (he lies or he might have seen a male, but this was not the killer). In that last case, the testimony does not tell You anything about the killer's sex. So the TBM analysis will give a belief 0.7 to M: bel(M) = 0.7 (and bel(Not M) = 0).The information relative the population of killers (the 0.5) is not relevant to Your problem. Similarly, the fact that almost all crimes are committed by the members of some particular group of individuals may not be used to prove your case.

Conditioning

Suppose You have some belief on Ω represented by the bba m. Then some further evidence becomes available to You and this piece of information implies that the actual world cannot be one of the worlds in not-A. Then the mass m(B) that initially was supporting that the actual world is in B now supports that the actual world is in B∩A as every world in not-A must be "eliminated". So m(B) is transferred to B∩A after conditioning on A. (The model gets its name from this transfer operation.)

This operation leads to the conditional bba. This rule is called the Dempster's rule of conditioning.

Example

Continuing with the murder case, suppose there are only two potential male suspects: Phil and Tom, so m({Phil, Tom}) = 0.7. Then You learn that Phil is not the killer. The initial testimony now supports that the killer is Tom. The reliability 0.7 You gave to the testimony initially supported "the killer is Phil or Tom". The new information about Phil implies that the value 0.7 now supports "the killer is Tom".

After conditioning, a mass can be given to Ø. It represents the conflict between the previous beliefs given to not-A with the new conditioning piece of evidence that states that A holds. In probability theory and in the model initially developed by Shafer, this conflict is hidden. In the TBM, we keep it and use it to develop expert systems built for conflict resolutions. Note that some positive mass given to Ø may also result from the non exhaustivity of the frame of discernment.

Further Results

Since Shafer seminal work, many new concepts have been developed. For lack of space, we cannot present them. Reader is referred to the author web site for downloadable papers (http://iridia.ulb.ac.be/ ~ psmets/).

On the theoretical side, the next issues have been solved, among which:

1. The concept of open and close world assumptions, so non-exhaustive frames of discernment are allowed.
2. The disjunctive rule of combination, the general combination rules, the belief function negation.
3. The generalized Bayesian theorem to build a belief on space Y from the conditional belief on space X given each value of Y and an observation on X (Delmotte & Smets, 2004).
4. The pignistic transformation to build the probability function needed for decision-making.
5. The discounting of beliefs produced by partially reliable sources.
6. The manipulation of the conflict (Lefevre, Colot, & Vannooremberghe, 2002).
7. The canonical decompositions of any belief functions in simple support functions.
8. The specialization, cautious combinations, alpha-junctions.
9. The belief functions defined on the reals.
10. Belief ordering and least commitment principle.
11. Doxastic independence that translates stochastic independence into belief function domain (Ben Yaghlane, Smets, & Mellouli, 2001).
12. Evidential networks, directed or undirected, for the efficient propagation of beliefs in networks (Shenoy, 1997).
13. Fast Mobius transforms to transform masses into belief and plausibility functions and vice versa.
14. Approximation methods (Denoeux & Ben Yaghlane, 2002; Haenni & Lehmann, 2002).
15. Matrix notation for manipulating belief functions (Smets, 2002b).
16. Axiomatic justifications of most concepts.

The TBM has been applied to many problems among which:

1. Kalman filters and joint tracking and classifications.
2. Data association and determination of the number of detected objects (Ayoun & Smets, 2001).
3. Data clustering (Denoeux & Masson, 2004).

4. Expert systems for conflict management (Milisavljevic, Bloch, & Acheroy, 2000).
5. Belief assessment (similarity measures, frequencies).
6. TBM classifiers: case base and model base.
7. Belief decision trees (Elouedi, Mellouli, & Smets, 2001).
8. Planning and pre-posterior analyses.
9. Sensors with limited knowledge, limited communication bandwidth, self-repeating, decaying memory, varying domain granularity.
10. Tuning reliability coefficients for partially reliable sensors (Elouedi, Mellouli, & Smets, 2004).

The author has developed a computer program TBMLAB, which is a demonstrator for the TBM written in MATLAB. It is downloadable from the web site: http://iridia.ulb.ac.be/~psmets/. Many tools, tutorials and applications dealing with the TBM can be found in this freeware.

FUTURE TRENDS

The TBM is supposed to cover the same domain as probability theory, hence the task is enormous. Many problems have not yet been considered and are open for future work.

One major problem close to be solved is the concept of credal inference, i.e., the equivalent of statistical inference (in its Bayesian form) but within the TBM realm. The advantage will be that inference can be done with an a priori that really represents ignorance. Real life successful applications start to show up, essentially in the military domain, for object recognitions issues.

CONCLUSIONS

We have very shortly presented the TBM, a model for the representation of quantified beliefs based on belief functions. The whole theory has enormously increased since Shafer's seminal work. We only present very general ideas and provide pointers to the papers where the whole theory is presented. Full details must be found in the recent up to date literature.

KEY TERMS

Basic Belief Assignment: M(A) is the parts of belief that support that the actual world is in A without supporting any more specific subset of A.

Belief Function: Bel(A) is the total amount of belief that support that the actual world is in A without supporting its complement.

Conditioning: Revision process of a belief by a fact accepted as true.

Conjunctive Combination: The combination of the beliefs induced by several sources into an aggregated belief.

Open World Assumption: The fact that the frame of discernment might not be exhaustive.

Pignistic Probability Function: BetP is the probability function used for decision making.

Plausibility Function: Pl(A) is the total amount of belief that might support that the actual world is in A.

Tree and Graph Mining

Dimitrios Katsaros
Aristotle University, Greece

Yannis Manolopoulos
Aristotle Univeristy, Greece

INTRODUCTION

During the past decade, we have witnessed an explosive growth in our capabilities to both generate and collect data. Various data mining techniques have been proposed and widely employed to discover valid, novel and potentially useful patterns in these data. Data mining involves the discovery of patterns, associations, changes, anomalies, and statistically significant structures and events in huge collections of data.

One of the key success stories of data mining research and practice has been the development of efficient algorithms for discovering frequent itemsets – both sequential (Srikant & Agrawal, 1996) and non-sequential (Agrawal & Srikant, 1994). Generally speaking, these algorithms can extract co-occurrences of items (taking or not taking into account the ordering of items) in an efficient manner. Although the use of sets (or sequences) has effectively modeled many application domains, like market basket analysis, medical records, a lot of applications have emerged whose data models do not fit in the traditional concept of a set (or sequence), but require the deployment of richer abstractions, like graphs or trees. Such graphs or trees arise naturally in a number of different application domains including network intrusion, semantic Web, behavioral modeling, VLSI reverse engineering, link analysis and chemical compound classification.

Thus, the need to extract complex tree-like or graph-like patterns in massive data collections, for instance, in bioinformatics, semistructured or Web databases, became a necessity. The class of exploratory mining tasks, which deal with discovering patterns in massive databases representing complex interactions among entities, is called *Frequent Structure Mining* (FSM) (Zaki, 2002).

In this article we will highlight some strategic application domains where FSM can help provide significant results and subsequently we will survey the most important algorithms that have been proposed for mining graph-like and tree-like substructures in massive data collections.

BACKGROUND

As a motivating example for graph mining consider the problem of mining chemical compounds to discover recurrent (sub) structures. We can model this scenario using a graph for each compound. The vertices of the graphs correspond to different atoms and the graph edges correspond to bonds among the atoms. We can assign a label to each vertex, which corresponds to the atom involved (and maybe to its charge) and a label to each edge, which corresponds to the type of the bond (and maybe to information about the 3D orientation). Once these graphs have been generated, recurrent substructures become frequently occurring subgraphs. These graphs can be used in various tasks, for instance, in classifying chemical compounds (Deshpande, Kuramochi, & Karypis, 2003).

Another application domain where graph mining is of particular interest arises in the field of Web usage analysis (Nanopoulos, Katsaros, & Manolopoulos, 2003). Although various types of usage (traversal) patterns have been proposed to analyze the behavior of a user (Chen, Park, & Yu, 1998), they all have one very significant shortcoming; they are one-dimensional patterns and practically ignore the link structure of the site. In order to perform finer usage analysis, it is possible to look at the entire forward accesses of a user and to mine frequently accessed subgraphs of that site.

Looking for examples where tree mining has been successfully applied, we can find a wealth of them. A characteristic example is XML, which has been a very popular means for representing and storing information of various kinds, because of its modeling flexibility. Since tree-structured XML documents are the most

widely occurring in real applications, one would like to discover the commonly occurring subtrees that appear in the collections. This task could benefit applications, like database caching (Yang, Lee, & Hsu, 2003), storage in relational databases (Deutsch, Fernandez, & Suciu, 1999), building indexes and/or wrappers (Wang & Liu, 2000) and many more.

Tree patterns arise also in bioinformatics. For instance, researchers have collected large amounts of RNA structures, which can be effectively represented using a computer data structure called tree. In order to deduce some information about a newly sequenced RNA, they compare it with known RNA structures, looking for common topological patterns, which provide important insights to the function of the RNA (Shapiro & Zhang, 1990). Another application of tree mining in bioinformatics is found in the context of constructing phylogenetic trees (Shasha, Wang, & Zhang, 2004), where the task of phylogeny reconstruction algorithms it to use biological information about a set of e.g., taxa, in order to reconstruct an ancestral history linking together all the taxa in the set.

There are two distinct formulations for the problem of mining frequent graph (tree) substructures and are referred to as the *graph-transaction* (*tree-transaction*) setting and the *single-graph* (*single-tree*) setting. In the graph-transaction setting, the input to the pattern-mining algorithm is a set of relatively small graphs (called transactions), whereas in the single-graph setting the input data is a single large graph. The difference affects the way the frequency of the various patterns is determined. For the former, the frequency of a pattern is determined by the number of graph transactions that the pattern occurs in, irrespective of how many times a pattern occurs in a particular transaction, whereas in the latter, the frequency of a pattern is based on the number of its occurrences (i.e., embeddings) in the single graph. The algorithms developed for the graph-transaction setting can be modified to solve the single-graph setting, and vice-versa.

Depending also on the application domain, the considered graphs (trees) can be ordered or unordered, directed or undirected. No matter what these characteristics are, the (sub)graph mining problem can be defined as follows. (A similar definition can be given for the tree mining problem.) Given as input a database of graphs and a user-defined real number $0<\sigma\leq 1$, we need to find all frequent subgraphs, where the word "frequent" implies those subgraphs with frequency larger than or equal to the threshold σ. (In the following, equivalently to the term *frequency*, we use the term *support*.) We illustrate this problem for the case of graph-transaction, labeled, undirected graphs, with $\sigma=2/3$. The input and output of such an algorithm are given in Figure 1.

Although the very first attempts to deal with the problem of discovering substructure patterns from massive graph or tree data are dated back to the early 90's (Cook & Holder, 1994), only recently the field of mining for graph and tree patterns has flourished. A wealth of algorithms has been proposed, most of which are based on the original level-wise *Apriori* algorithm for mining frequent itemsets (Agrawal & Srikant, 1994). Next, we will survey the most important of them.

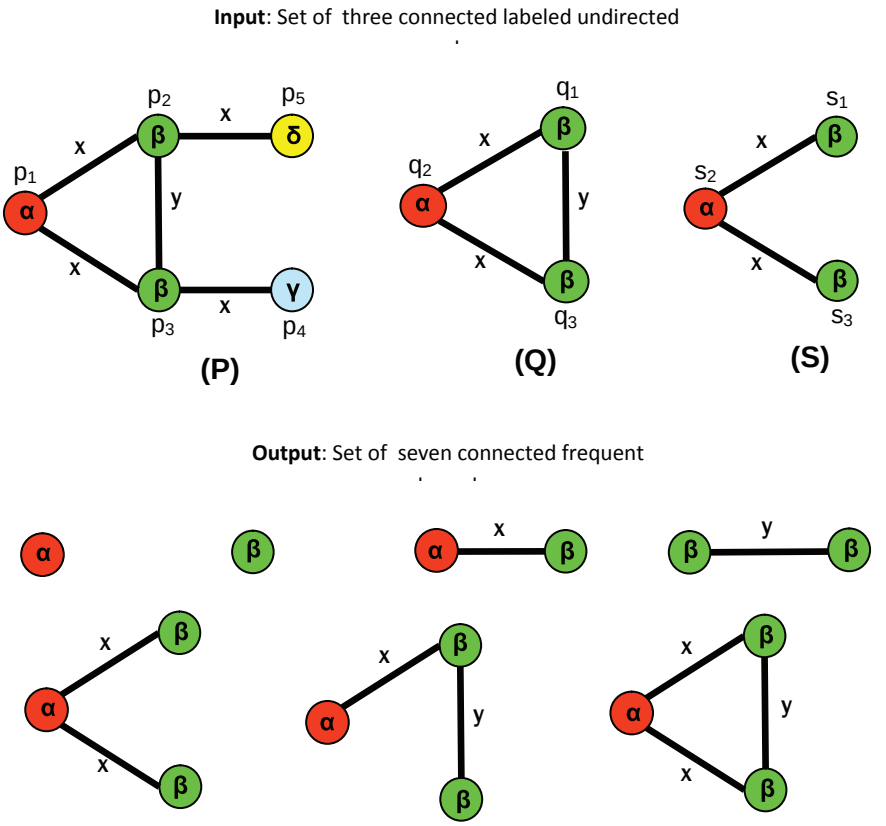
ALGORITHMS FOR GRAPH MINING

The graph is one of the most fundamental constructions studied in mathematics and thus, numerous classes of substructures are targeted by graph mining. These substructures include the *generic subgraph*, *induced subgraph*, *connected subgraph*, (ordered and unordered) *tree* and *path* (see Figure 2). We give the definitions of these substructures in the next paragraph and subsequently present the graph mining algorithms, able to discover all frequent substructures of any kind mentioned earlier.

Following mathematical terminology, a graph is represented as G(V, E, f), where V is a set of vertices, E is a set of edges connecting pairs of vertices and f is a function $f:E\rightarrow VxV$. For instance, in Figure 2 we see that $f(e_1)=(v_1,v_2)$. We say that *GS*(Vs,Es,f) is a *generic subgraph* of G, if $Vs\subset V$, $Es\subset E$ and $v_i,v_j\in Vs$ for all edges $f(e_k)=(v_i,v_j)\in Es$. An *induced subgraph ISG*(Vs,Es,f) of G has a subset of vertices of G and the same edges between pairs of vertices as in G, in other words, $Vs\subset V$, $Es\subset E$ and $\forall v_i,v_j\in Vs$, $e_k=(v_i,v_j)\in Es\Leftrightarrow f(e_k)=(v_i,v_j)\in E$. We say that *CSG*(Vs,Es,f) is a connected subgraph of G, if $Vs\subset V$, $Es\subset E$ and all vertices in Vs are reachable through some edges in Es. An acyclic subgraph of G is called a *tree T*. Finally, a tree of G which does not include any braches is a *path P* in G.

The first algorithm for mining all frequent subgraph patterns is *AGM* (Inocuchi, Washio, & Motoda, 2000, 2003). AGM can mine various types of patterns, namely generic subgraphs, induced subgraphs, connected subgraphs, ordered and unordered trees and subpaths.

Figure 1. Mining frequent labeled undirected graphs.



AGM is based on a labeling of the graph's vertices and edges, a "canonical labeling" (Washio & Motoda, 2003) for the adjacency matrix of the graph, which allows for the unambiguous representation of the graph. The basic principle of AGM is similar to that of Apriori for basket analysis. Starting from frequent graphs, where each graph is a single vertex, the frequent graphs having larger sizes are searched in bottom up manner by generating candidates having an extra vertex.

A similar canonical labeling and the Apriori-style is also followed by *FSG* (Kuramochi & Karypis, 2004b), by its variations like *gFSG* (2002), *HSIGRAM* and *VSIGRAM* (2004), and by the algorithm proposed in (Vanetik, Gudes, & Shimony, 2002).

Finally, based on the same principles as above, (Huan, Wang, & Prins, 2003) proposed an interesting labeling for graphs based on the adjacency matrix representation, which can drastically reduce the computation complexity of the candidate generation phase.

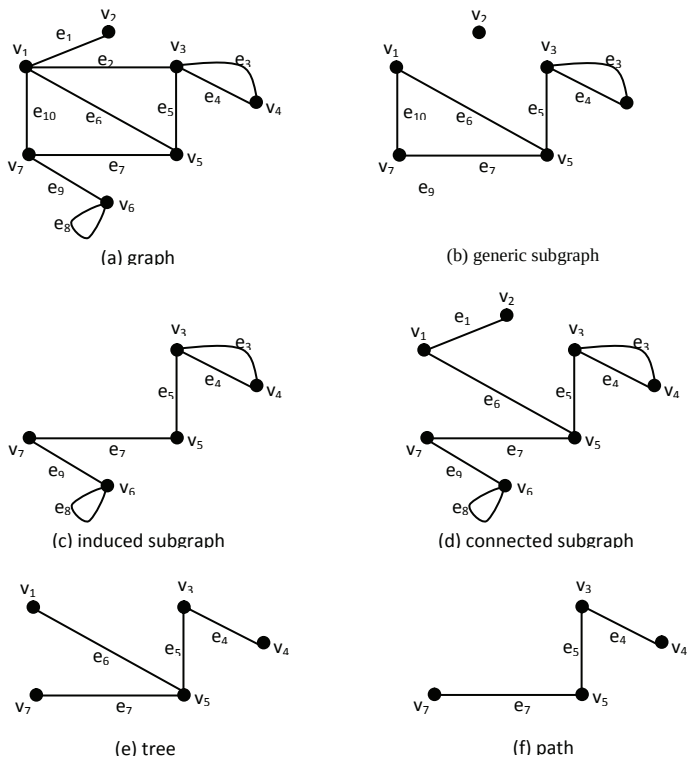
Recently, a depth-first-searching (DFS) "canonical labeling" was introduced by *gSpan* (Yan & Han, 2002) and its variation for mining closed frequent graph patterns, the *CloseGraph* (2003). The main difference of their coding from other approaches is that they use a tree representation of each graph instead of the adjacency matrix to define the code of the graph.

ALGORITHMS FOR TREE MINING

There has been very little work in mining all frequent subtrees; only a handful of algorithms can be found in the literature. Although graph mining algorithms can be applied to this problem as well, they are likely to be too general, since they do not exploit the existence of the root and the lack of cycles. Thus, they are most probably very inefficient.

The first effort towards tree mining was conducted by Ke Wang (Cong, Yi, Liu, & Wang, 2002; Wang & Liu, 2000). Their algorithm is an application of the original level-wise Apriori to the problem of mining frequently occurring collections of paths, where none of them is a prefix of the other and thus they

Figure 2. Characteristic graph substructures.



correspond to trees. Later, (Katsaros, Nanopoulos, & Manolopoulos, 2004) developed a numbering scheme for labeled, ordered trees in order to speed-up the execution of Wang's algorithm, and (Katsaros, 2003) proposed the *DeltaSSD* algorithm to study the efficient maintenance of the discovered tree substructures under database updates.

Departing from the Apriori paradigm, (Zaki, 2002) proposed the *TREEMINER* and (Abe, Kawasoe, Asai, Arimura, & Arikawa, 2002; Asai et al., 2002; Asai, Arimura, Uno, & Nakamo, 2003) proposed the *FREQT* algorithms. These tree mining algorithms are very similar; they are both based on an efficient enumeration technique that allows for the incremental construction of the set of frequent tree patterns and their occurrences level by level. TREEMINER performs a depth-first search for frequent subtrees and uses a vertical representation for the trees in the database for fast support counting. FREQT uses the notion of rightmost expansion to generate candidate trees by attaching nodes only to the rightmost branch of a frequent subtree. Similar, in spirit are the algorithms proposed by (Chi, Yang, & Muntz, 2003, 2004). Finally, Xiao, Yao, Li, and Dunham (2003) proposed a method for discovering only the maximal frequent subtrees using a highly condensed data structure for the representation and finding of the maximal frequent trees of the database.

The tree mining problem is also related to the *tree isomorphism* and *tree pattern matching* problems. Though, the fundamental difference between the tree mining and the other two research problems is the fact that the tree mining algorithms focus on discovering *all* frequent tree substructures, and not only deciding whether or not a particular instance of a tree is "contained" in another larger tree.

FUTURE TRENDS

The field of tree and graph mining is still in its infancy. To date research and development have focused on the discovery of very simple structural patterns. Although, it is difficult to foresee the future directions in the field, because they depend on the application requirements, we believe that the discovery of richer patterns requires new algorithms. For instance, algorithms are needed

for the mining of weighted trees or graphs. Moreover, the embedding of the tree and graph mining algorithms into clustering algorithms will be a very active area for both research and practice.

CONCLUSION

During the past decade, we have witnessed the emergence of the data mining field as a novel research area, investigating interesting problems and developing real-life applications. Initially, the targeted data formats were limited to relational tables, comprised by unordered collections of rows, where each row of the table is treated as a set. Due to the rapid proliferation of many applications from biology, chemistry, bioinformatics and communication networking, whose data model can only be described by a graph or a tree, the research field of *graph* and *tree mining* started to emerge. The field provides many attractive topics for both theoretical and engineering achievements and it is expected to be one of the key fields in data mining research for the years ahead.

KEY TERMS

Closed Frequent Graph: A frequent graph pattern G is *closed* if there exists no proper super-pattern of G with the same support in the dataset.

Correlation: describes the strength or degree of linear relationship. That is, correlation lets us specify to what extent the two variables behave alike or vary together. Correlation analysis is used to assess the simultaneous variability of a collection of variables. For instance, suppose one wants to study the simultaneous changes with age of height and weight for a population. Correlation analysis describes the how the change in height can influence the change in weight.

Embedded Subtree: Let T(N,B) be a tree, where N represents the set of its nodes and B the set of its edges. We say that a tree S(Ns,Bs) is an *embedded subtree* of T provided that: i) $Ns \subseteq N$, ii) $b=(n_x,n_y) \in Bs$ if and only if n_x is an ancestor of n_y in T. In other words, we require that a branch appear in S if and only if the two vertices are on the same path from the root to a leaf in T.

Exploratory Data Analysis (EDA): comprises a set of techniques used to identify systematic relations between variables when there are no (or not complete) a priori expectations as to the nature of those relations.

In a typical exploratory data analysis process, many variables are taken into account and compared, using a variety of techniques in the search for systematic patterns.

Free Tree: Let G be a connected acyclic labeled graph. If we label the leaves (because of its acyclicity, each connected acyclic labeled graph has at least one node which is connected to the rest of the graph by only one edge, that is, a leaf) with zero and the other nodes recursively with the minimal label of its neighbors plus one, then we get an unordered, unrooted tree-like structure, a so-called *free tree*. It is a well-known fact that every free tree has at most two nodes, which minimize the maximal distance to all other nodes in the tree, the so-called *centers*.

Induced Subtree: Let T(N,B) be a tree, where N represents the set of its nodes and B the set of its edges. We say that a tree S(Ns,Bs) is an *induced subtree* of T provided that: i) $Ns \subseteq N$, ii) $b=(n_x,n_y) \subseteq Bs$ if and only if n_x is a parent of n_y in T. Thus, induced subtrees are a specialization of embedded subtrees.

Linear Regression: is used to make predictions about a single value. Simple linear regression involves discovering the equation for a line that most nearly fits the given data. That linear equation is then used to predict values for the data. For instance, if a cost modeler wants to know the prospective cost for a new contract based on the data collected from previous contracts, then s/he may apply linear regression.

Uncertainty Operators in a Many-Valued Logic

INTRODUCTION

This article investigates different tools for knowledge representation and modelling in decision making problems. In this variety of AI systems the experts' knowledge is often heterogeneous, that is, expressed in many forms: numerical, interval-valued, symbolic, linguistic, etc. Linguistic concepts (adverbs, sentences, sets of words…) are sometimes more efficient in many expertise domains rather than precise, interval-valued or fuzzy numbers. In these cases, the nature of the information is qualitative and the use of such concepts is appropriate and usual. Indeed, in the case of fuzzy logic for example, data are represented through fuzzy functions that allow an infinite number of truth values between 0 and 1. Instead, it can be more appropriate to use a finite number of qualitative symbols because, among other reasons, any arbitrary fuzzification becomes useless; because an approximation will be needed at the end anyway; etc. A deep study has been recently carried out about this subject in (Gottwald, 2007).

In this article we propose a survey of different tools manipulating these symbols as well as human reasoning handles with natural linguistic statements. In order to imitate or automatize expert reasoning, it is necessary to study the representation and handling of discrete and linguistic data (Truck & Akdag, 2005; Truck & Akdag, 2006). One representation is the *many-valued logic* framework in which this article is situated.

The many-valued logic, which is a generalization of classical boolean logic, introduces truth degrees which are intermediate between *true* and *false* and enables the partial truth notion representation. There are several many-valued logic systems (Lukasiewicz's, Gödel's, etc.) comprising finite-valued or infinite-valued sets of truth degrees. The system addressed in this article is specified by the use of $\mathcal{L}_M = \{\tau_0,...,\tau_i,...,\tau_{M-1}\}$ [1] a totally ordered finite set[2] of truth-degrees ($\tau_i \leq \tau_j \Leftrightarrow i \leq j$) between τ_0 (false) and τ_{M-1} (true), given the operators $\vee$ (max), $\wedge$ (min) and $\neg$ (negation or symbolic complementation, with $\neg\tau_j = \tau_{M-j-1}$) and the following Lukasiewicz implication $\rightarrow_L$: $\tau_i \rightarrow_L \tau_j = \min(\tau_{M-1}, \tau_{M-1-(i-j)})$

These degrees can be seen as membership degrees: x partially belongs to a multiset[3] A with a degree τ_i if and only if $x \in_{\tau_i} A$. The many-valued logic presented here deals with linguistic statements of the following form: x is v_α A where x is a variable, v_α a scalar adverb (such as "very", "more or less", etc.) and A a gradable linguistic predicate (such as "tall", "hot", "young"...). The predicate A is satisfiable to a certain degree expressed through the scalar adverb v_α. The following interpretation has been proposed (Akdag, De Glas & Pacholczyk, 1992):

x is v_α $A \Leftrightarrow$ "x is A" is τ_α – true

Qualitative degrees constitute a good way to represent uncertain and not quantified knowledge, indeed they can be associated with Zadeh's linguistic variables (Zadeh, 2004) that model approximate reasoning well. Using this framework, several qualitative approaches for uncertainty representation have been presented in the literature. For example, in (Darwiche & Ginsberg, 1992; Seridi & Akdag, 2001) the researchers want to find a model which simulates cognitive activities, such as the management of uncertain statements of natural language that are defined in a finite totally ordered set of symbolic values. The approach consists in representing and exploiting the uncertainty by qualitative degrees, as probabilities do with numerical values. In order to manipulate these symbolic values, four elementary operators are outlined: multiplication, addition, subtraction and division (Seridi & Akdag, 2001). Then two other kinds of operators are given: modification tools based on scales and symbolic aggregators.

BACKGROUND

Extending the work of Akdag, De Glas & Pacholczyk on the representation of uncertainty via the many-valued logic (Akdag, De Glas & Pacholczyk, 1992), several studies have been led where an axiomatic system for symbolic probability theory has been proposed (Seridi & Akdag, 2001; Khayata, Pacholczyk & Garcia, 2002).

The qualitative uncertainty theory we present here takes place between the classical probability theory and possibility theory. The idea is to translate the four basic operations respecting required properties with well-chosen formulas. The qualitative and the numerical models are linked together using the four symbolic operators that compute the qualitative operations.

These works related to the qualitative uncertainty theory have in common the following points:

- They are based on the association "probability degrees / logic": In their work, laws of probabilities are obtained thanks to logical operators.
- They have developed an axiomatic theory, which allows obtaining results either from axioms, or from theorems.
- In addition, they permit the use of uncertainty (and imprecision) expressed in the qualitative form.

The considered qualitative degrees of uncertainty belong to the graduated scale $\mathcal{L}_M$. The first step is to introduce a total order in the scale of degrees. Then in order to be able to translate in symbolic the different axioms and theorems of the classical probability theory, three elementary operators must be defined as in (Darwiche & Ginsberg, 1992). Indeed a symbolic addition (or a symbolic t-conorm, to generalize the addition), a symbolic multiplication (or a symbolic t-norm in order to be able to translate the disconditioning and the independence) and a symbolic division (to translate the conditioning) must be provided.

Moreover, another constraint is introduced: "*it is necessary that if C is the result of the division of A by B then B multiplied by C gives A*" (relationship between the qualitative multiplication and the qualitative division). This intuitive constraint has been proposed for the first time in (Seridi & Akdag, 2001). Another originality lies in the definition of a qualitative subtraction instead of the use (sometimes artificially) of the complementation operator. Thus, a symbolic difference and a symbolic distance are defined to translate both the subtraction and the absolute value of the subtraction.

Formulas for Uncertainty Qualitative Theory

A qualitative multiplication of two degrees τ_α and τ_β is defined by the function MUL from $\mathcal{L}_M \times \mathcal{L}_M$ to $\mathcal{L}_M$ that verifies the properties of a t-norm to which are added the absorbent element τ_0 and the complementarity property: $\text{MUL}(\tau_\alpha,\neg\tau_\alpha) = \tau_0$.

Similarly, a qualitative addition of two degrees τ_α and τ_β is a function ADD from $\mathcal{L}_M \times \mathcal{L}_M$ to $\mathcal{L}_M$ that verifies the properties of a t-conorm to which are added the absorbent element τ_{M-1} and the complementarity property: $\text{ADD}(\tau_\alpha,\neg\tau_\alpha) = \tau_{M-1}$.

The qualitative subtraction of two degrees τ_α and τ_β such that $\tau_\beta \le \tau_\alpha$ is defined by the function SOUS from $\mathcal{L}_M \times \mathcal{L}_M$ to $\mathcal{L}_M$ that verifies the following properties: increasing relatively to the first argument; decreasing relatively to the second argument; SOUS has a neutral element τ_0 and the subtraction of two identical degrees gives the neutral element.

SOUS allows us to define an important axiom linking probability of the union to the probability of the intersection (see U6 below). SOUS corresponds in fact to the bounded difference of Zadeh, defined in the fuzzy logic framework.

The qualitative division of two degrees τ_α and τ_β and such that $\tau_\alpha \le \tau_\beta$ with $\tau_\beta \neq \tau_0$ is defined by the function DIV from $\mathcal{L}_M \times \mathcal{L}_M$ to $\mathcal{L}_M$ that verifies the following properties: increasing relatively to the first argument; decreasing relatively to the second argument; DIV has an absorbent element τ_0 and a neutral element τ_{M-1} and the division of two identical degrees, except for the absorbent element, gives the neutral element (boundary conditions).

Our choices for the four operators are the following:

1. $\text{MUL}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) = \neg(\tau_\alpha \rightarrow_L \neg\tau_\beta) = \tau_\gamma$ therefore $\gamma = \max(\alpha+\beta-(M-1),0)$

2. $\text{ADD}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) = (\neg\tau_\alpha \rightarrow_L \tau_\beta) = \tau_\delta$ therefore $\delta = \min(\alpha+\beta,M-1)$

3. $\text{SOUS}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) = \neg(\tau_\alpha \rightarrow_L \tau_\beta) = \tau_S$ therefore $S = \max(\alpha-\beta,0)$

The 4th Operator

$$\begin{cases} \text{DIV}_{\mathcal{L}}(\tau_0,\tau_\beta) = \text{MUL}_{\mathcal{L}}(\tau_0,\tau_\beta) \text{ if } \tau_\beta \neq \tau_0 \\ \text{DIV}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) = \text{ADD}_{\mathcal{L}}(\tau_\alpha,\neg\tau_\beta) \text{ if } \tau_\alpha \neq \tau_0 \text{ and } \tau_\beta \neq \tau_0 \text{ and } \tau_\alpha \leq \tau_\beta \\ \text{otherwise } \text{DIV}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) \text{ is undefined} \end{cases}$$

We shall also define a fifth operator corresponding to the distance and specified according to SOUS:

$$\text{DIST}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) = \begin{cases} \text{SOUS}_{\mathcal{L}}(\tau_\alpha,\tau_\beta) & \text{if } \tau_\alpha \geq \tau_\beta \\ \text{SOUS}_{\mathcal{L}}(\tau_\beta,\tau_\alpha) & \text{otherwise} \end{cases}$$

Axiomatic System for Qualitative Uncertainty Theory

Inside this qualitative uncertainty concept, a new axiomatic system has been given in (Seridi & Akdag, 2001) by using the predicate ***Inc*** of the many-valued logic. Thus, the proposition "*A* is τ_α–certain" is translated into $Inc(A) = \tau_\alpha$. The first axioms[4] are those proposed in (Akdag, De Glas & Pacholczyk, 1992):

U1. If $\models_{\tau_{M-1}} A$ then $Inc(A) = \tau_{M-1}$
i.e. if *A* is a tautology then *A* is certain
U2. If $\models_{\tau_0} A$ then $Inc(A) = \tau_0$
i.e. if *A* is false then *A* is impossible
U3. If $\models_{\tau_\alpha} A$ then $Inc(\neg A) = \neg\tau_\alpha$
i.e. if *A* is τ_α–certain then $\neg A$ is $\neg\tau_\alpha$–certain
U4. If $A \equiv B$ then $Inc(A) = Inc(B)$
i.e. if *A* is equivalent to *B* then $Inc(A) = Inc(B)$

This permits to have trivial theorems:

T1. If $Inc(A) = \tau_{M-1}$ then $Inc(\neg A) = \tau_0$
T2. If $Inc(A) = \tau_0$ then $Inc(\neg A) = \tau_{M-1}$

Definition. Let *A* and *B* be two quasi-independent events. If $Inc(A) = \tau_\alpha$ and $Inc(B) = \tau_\beta$ then $Inc(A \cap B) = \tau_\gamma$ where $\tau_\gamma = \text{MUL}_{\mathcal{L}}(\tau_\alpha,\tau_\beta)$

We obtain the following axioms:

U5. If $Inc(A) = \tau_\alpha$ and $Inc(B) = \tau_\beta$ and $Inc(A \cap B) = \tau_0$
then $Inc(A \cup B) = \text{ADD}_{\mathcal{L}}(\tau_\alpha,\tau_\beta)$
U6. If $Inc(A) = \tau_\alpha$ and $Inc(B) = \tau_\beta$ and $B \subset A$
then $Inc(A \cap \neg B) = \text{SOUS}_{\mathcal{L}}(\tau_\alpha,\tau_\beta)$
U7. If $Inc(A) = \tau_\alpha$ and $Inc(B) = \tau_\beta$ and $Inc(A \cap B) = \tau_\gamma$
then $Inc(A \cup B) = \text{ADD}_{\mathcal{L}}(\text{SOUS}_{\mathcal{L}}(\tau_\alpha,\tau_\gamma),\tau_\beta)$
U8. If $Inc(A \cap B) = \tau_\gamma$ and $Inc(A) = \tau_\alpha$
then $Inc(B/A) = \text{DIV}_{\mathcal{L}}(\tau_\gamma,\tau_\alpha)$

A particularity of axiom (U7) is that it is necessary to perform first the subtraction then the addition. The goal of this axiomatic system is to show that the chosen symbolic operators permit to demonstrate properties that can be compared to the classical results of probability theory (Seridi & Akdag, 2001). The approach proposed for the representation and management of qualitative uncertainty is in agreement with the intuition, especially through the four symbolic arithmetic operations. Moreover, with its axiomatic of symbolic probabilities, this model constitutes an interesting alternative to the classical probability theory. Advanced theorems of this axiomatic (Truck & Akdag, 2006) permit to manipulate Bayesian networks and to manage uncertainties in Knowledge-Based Systems in case of lack of reliability quantitative estimation. In other terms, they allow us to reason under uncertainty or imprecision. An interesting application of these operators has been proposed in (Revault d'Allonnes, Akdag & Poirel, 2007) where the authors use them to qualify and evaluate an information's certainty based on a confirmation criterion and weighted by its source's credibility.

MAIN FOCUS

In many practical cases, a fixed number of degrees is used (e.g. the set of seven degrees, $\mathcal{L}_7$). Thus, in a reasoning process, some results of a cognitive operator

will be expressible and some others won't, especially when the result is between two consecutive degrees. In this last case, an approximation is needed. Indeed, one cannot express a piece of knowledge with more (or less) precision than the granularity of the range, at this stage. This point is treated in (Truck & Akdag, 2006) where we propose tools to handle this problem.

The issue of data modification has been addressed by several authors. See for example (Bouchon-Meunier & Marsala, 2001; López de Mántaras & Arcos, 2002; Truck, Borgi & Akdag, 2002; Zadeh, 2004; etc.). Zadeh has introduced the notion of linguistic hedges and defined reinforcing and weakening fuzzy modifiers. This notion of modifiers is useful in many fields where the perception plays an important role. For example, in the context of music, López de Mántaras & Arcos have presented a system able to generate expressive music by means of fuzzy modification of parameters (e.g. vibrato, dynamics, rubato...). In the context of color, Aït Younes et al. use fuzzy subsets and modifiers to obtain certain colors in queries for image retrieval (Aït Younes, Truck & Akdag, 2007).

Towards Scales

In another context, Herrera et al. have proposed a pair to represent the modification between two fuzzy subsets (Herrera, Martínez & Sánchez, 2005). This pair composed of a *linguistic term* and a *translation* depends on a certain *hierarchy* or precision level inside a scale of non-uniformly distributed symbols. Several hierarchies are used to express the distribution of symbols in a fuzzy way. In the many-valued logic context, another approach of data modification using uniformly distributed scales has been proposed (Akdag, Truck, Mellouli & Borgi, 2001). These scales take place in the measure theory. Usually the measure scales are divided into four classes: nominal, ordinal, interval and ratio scales (Grabisch, 2001). A nominal scale does not express any value or relationship between variables (except equality). An ordinal scale is a scale on which data is shown simply in order of magnitude. These scales permit the measurement of degrees of difference, but not the specific amount of difference. An interval scale is a scale according to which the differences between values can be quantified in absolute but not relative terms and for which any zero is merely arbitrary. A ratio scale permits the comparison of differences of values. It has a fixed zero value. In (Akdag, Truck, Borgi & Mellouli, 2001) we have proposed *qualitative modifiers* that permit the refinement of a symbolic variable. These modifiers act on degrees as well as on scales themselves and they permit to modify data at will, i.e. to reach the needed level of precision. The scales we use are interval scales since there is no fixed zero value and differences of values cannot always be compared.

The Generalized Symbolic Modifiers

Going from one degree to another implies a change of both the degree and the scale. In particular, it implies a dilation and/or erosion of scales. Thus this permits to obtain modifiers that are functions allowing us to go from a degree to another. These *linguistic symbolic modifiers* have been formalized in (Akdag, Truck, Borgi & Mellouli, 2001): the *generalized symbolic modifiers* (GSMs). Information is converted into sets of ordered degrees attached to variables. The GSMs deal with linguistic expressions such as "much more than"... Three families of GSMs have been proposed: weakening, reinforcing and centring ones. They are characterized through formal definitions and entail an order relation. Thus, they can be presented in a lattice. Moreover, in order to express any kind of modification, it is possible to combine GSMs: mathematical compositions of some specific families of GSMs with others are proposed in (Truck & Akdag, 2005).

In the aforementioned studies, the symbolic degrees all have the same importance. But in many cases, such as opinion polls, weights associated to degrees are usually not the same. Weights may express the confidence or significance level of a judgment. The challenge is to give the most representative judgment.

The Symbolic Weighted Median

In (Truck, Akdag & Borgi, 2003) we have proposed a tool to answer this question: the *symbolic weighted median* (SWM) that gives the emergent element of a set of ordered weighted degrees. The introduced operator is constructed using the generalized symbolic modifiers. Indeed, the SWM gives as a representative element, an element from the initial set of weighted degrees, more or less *modified*. This means that GSMs and SWM are closely related. The SWM satisfies the properties of identity, monotonicity, symmetry, idempotence, compensation, boundary conditions, continuity and counterbalancement.

As mentioned above, the compositions of GSMs permit to express linguistic assertions composed of more than one adverb. Moreover, a certain composition of GSMs can express the result of an aggregation. This explains why computation of the SWM is expressed in terms of the GSMs. When computing the SWM with the GSMs, an association is implicitly done between modifiers and aggregation. Actually this kind of aggregation can be seen as finding a *modification* of an element from the initial set.

The Symbolic Average

Many other kinds of combination operators exist: for example, arithmetic mean, geometric mean, standard deviation... so, according to the same model than above we consider a symbolic average aggregator based on the classical average: the Symbolic Average (SA). In this article, we only focus on a binary SA (BSA) that merges two truth degrees.

According to Dubois & Prade, an averaging operator (or a mean) is a function $\mathcal{A} : [0,1] \times [0,1] \rightarrow [0,1]$ that satisfies (Dubois & Prade, 1985):

i. $x \wedge y \leq \mathcal{A}(x,y) \leq x \vee y$
ii. $\mathcal{A}(x,y) = \mathcal{A}(y,x)$ (commutativity)
iii. $\mathcal{A}$ is increasing and continuous
iv. $\mathcal{A}(x,x) = x$ (idempotency)

Thus in our context the BSA is a function AVE from $\mathcal{L}_M \times \mathcal{L}_M$ to $\mathcal{L}_M$ that verifies the properties above and also the following:

$$\text{DIST}(\text{SOUS}(\tau_i,\text{AVE}(\tau_i,\tau_j)),\text{SOUS}(\text{AVE}(\tau_i,\tau_j)),\tau_j) \leq \tau_1$$

Let $\text{AVE}(\tau_i,\tau_j) = \tau_\mu$. We propose two BSAs ($\text{AVE}_{\mathcal{L}}^{\text{low}}$ and $\text{AVE}_{\mathcal{L}}^{\text{up}}$):

- ***Lower BSA (denoted* $\mathbf{AVE}_{\mathcal{L}}^{\mathbf{low}}$*).***

$\text{SOUS}_{\mathcal{L}}(\tau_i,\text{AVE}_{\mathcal{L}}(\tau_i,\tau_j)) = \text{SOUS}_{\mathcal{L}}(\text{AVE}_{\mathcal{L}}(\tau_i,\tau_j),\tau_j)$ or $\text{SOUS}_{\mathcal{L}}(\tau_i,\text{AVE}_{\mathcal{L}}^{\text{low}}(\tau_i,\tau_j)) = \text{SOUS}_{\mathcal{L}}(\text{AVE}_{\mathcal{L}}^{\text{up}}(\tau_i,\tau_j),\tau_j)$.
Thus $\mu = \lfloor (i+j-1)/2 \rfloor$

- ***Upper BSA (denoted* $\mathbf{AVE}_{\mathcal{L}}^{\mathbf{up}}$*).***

$\text{SOUS}_{\mathcal{L}}(\tau_i,\text{AVE}_{\mathcal{L}}(\tau_i,\tau_j)) = \text{SOUS}_{\mathcal{L}}(\text{AVE}_{\mathcal{L}}(\tau_i,\tau_j),\tau_j)$ or $\text{SOUS}_{\mathcal{L}}(\tau_i,\text{AVE}_{\mathcal{L}}^{\text{up}}(\tau_i,\tau_j)) = \text{SOUS}_{\mathcal{L}}(\text{AVE}_{\mathcal{L}}^{\text{low}}(\tau_i,\tau_j)),\tau_j)$.
Thus $\mu = \lfloor (i+j+1)/2 \rfloor$

We notice that the BSA is equivalent to the SWM when the two truth degrees' weights are equal and when an approximation is *not* needed. It should be advisable that the SA (generalization of the BSA) when computed with more than two degrees, give results different from those of the SWM.

FUTURE TRENDS

Inside this many-valued logic, it would be interesting to provide a complete panel of qualitative operators in order to be able to propose several tools for reasoning under imprecision and uncertainty. Depending on the application (databases, processes control, image processing…) knowledge representation and manipulation will involve the use of one qualitative operator or another.

CONCLUSION

In decision-making problems, the environment is often linguistic. For example, when evaluating the comfort of a room, linguistic terms expressing the "temperature" or the "sound level" such as "warm", "quiet"… are used. In this article, we have outlined a many-valued logic with a finite-valued system that suits well with these kinds of problems. Moreover we have presented several operators that deal with symbols and make computations on the linguistic symbols' indexes. In particular we focused on the four arithmetical operations (addition, subtraction, multiplication and division), on a modification operator and on two aggregators.

KEY TERMS

Generalized Linguistic Modifiers: Linguistic Modifiers are tools that permit to express a more or less important modification on a linguistic value. The Generalized ones allow several kinds of modification (by dilation, erosion or conservation of the scales).

Linguistic Variables: Inside the framework called "Computing with Words", the variables used to manipulate human concepts are the *linguistic variables*.

Many-Valued Logic: A logic with more than two values to express the dependability of objects such as facts, sentences... The notion of partial membership underlies this logic.

Symbolic Aggregation: Permits to combine and summarize symbolic data. New aggregators must be defined because symbolic data can't assume the arithmetical properties of numerical values.

Symbolic Average: An original aggregator that combines symbolic data according to the algorithm of average computation. It also assumes the properties of the classical average.

Symbolic Data: Contains all kinds of data that are not intervals, neither fuzzy nor real numbers. In other words, it contains sentences, adverbs, symbols, words, sets of words, truth degrees, etc.

Symbolic Weighted Median: An aggregator that combines symbolic data according to the algorithm

of the weighted median, but with an original way to express the level of granularity (it uses the generalized symbolic modifiers). It also assumes the properties of the classical weighted median.

ENDNOTES

1 With M a non null positive integer.

2 $\mathcal{L}_M$ can also be considered as a *scale*.

3 A multiset is a generalization of a set: elements may *partially* belong to a multiset (to a certain degree).

4 They allow us to translate: $P(\varnothing) = 0$, $P(\Omega) = 1$, $P(\neg A) = 1 - P(A)$.

A User-Aware Multi-Agent System for Team Building

INTRODUCTION

In this chapter we present a system for the management of team building and team update activities in the current human resource management scenario. The proposed system presents three important characteristics that appear particularly relevant in this scenario. Firstly, it exploits a suitable standard to uniformly represent and handle expert skills. Secondly, it is highly distributed and, therefore, is well suited for the typical organization of the current job market where consulting firms are intermediating most job positions. Finally, it considers not only experts' technical skills but also their social and organizational capabilities, as well as the affinity degree possibly shown by them when they worked together in the past.

BACKGROUND

In the last years job market and organization have undergone deep changes. In fact, centralized job organization, where a company directly recruits its experts and assigns them to its activities, has been substituted by a distributed organization, where a company outsources most of its activities to external consulting firms. These last are often very large and complex; moreover, they frequently share the same clients or, even, the same projects and, consequently, they are enforced to cooperate. In the current human resource management scenario, most of available experts are recruited by these firms that send them to their final clients to run specific project tasks. It often happens that experts belonging to different consulting firms work together in the same project of interest to a final client (Meister, 1997).

In this highly distributed and flexible scenario, team building activities play a crucial role (Becerra & Fernandez, 2006). Interestingly enough, these activities are often known as task allocation activities (Dash, Vytelingum, Rogers, David & Jennings, 2007; Manisterski, David, Kraus & Jennings, 2006; Rahwan, Ramchurn, Dang, Giovannucci & Jennings, 2007). However, in the context of human resource management, team building problem presents some specific features (West, 2003) that make it more difficult and delicate to be handled w.r.t. the more general task allocation problem. Specifically, there are at least three main challenges to face.

The first challenge regards the highly distributed context; in fact, if experts of different consulting firms are enrolled to work together, then centralized team building approaches do not appear adequate.

The second challenge concerns the need of a standard for representing expert skills and capabilities (Hefke & Stojanovic, 2004; Harzallah, Leclere & Trichet, 2002; Biesalski, 2003); in fact, if consulting firms and/or their final clients use different ways to represent the skills of available experts and/or the skills desired for a project, then the comparison of experts and the matching between expert skills and project requirements may become difficult and unclear (Colucci, Di Noia, Di Sciascio, Donini & Ragone, 2007; Hefke & Stojanovic, 2004); as a consequence, there is a high

risk that constructed teams are not adequate for the projects assigned to them and, consequently, that final clients will be unsatisfied.

The third challenge regards the type of expert skills that must be considered during a team construction. In fact, technical skills, even if extremely important, cannot be the only criterion for choosing team members (Coutts & Gruman, 2005; Mehandjiev & Odgers, 1999). Indeed, other skills, such as social and organizational ones, appear equally important (Drach-Zahavy & Somech, 2002). As a confirmation of this claim, it is currently well known that a team wholly composed by technically talented experts is often characterized by a negative form of competition because its members tend to assert themselves each other by nature (LaFasto & Larson, 2001).

MAIN THRUST OF THE CHAPTER

System Overview

This chapter proposes a multi-agent system that exploits the Europass Curriculum Vitae (hereafter, Europass CV) standard to perform team building and team update activities. Europass CV is one of the standards defined by Europass (Europass, 2007); Europass is an initiative of the European Commission for achieving transparency of competencies and qualifications of an individual. Europass CV includes categories for describing past work experiences as well as technical skills and educational attainments; moreover, it records various additional competencies held by an individual, especially his social and organizational skills. The sections and the entries of this standard have been defined in such a way as to guarantee a company or an educational agency to obtain effective and suitable data about a candidate.

For each pair of experts, our system registers also the affinity degree showed by them in the projects where they worked together in the past. A project is represented as a collection of tasks; each task is described by a profile indicating the technical, social and organizational skills it requires to an expert if he wants to be eligible to execute it.

Each time a new team must be built for handling a project, our system generates a set of potentially adequate teams. Candidate teams are built on the basis of project tasks' requirements, as well as on the basis of technical, social and organizational skills of available experts. Once candidate teams have been built, our system selects, among them, that showing the highest value of internal cohesiveness. Our system is also capable of supporting team update activity; the algorithm underlying this task performs those updates that tend to optimize team performance and cohesiveness.

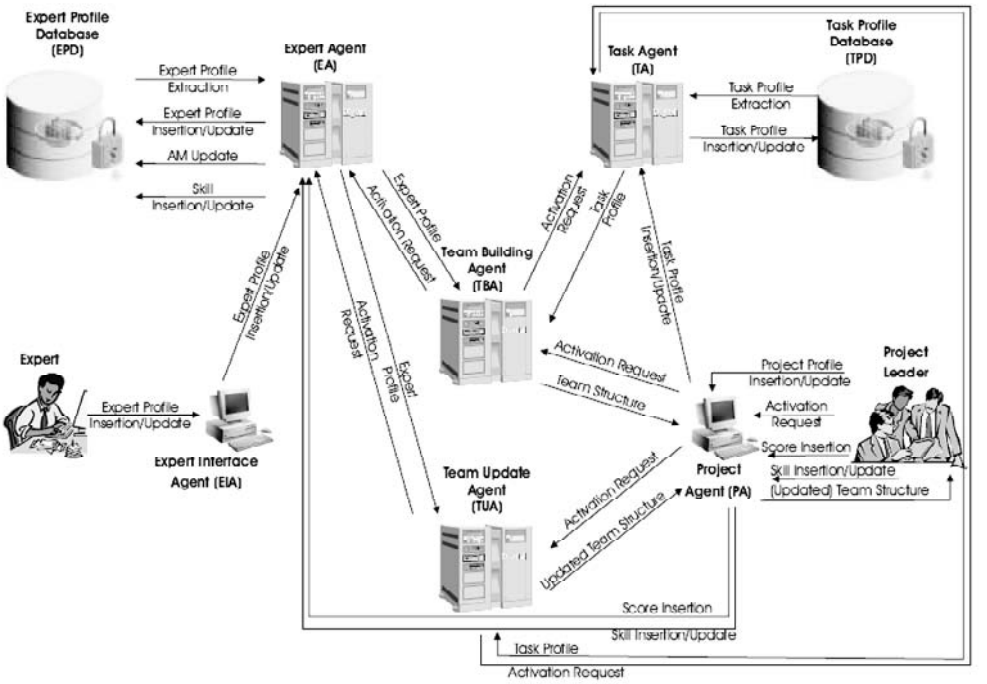
System Architecture and Behaviour

The architecture of our system is shown in Figure 1. It refers to a scenario in which *p* projects, each consisting of a certain number of tasks, must be handled by *n* experts (possibly enrolled from different consulting firms). Each project is uniquely assigned to a *project leader* who is in charge of insuring the fulfillment of its goals.

As shown in Figure 1, our system requires the presence of two databases, namely:

- *The Expert Profile Database* (hereafter, *EPD*); it stores both expert profiles and a support data structure called *Affinity Matrix* (hereafter, *AM*). The profile of an expert registers his personal data, the set of technical skills acquired by him in the past, as well as the set of his social and organizational skills. It is structured and organized according to the directives of the Europass CV standard. *AM* is a $n \times n$ matrix; its generic element *AM[i,l]* consists of a pair $<NP_{il}, S_{il}>$, where: *(i)* NP_{il} represents the overall number of projects on which the experts Exp_i and Exp_l worked together in the past; *(ii)* S_{il} stores the weighted sum of the scores obtained by Exp_i and Exp_l in the past; in other words, $S_{il} = \sum_{k=1}^{NP_{il}} k \cdot sc_{il}^{k}$ where sc_{il}^{k} is a score, belonging to the real interval [0,1], denoting how much Exp_i and Exp_l positively interacted in the fulfillment of the k^{th} project. The presence of *k* in this formula allows our system to give more importance to the scores obtained by Exp_i and Exp_l for their recent collaborations w.r.t. the scores assigned to them for their earliest collaborations.
- *The Task Profile Database* (hereafter, *TPD*); it stores the profiles of the tasks associated with the projects into consideration. The profile of a task registers the set of technical, social and organizational skills necessary to perform it.

Figure 1. Agents, databases, users and information flows involved in our system



The agents operating in our system are the following:

- *The Expert Interface Agent* (hereafter, *EIA*); it supports an expert in the insertion/update of his profile.
- *The Expert Agent* (hereafter, *EA*); it is in charge of handling all activities that someway concern the access to *EPD* data.
- *The Task Agent* (hereafter, *TA*); it supports all activities someway concerning the access to *TPD* data.
- *The Project Agent* (hereafter, *PA*); it supports all activities concerning the management of a project.
- *The Team Building Agent* (hereafter, *TBA*); it is the core of our system since it is in charge of building the best team for a new project. The team building approach performed by *TBA* receives a project consisting of a set $TaskSet = \{Task_1, \ldots, Task_m\}$ of m tasks, and a set $ExpSet = \{Exp_1, \ldots, Exp_n\}$ of n experts such that $m \leq n$. It returns a team represented as a set of m pairs of the form $\langle Exp_i, Task_j \rangle$, indicating that the expert Exp_i has been assigned to the task $Task_j$. The team building algorithm consists of three phases:
  - During the first phase a set *CandTeamSet* of q candidate teams is constructed. This activity is performed by considering how much the technical, social and organizational skills of each expert match with the corresponding requirements of the tasks of *TaskSet*.
  - During the second phase the teams of *CandTeamSet* are ranked according to their relevance to the tasks of *TaskSet*. Specifically, given a candidate team $Team_k = \{\langle Exp_{k1}, Task_{k1} \rangle, \ldots, \langle Exp_{km}, Task_{km} \rangle\}$, a *Team Adequacy* function, assessing the overall adequacy of a team in facing the tasks of *TaskSet*, is computed. This function is defined as follows:

$$TAdq(Team_k) = \frac{\sum_{u=1}^{m} Adq(Exp_{ku}, Task_{ku})}{m}$$

Here, *Adq* measures the adequacy of the expert Exp_{ku} for the task $Task_{ku}$; it is computed as a weighted sum of three functions measuring the adequacy of the technical, social and organizational skills of Exp_{ku} for the technical, social and organizational requirements of $Task_{ku}$. The values of *Adq*

and *TAdq* range in the real interval [0,1]; the higher the value of Team Adequacy is, the more adequate $Team_k$ will be for *TaskSet*. The teams of *CandTeamSet* are ranked according to the corresponding Team Adequacy values in a descending order. After this ranking activity, the top *h* teams are selected and put in a set *TopCandSet*.

- During the third phase a suitable *Cohesiveness* function is computed for each element of *TopCandSet*. The cohesiveness of a team takes the affinities of the corresponding members into account as stored in the Affinity Matrix. After this, the team having the maximum cohesiveness value is selected; if two or more teams have the same maximum cohesiveness value, then one of the teams having the maximum Team Adequacy value is randomly selected among them. It is worth pointing out that the team selected at the end of this phase is not necessarily that having the highest Team Adequacy value, among those of *TopCandSet*. This choice allows the third challenge specified in the Background to be faced.

- *The Team Update Agent* (hereafter, *TUA*); it is in charge of incrementally updating a team for a project. It is activated by a project leader, via the associated *PA*, when it is necessary to carry out some modification on an already existing team. However, it can also autonomously suggest a team update when it has found that a new expert is available for a project and that he can improve the corresponding Team Adequacy without lowering the corresponding cohesiveness. Our Team Update algorithm implements a hill climbing meta-heuristics. Specifically, it constructs a new candidate team by applying on the current team a suitable operation aiming to produce the highest increase of *TAdq* without lowering the Cohesiveness function. In order to preserve the network of human relationships constructed previously, the implemented meta-heuristics must satisfy the following requirements: *(i)* the structure of a team should be preserved as much as possible; *(ii)* a new free expert should not privileged w.r.t. already existing team members.

In order to describe the behaviour of our system, two possible operating scenarios, namely the construction of a new team and the incremental update of an existing one, must be considered.

In the first scenario the behaviour of our system is as follows: at the beginning, a project leader activates the corresponding *PA* and provides information about the new project and the corresponding tasks. *PA* sends task information to *TA* which is in charge of storing it in *TPD*. After this, *PA* activates *TBA* to construct a team for the new project. *TBA* first activates *EA* and requires it the profile of the experts who might be involved in the project; then it activates *TA* and requires the profile of the tasks of the current project. After this, it applies the team building algorithm described above and constructs the team for the project. Finally, it sends its results to the project leader via *PA*. At the end of the project execution, the project leader is required to fill an appraisal form in order to assign an affinity score to each pair of team members. These scores are used to update the Affinity Matrix *AM* stored in *EPD*. Once *AM* has been updated, the project leader must fill a further form to specify, for each expert, the skills acquired or improved by him during the project execution. This information is stored in *EPD* via *PA* and *EA*.

As far as the second reference scenario is concerned, three possible situations might occur, namely: *(i)* an expert leaves a team; *(ii)* a new expert is available and his skills are particularly adequate for one or more project tasks; *(iii)* one or more tasks must be added to the current project. The first and the third situations make the current team obsolete; in these cases *TUA* is activated by the project leader; its behaviour is, therefore, reactive. By contrast, the second situation does not necessarily impose a team update; in fact, it requires to verify the advantages and the disadvantages arising if the new expert would be added to the team; in this situation *TUA* shows a proactive behaviour since it autonomously activates the verification specified above when it recognizes the availability of a new expert. Observe that this team update problem might be seen as a special case of the team building problem examined above; as a consequence, it would be possible to determine a new team configuration by ignoring the existing one. However, in a real scenario, when a team is updated, managers try to minimize the modifications on task assignments; in fact, modifications are performed only if they are strictly necessary or if their advantages significantly exceed their disadvantages.

This reasoning led us to define suitable policies for incrementally updating a team.

Each time a team must be incrementally updated, our system behaves as follows. First *TUA* activates *TA* and requires information about the tasks of the project into consideration; after this, it activates *EA* and requires information about both those experts already assigned to these tasks and those experts currently eligible to be aggregated to the team. Once all profiles are available, *TUA* performs the incremental team update activity. Finally, it sends obtained results to the project leader via *PA*.

Discussion

Our system is capable of facing all the three challenges mentioned in the Background section. First, in order to determine the adequacy of an expert for a task, it examines not only the technical skills of the expert and the technical requirements of the task, but also the corresponding social and organizational skills and requirements. In addition, it does not necessarily select the team showing the highest technical adequacy with the project into examination; by contrast, it selects, among those teams which satisfy the project technical minimal requirements, that showing the highest internal cohesiveness. This behaviour allows our system to face the third challenge mentioned in the Background section.

The exploitation of Europass CV standard favours a uniform representation of both the skills owned by experts and those required by project tasks. Interestingly enough, thanks to the choice of using this standard, skill representation adopted by our system is derived from real life, i.e., from the real format used by experts to represent their curricula vitae. This choice allows our system to face the second challenge mentioned in the Background section.

Finally, multi-agent paradigm is well suited to manage the largely distributed scenario characterizing the current job market. Moreover, the presence of an agent that registers the profiles of available experts and updates them at the end of a project, on the basis of their behaviour, allows our system to fruitfully benefit from the learning capability typical of Intelligent Agents. Finally, message exchanges designed for our system allow experts and project leaders to easily communicate, on the basis of a standard "language" (i.e., the Europass CV standard), in such a way that the former can precisely specify their skills and capabilities to the latter. Thus, our system is capable of facing also the first challenge mentioned in the Background section.

FUTURE TRENDS

As for future trends, a team building system could be integrated in a more complex Enterprise Resource Planning system capable of fully bringing out the human capital of a firm. Specifically, it would be possible to design tools for identifying and tracking "high-potential" employees; this would support firm managers to implement career advancement plans and training courses in such a way as to prepare talented junior experts to assume leadership roles.

In addition, it is possible to design a performance-oriented compensation process, i.e., an incentive mechanism that stimulates employees to achieve ambitious business goals. To this purpose, a team building system could be integrated with sophisticated machine learning techniques, like the Q-Learning algorithm.

CONCLUSION

In this chapter we have proposed a new system aiming to handle team building and team update activities in the current job market scenario. The proposed system exploits the Europass CV standard to uniformly represent and handle expert skills. Moreover, it is highly distributed and, therefore, is particularly adequate to the typical organization of the current job market where consulting firms are currently intermediating most job positions. Finally, it considers not only technical skills of experts but also their social and organizational capabilities, as well as the affinity showed by them in the past.

KEY TERMS

Agent: A computational entity capable of both perceiving dynamic changes in the environment it is operating in and autonomously performing user delegated tasks, possibly by communicating and co-operating with other similar entities.

Europass: An initiative of the European Commission that aims to provide people with tools and services capable of making their skills and competences clearly understood in different countries.

Europass Curriculum Vitae: One of the standards proposed by Europass. It allows the learning and the work experiences of an individual to be specified; the section and the entries of this standard have been defined in such a way as to guarantee a company or an educational agency to obtain effective and suitable data about a candidate.

Multi-Agent System (MAS): A loosely coupled network of software agents that interact to solve problems that are beyond the individual capacities or knowledge of each of them.

Team Building: The process of constructing a team capable of handling a project consisting of one or more tasks.

Team Update: The process of updating an already constructed team.

User Modelling: The process of gathering information specific to each user either explicitly or implicitly.

User Profile: A model of a user representing both her/his preferences and her/his behaviour.

Using Dempster–Shafer Theory in Data Mining

Malcolm J. Beynon
Cardiff University, UK

INTRODUCTION

The origins of Dempster-Shafer theory (DST) go back to the work by Dempster (1967) who developed a system of upper and lower probabilities. Following this, his student Shafer (1976), in their book "A Mathematical Theory of Evidence" developed Dempster's work, including a more thorough explanation of belief functions, a more general term for DST. In summary, it is a methodology for evidential reasoning, manipulating uncertainty and capable of representing partial knowledge (Haenni & Lehmann, 2002; Kulasekere, Premaratne, Dewasurendra, Shyu, & Bauer, 2004; Scotney & McClean, 2003).

The perception of DST as a generalisation of Bayesian theory (Shafer & Pearl, 1990), identifies its subjective view, simply, the probability of an event indicates the degree to which someone believes it. This is in contrast to the alternative frequentist view, understood through the "Principle of I sufficient reasoning", whereby in a situation of ignorance a Bayesian approach is forced to evenly allocate subjective (additive) probabilities over the frame of discernment. See Cobb and Shenoy (2003) for a contemporary comparison between Bayesian and belief function reasoning.

The development of DST includes analogies to rough set theory (Wu, Leung, & Zhang, 2002) and its operation within neural and fuzzy environments (Binaghi, Gallo, & Madella, 2000; Yang, Chen, & Wu, 2003). Techniques based around belief decision trees (Elouedi, Mellouli, & Smets, 2001), multi-criteria decision making (Beynon, 2002) and non-paramnteric regression (Petit-Renaud & Denœux, 2004), utilise DST to allow analysis in the presence of uncertainty and imprecision. This is demonstrated, in this article, with the 'Classification and Ranking belief Simplex' (CaRBS) technique for object classification, see Beynon (2005a).

BACKGROUND

The terminology inherent with DST starts with a finite set of hypotheses Θ (the frame of discernment). A *basic probability assignment* (*bpa*) or mass value is a function m: $2^\Theta \rightarrow [0, 1]$ such that $m(\varnothing) = 0$ ($\varnothing$ - the empty set) and

$$\sum_{A \in 2^\Theta} m(A) = 1$$ (2^Θ - the power set of Θ).

If the assignment $m(\varnothing) = 0$ is not imposed then the transferable belief model can be adopted (Elouedi, Mellouli, & Smets, 2001; Petit-Renaud & Denœux, 2004). Any $A \in 2^\Theta$, for which $m(A)$ is non-zero, is called a focal element and represents the exact belief in the proposition depicted by A. From a single piece of evidence, a set of focal elements and their mass values can be defined a *body of evidence* (BOE).

Based on a BOE, a *belief* measure is a function *Bel*: $2^\Theta \rightarrow [0, 1]$, defined by,

$$Bel(A) = \sum_{A \subseteq B} m(B),$$

for all $A \subseteq \Theta$. It represents the confidence that a specific proposition lies in A or any subset of A. The *plausibility* measure is a function *Pls*: $2^\Theta \rightarrow [0, 1]$, defined by,

$$Pls(A) = \sum_{A \cap B \neq \varnothing} m(B),$$

for all $A \subseteq \Theta$. Clearly $Pls(A)$ represents the extent to which we fail to disbelieve A. these measures are directly related to one another, $Bel(A) = 1 - Pls(\neg A)$ and $Pls(A) = 1 - Bel(\neg A)$, where $\neg A$ refers to its compliment 'not A'.

To collate two or more sources of evidence (e.g. $m_1(\cdot)$ and $m_2(\cdot)$), DST provides a method to combine them, using Dempster's rule of combination. If $m_1(\cdot)$ and $m_2(\cdot)$ are two independent BOEs, then the function $(m_1 \oplus m_2)$: $2^\Theta \rightarrow [0, 1]$, defined by:

$$(m_1 \oplus m_2)(y) = \begin{cases} 0 & y = \varnothing \\ (1-\kappa)^{-1} \sum_{A \cap B = y} m_1(A) m_2(B) & y \neq \varnothing \end{cases}$$

where $\kappa = \sum_{A \cap B = \varnothing} m_1(A) m_2(B)$,

is a mass value with $y \subseteq \Theta$. The term $(1 - \kappa)$, can be interpreted as a measure of conflict between sources. It is important to take this value into account for evaluating the quality of combination: when it is high, the combination may not make sense and possible lead to questionable decisions (Murphy, 2000). One solution to mitigate conflict is to assign noticeable levels of ignorance to all evidence, pertinently the case when low level measurements are considered (Gerig, Welti, Guttman, Colchester, & Szekely, 2000).

To demonstrate the utilization of DST, the example of the murder of Mr. Jones is considered, where the murderer was one of three assassins, Peter, Paul and Mary, so the frame of discernment Θ = {Peter, Paul, Mary}. There are two witnesses. Witness 1, is 80% sure that it was a man, the concomitant BOE, defined $m_1(\cdot)$, includes $m_1(\{\text{Peter, Paul}\}) = 0.8$. Since we know nothing about the remaining mass value it is considered ignorance and allocated to Θ, hence $m_1(\{\text{Peter, Paul, Mary}\}) = 0.2$. Witness 2, is 60% confident that Peter was leaving on a jet plane when the murder occurred, so a BOE defined $m_2(\cdot)$ includes, $m_2(\{\text{Paul, Mary}\}) = 0.6$ and $m_2(\{\text{Peter, Paul, Mary}\}) = 0.4$.

The aggregation of these two sources of information (evidence), using Dempster's combination rule, is based on the intersection and multiplication of focal elements and mass values from the BOEs, $m_1(\cdot)$ and $m_2(\cdot)$. Defining this BOE $m_3(\cdot)$, it can be found; $m_3(\{\text{Paul}\}) = 0.48$, $m_3(\{\text{Peter, Paul}\}) = 0.32$, $m_3(\{\text{Paul, Mary}\}) = 0.12$ and $m_3(\{\text{Peter, Paul, Mary}\}) = 0.08$. This combined evidence has a more spread-out allocation of mass values to varying subsets of the frame of discernment Θ. Further, there is a general reduction in the level of ignorance associated with the combined evidence. In the case of the belief (*Bel*) and plausibility (*Pls*) measures, considering the subset {Peter, Paul}, then $Bel_3(\{\text{Peter, Paul}\}) = 0.8$ and $Pls_3(\{\text{Peter, Paul}\}) = 1.0$. Smets (1990) offers a comparison on a variation of this example with how it would be modelled using traditional probability and the transferable belief model.

A second larger example supposes that the weather in New York at noon tomorrow is to be predicted from the weather today. We assume that it is in exactly one of the three states: dry (D), raining (R) or snowing (S). Hence the frame of discernment is represented by Θ = {D, R, S}. Let us assume that two pieces of evidence have been gathered: *i*) The temperature today is below freezing, and *ii*) The barometric pressure is falling; i.e., a storm is likely. These pieces of evidence are represented by the two BOE, $m_{\text{freeze}}(\cdot)$ and $m_{\text{storm}}(\cdot)$, respectively, and are reported in Table 1.

For each BOE in Table 1, the exact belief (mass) is distributed among the focal elements (excluding ∅). For $m_{\text{freeze}}(\cdot)$, greater mass is assigned to {S} and {R, S}, for $m_{\text{storm}}(\cdot)$, greater mass is assigned to {R} and {R, S}. Assuming that $m_{\text{freeze}}(\cdot)$ and $m_{\text{storm}}(\cdot)$ represent items of evidence which are independent of one another, a new BOE $m_{\text{both}}(\cdot)$ is given by Dempster's rule of combination; with $m_{\text{both}}(\cdot) = m_{\text{freeze}}(\cdot) \oplus m_{\text{storm}}(\cdot)$, shown in Table 2.

The BOE $m_{both}(\cdot)$ represented in Table 2 has a lower level of local ignorance ($m_{both}(\Theta) = 0.0256$), than both of the original BOEs, $m_{\text{freeze}}(\cdot)$ and $m_{\text{storm}}(\cdot)$. Amongst the other focal elements, more mass is assigned to {R} and {S}, a consequence of the greater mass assigned to the associated focal elements in the two constituent

Table 1. Mass values and focal elements for $m_{freeze}(\cdot)$ and $m_{storm}(\cdot)$

BOE	∅	{D}	{R}	{S}	{D, R}	{D, S}	{R, S}	Θ
$m_{\text{freeze}}(\cdot)$	0.0	0.1	0.1	0.2	0.1	0.1	0.2	0.2
$m_{\text{storm}}(\cdot)$	0.0	0.1	0.2	0.1	0.1	0.1	0.3	0.1

Table 2. Mass values and focal elements for the BOE $m_{both}(\cdot)$

BOE	∅	{D}	{R}	{S}	{D, R}	{D, S}	{R, S}	Θ
$m_{\text{freeze}}(\cdot)$	0.0	0.1282	0.2820	0.2820	0.0513	0.0513	0.1795	0.0256

BOEs. The other focal elements all exhibit net losses in their mass values. As with the assassin example, measures of belief (*Bel*) and plausibility (*Pls*) can be found, to offer evidence (confidence) on combinations of states representing tomorrow's predicted weather. For example, the degree of belief in the proposition {R, S} based on the combined evidence, $Bel_{both}(\{R, S\}) = 0.2820 + 0.2820 + 0.1795 = 0.7435$, is substantially higher than that based on $m_{freeze}(\cdot)$ ($Bel_{freeze}(\{R, S\}) = 0.5$) and $m_{storm}(\cdot)$ ($Bel_{storm}(\{R, S\}) = 0.6$).

This section is closed with some cautionary words still true to this day (Pearl, 1990), "Some people qualify any model that uses belief functions as Dempster-Shafer. This might be acceptable provided they did not blindly accept the applicability of both Dempster's rule of combination. Such critical - and in fact often inappropriate - use of such rules explains most of the errors encountered in the so called Dempster-Shafer literature."

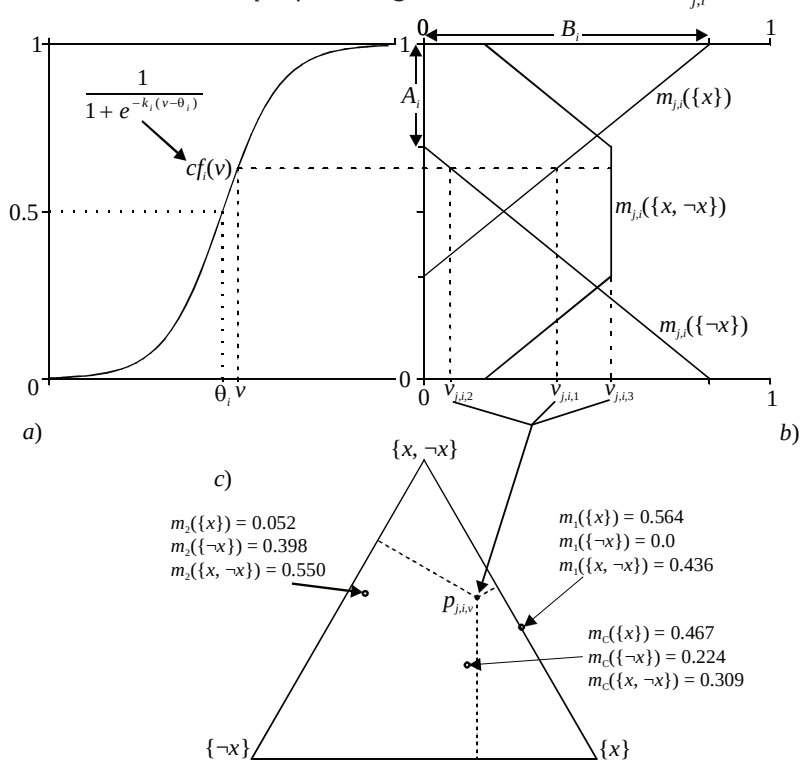
MAIN THRUST

This section outlines one of many different techniques which utilizes DST, called CaRBS (Classification and Ranking Belief System), within a data mining environment. It is a data mining technique for the classification, and subsequent prediction, of objects to a given hypothesis (x) and its compliment ($\neg x$), using a series of characteristic values (Beynon, 2005a). Since its introduction it has been applied in the areas of, credit ratings (Beynon, 2005b), osteoarthritic knee analysis (Jones, Beynon, Holt, & Roy, 2006) and US state long term care systems (Beynon & Kitchener, 2005).

The rudiments of the CaRBS technique are based on DST, and with two exhaustive outcomes works on a binary frame of discernment (BFOD). Subsequently, the aim of the CaRBS is to construct a BOE ($m(\{x\})$) for each characteristic value to quantify its evidential support for the classification of an object to x ($m(\{x\})$), $\neg x$ ($m(\{\neg x\})$) and concomitant ignorance $\{x, \neg x\}$ ($m(\{x, \neg x\})$), see Figure 1 for a brief exposition of its operational stages.

In Figure 1, stage *a*) shows the transformation of a characteristic value $v_{j,i}$ (j^{th} object, i^{th} characteristic) into a confidence value $cf_i(v_{j,i})$, using a sigmoid function, defined with the control variables k_i and θ_i. Stage *b*) transforms a characteristic value's confidence value $cf_i(v_{j,i})$ into a characteristic BOE, defined $m_{j,i}(\cdot)$, made

Figure 1. Stages within the CaRBS technique for a single characteristic value $v_{j,i}$



up of the three mass values, $m_{j,i}(\{x\})$, $m_{j,i}(\{\neg x\})$ and $m_{j,i}(\{x, \neg x\})$, from Gerig, Welti, Guttman, Colchester, & Szekely (2000), they are defined by;

$$m_{j,i}(\{x\}) = \frac{B_i}{1-A_i} cf_i(v_{j,i}) - \frac{A_i B_i}{1-A_i}, \; m_{j,i}(\{\neg x\}) = \frac{-B_i}{1-A_i} cf_i(v_{j,i}) + B_i,$$

and $m_{j,i}(\{x, \neg x\}) = 1 - m_{j,i}(\{x\}) - m_{j,i}(\{\neg x\})$,

where A_i and B_i are two further control variables utilised. When either $m_{j,i}(\{x\})$ or $m_{j,i}(\{\neg x\})$ are negative they are set to zero (before the calculation of $m_{j,i}(\{x, \neg x\})$). The control variable A_i depicts the dependence to $m_{j,i}(\{x\})$ on $cf_i(v_{j,i})$ and B_i is the maximum value assigned to $m_{j,i}(\{x\})$ or $m_{j,i}(\{\neg x\})$. Stage *c*) shows the mass values in a BOE $m_{j,i}(\cdot)$; $m_{j,i}(\{x\})$, $m_{j,i}(\{\neg x\})$ and $m_{j,i}(\{x, \neg x\})$, can be represented as a simplex coordinate (single point - $p_{j,i,v}$) in a simplex plot (equilateral triangle). That is, a point $p_{j,i,v}$ exists within an equilateral triangle such that the least distance from $p_{j,i,v}$ to each of the sides of the equilateral triangle are in the same proportion (ratio) to the values $v_{j,i,1}$, $v_{j,i,2}$ and $v_{j,i,3}$. Each corner (vertex) of the equilateral triangle is labelled with one of the three focal elements in the BOE (in the case of a BFOD – as here).

When the characteristics c_i, $i = 1, \ldots, n_C$, describe an object o_j, $j = 1, \ldots, n_O$, individual characteristic BOEs are constructed. Dempster's rule of combination is used to combine these (independent) characteristic BOEs to produce an object BOE $m_j(\cdot)$, associated with an object o_j and its level of classification to x or $\neg x$. To illustrate the method of combination employed here, two example BOEs, $m_1(\cdot)$ and $m_2(\cdot)$ are considered, with mass values in each BOE given in the vector form $[m_j(\{x\}), m_j(\{\neg x\}), m_j(\{x, \neg x\})]$ as, [0.564, 0.000, 0.436] and [0.052, 0.398, 0.550], respectively. The combination of $m_1(\cdot)$ and $m_2(\cdot)$ is evaluated to be [0.467, 0.224, 0.309], further illustrated in Figure 1*c*, where the simplex coordinates of the BOEs $m_1(\cdot)$ and $m_2(\cdot)$ are shown along with that of the resultant combined BOE $m_C(\cdot)$. Inspection of the simplex coordinate representation of the BOEs shows the effect of the combination of $m_1(\cdot)$ and $m_2(\cdot)$, including a decrease in the ignorance associated with the resultant BOE $m_C(\cdot)$.

The effectiveness of the CaRBS technique is governed by the values assigned to the incumbent control variables, k_i, θ_i, A_i and B_i, $i = 1, \ldots, n$. When the classification of each object is known, the necessary configuration is considered as a constrained optimisation problem. Since these variables are continuous in nature the recently introduced trigonometric differential evolution (TDE) method is utilised (Storn and Price, 1997; Fan and Lampinen, 2003). When the classification of a number of objects to some hypothesis and its complement is known, the effectiveness of a configured CaRBS system can be measured by a defined objective function (OB), two of which are described here.

Beynon (2005a) included an objective function which maximised the certainty in each object's final classification (minimising ambiguity and ignorance). This first OB, defined OB1, uses the mean simplex coordinates of the final object BOEs of objects known to be classified to $\{x\}$ or $\{\neg x\}$, the sets of objects are termed equivalence classes ($E(\cdot)$), defined $E(x)$ and $E(\neg x)$. Then the mean simplex coordinate of an equivalence class $E(\cdot)$ is

$$\left(\frac{1}{|E(\cdot)|} \sum_{o_j \in E(\cdot)} x_j, \frac{1}{|E(\cdot)|} \sum_{o_j \in E(\cdot)} y_j \right),$$

where (x_j, y_j) is the simplex coordinate of the object BOE associated with the object o_j and $|E(\cdot)|$ is the number of objects in the respective equivalence class. An OB traditionally uses a best fitness of zero, it follows the OB1 is seen in Box 1. Where (x_H, y_H) and (x_N, y_N) are the simplex coordinates of the $\{x\}$ and $\{\neg x\}$ vertices in the domain of the simplex plot, respectively. In general, the OB1 has range $0 \leq OB1 \leq \sqrt{(x_N - x_H)^2 + (y_N - y_H)^2}$. For a simplex plot with vertex coordinates (1, 0), (0, 0) and $(0.5, \sqrt{3}/2)$, it is an equilateral triangle with unit side, then $0 \leq OB1 \leq 1$.

The second objective function considered here was constructed in Beynon (2005b), which in contrast to OB1, considers optimisation through the minimisation of only the ambiguity in the classification of the set of objects. For objects in the equivalence classes, $E(x)$ and $E(\neg x)$, the optimum solution is to maximise the difference values $(m_j(\{x\}) - m_j(\{\neg x\}))$ and $(m_j(\{\neg x\}) - m_j(\{x\}))$, respectively. This objective function, defined OB2, where optimisation is minimisation with a lower limit of zero, is given by:

Box 1.

$$\mathrm{OB1}=\frac{1}{2}\left(\sqrt{\left(x_{\mathrm{H}}-\frac{1}{|E(x)|}\sum_{o_j\in E(x)}x_j\right)^2+\left(y_{\mathrm{H}}-\frac{1}{|E(x)|}\sum_{o_j\in E(x)}y_j\right)^2}+\sqrt{\left(x_{\mathrm{N}}-\frac{1}{|E(\neg x)|}\sum_{o_j\in E(\neg x)}x_j\right)^2+\left(y_{\mathrm{N}}-\frac{1}{|E(\neg x)|}\sum_{o_j\in E(\neg x)}y_j\right)^2}\right),$$

$$\mathrm{OB2}=\frac{1}{4}\left(\begin{array}{l}\dfrac{1}{|E(x)|}\displaystyle\sum_{o_j\in E(x)}(1-m_j(\{x\})+m_j(\{\neg x\}))+\\ \dfrac{1}{|E(\neg x)|}\displaystyle\sum_{o_j\in E(\neg x)}(1+m_j(\{x\})-m_j(\{\neg x\}))\end{array}\right).$$

In the limit, each of the difference values, $(m_j(\{x\}) - m_j(\{\neg x\}))$ and $(m_j(\{\neg x\}) - m_j(\{x\}))$, has domain [–1, 1], then $0 \le \mathrm{OB2} \le 1$. It is noted, maximising a difference value such as $(m_j(\{x\}) - m_j(\{\neg x\}))$ only indirectly affects the associated ignorance $(m_j(\{x, \neg x\}))$, rather than making it a direct issue, as with OB1.

To demonstrate the CaRBS technique and the defined objective functions, a small example data set is considered, made up of only ten objects, described by three characteristic values and whether they are associated with x or $\neg x$, their details given in Table 3.

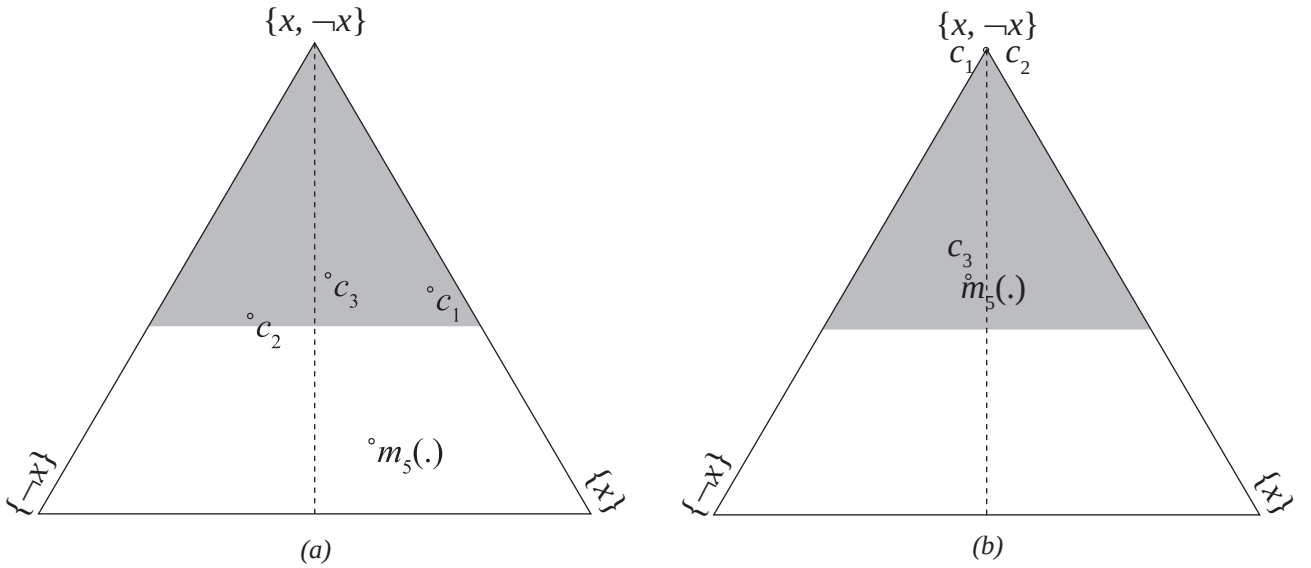
Using the CaRBS technique, to assimilate ignorance in the characteristics (their evidence), an upper bound of 0.6 is placed on each of the B_i control variables. The data set was also standardized (zero mean and unit standard deviation) allowing bounds on the k_i and θ_i control variables of [–3, 3] and [–2, 2], respectively (limited marginal effects on results). To utilize TDE, parameters are required for its operation. Following Fan and Lampinen (2003), amplification control F = 0.99, crossover constant CR = 0.85, trigonometric mutation probability Mt = 0.05 and number of parameter vectors NP = 10 × number of control variables = 90. The TDE was then applied and the subsequent control variables used to construct characteristics BOEs, and post combination an object BOE for each object, see Figure 3.

The first two simplex plots in Figure 3 represent the classification of the object o_5, depending on whether the objective functions, OB1 and OB2, were employed. In each simplex plot, the grey shaded region shows the domain that the characteristic BOEs can exist in. In Figure 3*a*, using OB1, all three characteristics offer evidence to its classification, two of which are offering incorrect evidence (c_1 and c_3), since the object o_5 is known to be associated with $\neg x$, see Table 3. These characteristic BOEs produce an object BOE $m_5(\cdot)$ shown further down, which is nearest the $\{x\}$ vertex, hence incorrectly classifying this object. In Figure 3*b*, using OB2, only c_3 offers evidence, the other two only offer total ignorance, so at the $\{x, \neg x\}$ vertex. The final object BOE is the same as for c_3, but is to the left hand-side

Table 3. Details of example data set

	o_1	o_2	o_3	o_4	o_5	o_6	o_7	o_8	o_9	o_{10}
c_1	0.61	1.00	1.12	1.50	0.62	1.27	0.73	0.51	0.45	0.58
c_2	0.98	0.75	0.68	0.46	0.80	0.64	1.18	0.95	0.85	0.71
c_3	0.02	0.15	0.31	–0.12	0.10	0.03	–0.02	0.11	–0.06	0.03
d_1	$\neg x$	$\neg x$	$\neg x$	$\neg x$	$\neg x$	x	x	x	x	x

Figure 3. Simplex plot based classification details of object o_5 (3a and 3b) and all objects (3c and 3d) using the objective functions OB1 (3a and 3c) and OB2 (3b and 3d)



of the vertical dashed line so is classified to being $\neg x$, which is now a correct classification.

The results in Figures 3*c* and 3*d* show the effect of the different objective functions utilized in the final classification of all ten objects (labels, $\neg x$ - circle and x - cross). While there is more ignorance associated with the results in Figure 3*d*, due to the allowance for ignorance in results (using OB2). While only a small data set, the results to show how the presence of ignorance is an importance issue and may effect the more traditional results of classification accuracy often used.

FUTURE TRENDS

The practical utilization and understanding of DST is a continuing debate, specific to its inherent generality, including the notion of ignorance (partial knowledge). This includes the practical construction of the required BOEs, without the constraining influence of an expert. This is an ardent possibility with the more subjective nature of DST over the relative frequentist form with a Bayesian based approach.

The CaRBS technique discussed is a data mining technique particular to object classification (and ranking). The trigonometric differential evolution method of constrained optimisation mitigates the influence of expert opinion in assigning values to the incumbent control variables. However, the effect of the limiting bounds on these control variables still needs further understanding.

CONCLUSION

The utilization of DST highlights the acknowledgement of the attempt to incorporate partial knowledge (ignorance/uncertainty) in functional data mining. The understanding and formulization of what ignorance is, and how to quantify it in general and application specific studies is an underlying problem. The future will undoubtedly produce directions of appropriate (and inappropriate) definitions to its quantification. Indeed, the results from the different objective functions considered to quantify the configuration undertaken show that allowing or not allowing for the presence of ignorance can affect results.

KEY TERMS

Belief: In Dempster-Shafer theory, a positive function that represents the confidence that a proposition lies in a focal element or any subset of it.

Evolutionary Algorithm: An algorithm that incorporates aspects of natural selection or survival of the fittest.

Focal Element: In Dempster-Shafer theory Subset of the frame of discernment with a positive mass value associated with it.

Frame of Discernment: In Dempster-Shafer theory, a finite non-empty set of hypotheses.

Dempster-Shafer Theory: General methodology, also known as the theory of belief functions, its rudiments are closely associated with uncertain reasoning.

Mass Value: In Dempster-Shafer theory, the level of exact belief in a focal element.

Plausibility: In Dempster-Shafer theory, a positive function that represents the extent to which we fail to disbelieve a proposition described by a focal element.

Using Prior Knowledge in Data Mining

Francesca A. Lisi
Università degli Studi di Bari, Italy

INTRODUCTION

One of the most important and challenging problems in current Data Mining research is the definition of the *prior knowledge* that can be originated from the process or the domain. This contextual information may help select the appropriate information, features or techniques, decrease the space of hypotheses, represent the output in a most comprehensible way and improve the process. Ontological foundation is a precondition for efficient automated usage of such information (Chandrasekaran *et al.*, 1999). An *ontology* is a formal explicit specification of a shared conceptualization for a domain of interest (Gruber, 1993). Among other things, this definition emphasizes the fact that an ontology has to be specified in a language that comes with a *formal semantics*. Due to this formalization ontologies provide the machine interpretable meaning of concepts and relations that is expected when using a semantic-based approach (Staab & Studer, 2004). In its most prevalent use in Artificial Intelligence (AI), an ontology refers to an engineering artifact (more precisely, produced according to the principles of *Ontological Engineering* (Gómez-Pérez *et al.*, 2004)), constituted by a specific vocabulary used to describe a certain reality, plus a set of explicit assumptions regarding the intended meaning of the vocabulary words. This set of assumptions has usually the form of a *First-Order Logic* (FOL) theory, where vocabulary words appear as unary or binary predicate names, respectively called concepts and relations. In the simplest case, an ontology describes a hierarchy of concepts related by subsumption relationships; in more sophisticated cases, suitable axioms are added in order to express other relationships between concepts and to constrain their intended interpretation.

Ontologies can play several roles in Data Mining (Nigro *et al.*, 2007). In this chapter we investigate the use of ontologies as prior knowledge in Data Mining. As an illustrative case throughout the chapter, we choose the task of Frequent Pattern Discovery, it being the most representative product of the cross-fertilization among Databases, Machine Learning and Statistics that has given rise to Data Mining. Indeed it is central to an entire class of descriptive tasks in Data Mining among which Association Rule Mining (Agrawal *et al.*, 1993; Agrawal & Srikant, 1994) is the most popular. A pattern is considered as an intensional description (expressed in a given language $\mathcal{L}$) of a subset of a data set **r**. The support of a pattern is the relative frequency of the pattern within **r** and is computed with the evaluation function *supp*. The task of Frequent Pattern Discovery aims at the extraction of all frequent patterns, i.e. all patterns whose support exceeds a user-defined threshold of minimum support. The blueprint of most algorithms for Frequent Pattern Discovery is the *levelwise search* (Mannila & Toivonen, 1997). It is based on the following assumption: If a generality order $\geq$ for the language $\mathcal{L}$ of patterns can be found such that $\geq$ is monotonic w.r.t. *supp*, then the resulting space $(\mathcal{L}, \geq)$ can be searched breadth-first by starting from the most general pattern in $\mathcal{L}$ and alternating candidate generation and candidate evaluation phases.

BACKGROUND

The use of prior knowledge is already certified in Data Mining. Proposals for taking concept hierarchies into account during the discovery process are relevant to our survey because they can be considered a less expressive predecessor of ontologies, e.g. concept hierarchies are exploited to mine multiple-level association rules (Han & Fu, 1995; Han & Fu, 1999) or generalized association rules (Srikant & Agrawal, 1995). Both extend the levelwise search method so that patterns can refer to multiple levels of description granularity. They differ in the strategy used in visiting the concept hierarchy: the former visits the hierarchy top-down, the latter bottom-up.

The use of prior knowledge is also the distinguishing feature of Inductive Logic Programming (ILP) which was born at the intersection of Machine Learning (more precisely, Inductive Learning) and Logic Programming (Nienhuys-Cheng & de Wolf, 1997). Due to the com-

mon roots between Logic Programming and relational databases (Ceri et al., 1990), ILP has been more recently proposed as a logic-based approach to *Relational Data Mining* (Džeroski, 1996; Džeroski & Lavrač, 2001; Džeroski, 2002). Relational Data Mining is intended to overcome some limits of traditional Data Mining, e.g., in Association Rule Mining, by representing patterns and rules either as Datalog conjunctive queries (Dehaspe & De Raedt, 1997; Dehaspe & Toivonen, 1999) or as tree data structures (Nijssen & Kok, 2001; Nijssen & Kok, 2003). Note that none of these proposals for Association Rule Mining can exploit the semantic information conveyed by concept hierarchies because both adopt a syntactic generality relation for patterns and rules. More generally, prior knowledge in ILP is often not organized around a well-formed conceptual model such as ontologies.

MAIN FOCUS

In this section we consider the task of mining multiple-level association rules extended to the more complex case of having an ontology as prior knowledge and tackled with an ILP approach (Lisi & Malerba, 2004). We focus on the phase of Frequent Pattern Discovery.

The data set **r** must encompass both a database and an ontology, loosely or tightly integrated, so that the semantics can flow from the ontology to the database. To represent one such data set, a logical language that treats relational and structural knowledge in a unified way is necessary. Among the logical languages proposed by Ontological Engineering, *Description Logics* (DLs) are the most widely used (Baader *et al.*, 2007). The relationship between DLs and databases is rather strong. Several investigations have been carried out on the usage of DLs to formalize semantic data models. In these proposals concept descriptions are used to present the schema of a database. Unfortunately, DLs offer a weaker than usual query language. This makes also pure DLs inadequate as a Knowledge Representation (KR) framework in Data Mining problems that exploit ontological prior knowledge. Hybrid languages that integrate DLs and Datalog appear more promising. In (Lisi & Malerba, 2004), the data set **r** is a knowledge base represented according to the KR framework of $\mathcal{AL}$-log (Donini *et al.*, 1998), thus composed of a relational database in Datalog (Ceri *et al.*, 1990) and an ontology in the DL $\mathcal{ALC}$ (Schmidt-Schauss & Smolka, 1991).

The language $\mathcal{L}$ of patterns must be able to capture the semantics expressed in the background ontology. In (Lisi & Malerba, 2004), $\mathcal{L}$ is a language of unary conjunctive queries in $\mathcal{AL}$-log where the distinguished variable is constrained by the reference concept and the other variables are constrained by task-relevant concepts. All these concepts are taken from the underlying ontology, thus they convey semantics. Furthermore, the language is multi-grained in the sense that patterns that can be generated describe data at multiple levels of granularity. These levels refer to levels in the background ontology.

The generality order $\geq$ for the language $\mathcal{L}$ of patterns must be based on a semantic generality relation, i.e. a relation that checks whether a pattern is more general than another with respect to the prior knowledge. Up to now, most algorithms have focussed on a syntactical approach. However, the use of background knowledge would greatly improve the quality of the results. First, patterns and rules which are not equivalent from a syntactical point of view, may be semantically equivalent. Taking into account the semantical relationships between patterns improves the comprehensibility while decreasing the size of the discovered set of patterns. Second, while the use of prior knowledge increases the expressivity and therefore comes with a cost, it also allows to better exploit the benefits of some optimizations. In (Lisi & Malerba, 2004), the space of patterns is structured according to the semantic generality relation of $\mathcal{B}$-subsumption (Lisi & Malerba, 2003a) and searched by means of a downward refinement operator (Lisi & Malerba, 2003b). It has been proved that $\mathcal{B}$-subsumption fulfills the monotonicity requirement of the levelwise search (Lisi & Malerba, 2004). Note that the support of patterns is computed with respect to the background ontology.

This ILP approach to Frequent Pattern Discovery within the KR framework of $\mathcal{AL}$-log has been very recently extended to Cluster Analysis (Lisi & Esposito, 2007).

FUTURE TRENDS

Using ontologies as prior knowledge in Data Mining will become central to any application area where ontologies are playing a key role and Data Mining can be of help to users, notably the *Semantic Web* (Berners-Lee *et al.*, 2001). In particular, the main focus of

the present chapter can contribute to the emerging field of *Semantic Web Mining* (Stumme *et al.*, 2006) with logic-based approaches that fit naturally the KR frameworks adopted in the Semantic Web. At present, the W3C standard mark-up language for ontologies in the Semantic Web, OWL (Ontology Web Language), is based on very expressive DLs (Horrocks *et al.*, 2003). Mark-up languages for Semantic Web rules aimed at extending or integrating ontologies with Logic Programming are still under discussion but are likely to be inspired by $\mathcal{AL}$-log.

Besides the Semantic Web application context, more methodological work on ontologies as prior knowledge in Data Mining is needed. In this sense the work of Lisi and Malerba (2004) can be considered as a source of inspiration. Also it can be considered as a starting point for a broader investigation of implementation solutions that can overcome the efficiency and scalability issues of the ILP approach and pave the way to more extensive experiments on real-world data. We call *Onto-Relational Data Mining* this new frontier of Data Mining that extends Relational Data Mining to account for prior knowledge in the form of ontologies.

CONCLUSION

Data Mining was born at the intersection of three research areas: Databases, Machine Learning, and Statistics. The different perspectives offered by these areas lay strong emphases on different aspects of Data Mining. The emphasis of the Database perspective is on *efficiency* because this perspective strongly concerns the whole discovery process and huge data volume. The emphasis of the Machine Learning perspective is on *effectiveness* because this perspective is heavily attracted by substantive heuristics working well in data analysis although they may not always be useful. As for the Statistics perspective, its emphasis is on *validity* because this perspective cares much for mathematical soundness behind discovery methods. In this chapter we have adopted a broader AI perspective in order to address the issue of *meaningfulness*. In particular we have shown one way of achieving this goal, i.e. to have ontologies as prior knowledge. As a final remark, we would like to stress the fact that the resulting Data Mining algorithms must be able to actually deal with ontologies, i.e. without disregarding their nature of FOL theories equipped with a formal semantics.

KEY TERMS

Description Logics (DL): Family of Knowledge Representation languages which can be used to represent the terminological knowledge of an application domain in a structured and formally well-understood way. The name DL refers, on the one hand, to concept descriptions used to describe a domain and, on the other hand, to the logic-based semantics which can

be given by a translation into First-Order Logic. DLs were designed as an extension to frames and semantic networks, which were not equipped with formal logic-based semantics.

First-Order Logic (FOL): Formal deductive system that extends propositional logic by allowing quantification over individuals of a given domain (universe) of discourse.

Formal Semantics (of a Language): Given by a mathematical model that describes the possible computations described by the language.

Inductive Logic Programming (ILP): Machine Learning approach born at the intersection between Inductive Learning and Logic Programming. Its distinguishing feature is the use of prior knowledge during the learning process. Originally concerned with the induction of rules from examples within the Knowledge Representation framework of Horn Clausal Logic and with the aim of prediction, it has recently broadened its scope of interest in order to investigate Inductive Learning in First-Order Logic fragments other than Horn Clausal Logic (e.g., Description Logics) and induction goals other than prediction (e.g., description).

Knowledge Representation (KR): AI research area that deals with the problem of representing, maintaining and manipulating knowledge about an application domain. Since virtually all AI systems have to address this problem, KR is a crucial AI subfield.

Logic Programming: Declarative programming paradigm based on a subset of First-Order Logic known under the name of Horn Clausal Logic.

Meaningfulness: Semantic validity with respect to prior knowledge.

Ontology: Formal explicit specification of a shared conceptualization for a domain of interest.

Ontological Engineering: The branch of Knowledge Engineering that studies ontologies as engineering artifact. It refers to the set of activities that concern the ontology development process, the ontology life cycle, the methods and methodologies for building ontologies, and the tool suites and languages that support them.

Relational Data Mining: The branch of Data Mining that studies methods and techniques having the relational data model as an invariant of the discovery process.

Semantic Web: An extension of the current World Wide Web in which information is given well-defined meaning, better enabling computers and people to work in cooperation.

Semantic Web Mining: Cross-fertilization between Web Mining and the Semantic Web in order to improve the results of Web Mining by exploiting the new semantic structures in the web, as well as to use Web Mining to help build the Semantic Web.

Utilizing Fuzzy Decision Trees in Decision Making

Malcolm J. Beynon,
Cardiff University, UK

INTRODUCTION

The seminal work of Zadeh (1965), namely fuzzy set theory (FST), has developed into a methodology fundamental to analysis that incorporates vagueness and ambiguity. With respect to the area of data mining, it endeavours to find potentially meaningful patterns from data (Hu & Tzeng, 2003). This includes the construction of if-then decision rule systems, which attempt a level of inherent interpretability to the antecedents and consequents identified for object classification (See Breiman, 2001).

Within a fuzzy environment this is extended to allow a linguistic facet to the possible interpretation, examples including mining time series data (Chiang, Chow, & Wang, 2000) and multi-objective optimisation (Ishibuchi & Yamamoto, 2004). One approach to if-then rule construction has been through the use of decision trees (Quinlan, 1986), where the path down a branch of a decision tree (through a series of nodes), is associated with a single if-then rule. A key characteristic of the traditional decision tree analysis is that the antecedents described in the nodes are crisp, where this restriction is mitigated when operating in a fuzzy environment (Crockett, Bandar, Mclean, & O'Shea, 2006).

This chapter investigates the use of fuzzy decision trees as an effective tool for data mining. Pertinent to data mining and decision making, Mitra, Konwar and Pal (2002) succinctly describe a most important feature of decision trees, crisp and fuzzy, which is their capability to break down a complex decision-making process into a collection of simpler decisions and thereby, providing an easily interpretable solution.

BACKGROUND

The development of fuzzy decision trees brings a linguistic form to the if-then rules constructed, offering a concise readability in their findings (see Olaru & Wehenkel, 2003). Examples of their successful application include in the areas of optimising economic dispatch (Roa-Serpulveda, Herrera, Pavez-Lazo, Knight, & Coonick, 2003) and the antecedents of company audit fees (Beynon, Peel, & Yang, 2004). Even in application based studies, the linguistic formulisation to decision making is continually investigated (Chakraborty, 2001; Herrera, Herrera-Viedma, & Martinez, 2000).

Appropriate for a wide range of problems, the fuzzy decision trees approach (with linguistic variables) allows a representation of information in a direct and adequate form. A linguistic variable is described in Herrera, Herrera-Viedma, & Martinez (2000), highlighting it differs from a numerical one, with it instead using words or sentences in a natural or artificial language. It further serves the purpose of providing a means of approximate characterization of phenomena, which are too complex, or too ill-defined to be amenable to their description in conventional quantitative terms.

The number of elements (words) in a linguistic term set which define a linguistic variable determines the granularity of the characterisation. The semantic of these elements is given by fuzzy numbers defined in the [0, 1] interval, which are described by their membership functions (MFs). Indeed, it is the role played by, and the structure of, the MFs that is fundamental to the utilization of FST related methodologies (Medaglia, Fang, Nuttle, & Wilson, 2002; Reventos, 1999). In this context, DeOliveria (1999) noted that fuzzy systems have the important advantage of providing an insight on the linguistic relationship between the variables of a system.

Within an inductive fuzzy decision tree, the underlying knowledge related to a decision outcome can be can be represented as a set of fuzzy if-then decision rules, each of the form:

If (A_1 is $T_{i_1}^1$) and (A_2 is $T_{i_2}^2$) … and (A_k is $T_{i_k}^k$) then C is C_j,

where $A_1, A_2, .., A_k$ and C are linguistic variables in the multiple antecedents (A_is) and consequent (C) statements, respectively, and $T(A_k) = \{T_1^k, T_2^k, .. T_{S_i}^k\}$ and $\{C_1, C_2, \ldots, C_L\}$ are their concomitant linguistic terms. Each linguistic term T_j^k is defined by the MF $\mu_{T_j^k}(x)$, which transforms a value in its associated domain to a grade of membership value to between 0 and 1. The MFs, $\mu_{T_j^k}(x)$ and $\mu_{C_j}(y)$, represent the grade of membership of an object's attribute value for A_j being T_j^k and C being C_j, respectively (Wang, Chen, Qiang, & Ye, 2000; Yuan & Shaw, 1995).

Different types of MFs have been proposed to describe fuzzy numbers, including triangular and trapezoidal functions (Lin & Chen, 2002; Medaglia, Fang, Nuttle, & Wilson, 2002). Yu and Li (2001) highlight that MFs may be (advantageously) constructed from mixed shapes, supporting the use of piecewise linear MFs. A general functional form of a piecewise linear MF (in the context of a linguistic term), is given by:

$$\mu_{T_j^k}(x)\begin{cases} 0 & \text{if } x \le \alpha_{j,1} \\ 0.5\dfrac{x-\alpha_{j,1}}{\alpha_{j,2}-\alpha_{j,1}} & \text{if } \alpha_{j,1} < x \le \alpha_{j,2} \\ 0.5+0.5\dfrac{x-\alpha_{j,2}}{\alpha_{j,3}-\alpha_{j,2}} & \text{if } \alpha_{j,2} < x \le \alpha_{j,3} \\ 1 & \text{if } x = \alpha_{j,3} \\ 1-0.5\dfrac{x-\alpha_{j,3}}{\alpha_{j,4}-\alpha_{j,3}} & \text{if } \alpha_{j,3} < x \le \alpha_{j,4} \\ 0.5-0.5\dfrac{x-\alpha_{j,4}}{\alpha_{j,5}-\alpha_{j,4}} & \text{if } \alpha_{j,4} < x \le \alpha_{j,5} \\ 0 & \text{if } \alpha_{j,5} < x \end{cases}$$

with the respective *defining values* in list form, $[\alpha_{j,1}, \alpha_{j,2}, \alpha_{j,3}, \alpha_{j,4}, \alpha_{j,5}]$. A Visual representation of this MF form is presented in Figure 1, which elucidates its general structure along with the role played by the respective sets of defining values.

The MF form presented in Figure 1 shows how the value of a MF is constrained within 0 and 1. The implication of the specific defining values is also illustrated, including the idea of associated support, the domain $[\alpha_{j,1}, \alpha_{j,5}]$ in Figure 1. Further, the notion of dominant support can also be considered, where a MF is most closely associated with an attribute value, the domain $[\alpha_{j,2}, \alpha_{j,4}]$ in Figure 1 (see Kovalerchuk & Vityaev, 2000).

Also included in Figure 1, using dotted lines are neighbouring MFs (linguistic terms), which collectively would define a linguistic variable, describing a continuous attribute. To circumvent the influence of expert opinion in analysis, the construction of the MFs should be automated. On this mater, DeOliveria (1999) considers the implication of Zadeh's principle of incompatibility - that is, as the number of MFs increase, so the precision of the system increases, but at the expense of decreasing relevance.

MAIN THRUST

Formulization of Fuzzy Decision Tree

The first fuzzy decision tree reference is attributed to Chang and Pavlidis (1997). A detailed description on the concurrent work of fuzzy decision trees is presented in Olaru & Wehenkel (2003). It highlights how methodologies include the fuzzification of a crisp decision tree post its construction (Pal & Chakraborty, 2001), or approaches that directly integrate fuzzy techniques during the tree-growing phase. The latter formulization is described here, with the inductive method proposed by Yuan and Shaw (1995) considered, based on measures of cognitive uncertainties.

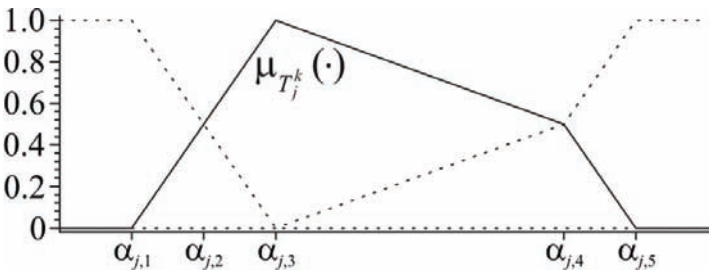
A MF $\mu(x)$ from the set describing a fuzzy linguistic variable Y defined on X, can be viewed as a possibility distribution of Y on X, that is $\pi(x) = \mu(x)$, for all $x \in X$ the values taken by the objects in U (also normalized so $\max_{x \in X}\pi(X) = 1$). The possibility measure $E_\alpha(Y)$ of ambiguity is defined by $E_\alpha(Y) = g(\pi) = \sum_{i=1}^{n}(\pi_i^* - \pi_{i+1}^*)\ln[i]$, where $\pi^* = \{\pi_1^*, \pi_2^*, \ldots, \pi_n^*\}$ is the permutation of the normalized possibility distribution $\pi = \{\pi(x_1), \pi(x_2), \ldots, \pi(x_n)\}$, sorted so that $\pi_i^* \ge \pi_{i+1}^*$ for $i = 1, .., n$, and $\pi_{i+1}^* = 0$. In the limit, if $\pi_2^* = 0$, then $E_\alpha(Y) = 0$, indicates no ambiguity, whereas if $\pi_n^* = 1$, then $E_\alpha(Y) = \ln[n]$, which indicates all values are fully possible for Y, representing the greatest ambiguity.

The ambiguity of attribute A (over the objects $u_1, .., u_m$) is given as:

$$E_\alpha(A) = \frac{1}{m}\sum_{i=1}^{m} E_\alpha(A(u_i)),$$

where

Figure 1. Definition of a piecewise linear MF (including defining values)



$$E_\alpha(A(u_i)) = g(\mu_{T_s}(u_i) \Big/ \max_{1 \le j \le s}(\mu_{T_j}(u_i))),$$

with $T_1, \ldots, T_s$ the linguistic terms of an attribute (antecedent) with m objects. When there is overlapping between linguistic terms (MFs) of an attribute or between consequents, then ambiguity exists.

For all $u \in U$, the intersection $A \cap B$ of two fuzzy sets is given by $\mu_{A \cap B} = \min[\mu_A(u), \mu_B(u)]$. The fuzzy subsethood $S(A, B)$ measures the degree to which A is a subset of B, and is given by,

$$S(A, B) = \sum_{u \in U} \min(\mu_A(u), \mu_B(u)) \Big/ \sum_{u \in U} \mu_A(u).$$

Given fuzzy evidence E, the possibility of classifying an object to the consequent C_i can be defined as,

$$\pi(C_i|E) = S(E, C_i) / \max_j S(E, C_j),$$

where the fuzzy subsethood $S(E, C_i)$ represents the degree of truth for the classification rule ('if E then C_i'). With a single piece of evidence (a fuzzy number for an attribute), then the classification ambiguity based on this fuzzy evidence is defined as: $G(E) = g(\pi(C|E))$, which is measured using the possibility distribution $\pi(C|E) = (\pi(C_1|E), \ldots, \pi(C_L|E))$.

The classification ambiguity with fuzzy partitioning $P = \{E_1, \ldots, E_k\}$ on the fuzzy evidence F, denoted as $G(P|F)$, is the weighted average of classification ambiguity with each subset of partition:

$$G(P|F) = \sum_{i=1}^{k} w(E_i|F) G(E_i \cap F),$$

where $G(E_i \cap F)$ is the classification ambiguity with fuzzy evidence $E_i \cap F$, and where $w(E_i|F)$ is the weight which represents the relative size of subset $E_i \cap F$ in F:

$$w(E_i|F) = \sum_{u \in U} \min(\mu_{E_i}(u), \mu_F(u)) \Big/ \sum_{j=1}^{k} \left(\sum_{u \in U} \min(\mu_{E_j}(u), \mu_F(u)) \right).$$

In summary, attributes are assigned to nodes based on the lowest level of classification ambiguity. A node becomes a leaf node if the level of subsethood is higher than some truth value β assigned to the whole of the fuzzy decision tree. The classification from the leaf node is to the decision group with the largest subsethood value. The truth level threshold β controls the growth of the tree; lower β may lead to a smaller tree (with lower classification accuracy), higher β may lead to a larger tree (with higher classification accuracy).

Illustrative Application of Fuzzy Decision Tree Analysis to Audit Fees Problem

The data mining of an audit fees model may be useful to companies in assessing whether the audit fee they are paying is reasonable. In this analysis, a sample of 120 UK companies is used for training (growing) a fuzzy decision tree (Beynon, Peel, & Tang, 2004).

The variables used in this study, are the decision attribute, AFEE: Audit fee (£000's) and condition attributes; SIZE: Sales (£000's), SUBS: Number of subsidiaries, FORS: ratio of foreign to total subsidiaries, GEAR: Ratio of debt to total assets, CFEE: Consultancy fees (£000's), TOTSH: proportion of shares held by directors and substantial shareholders, BIG6: 1 = Big 6 auditor, zero otherwise, LOND: 1 = audit office in London, zero otherwise.

The construction of the MFs (their defining values), which define the linguistic terms for a continuous attribute (linguistic variable) is based on an initial intervalisation of their domains. Then the subsequent

construction of estimated distributions of the values in each defined interval, see Figure 2.

In Figure 2(left), the decision attribute AFEE is intervalized, and three estimated distributions constructed (using probability distribution functions – *pdf*s). Using the centre of area of a distribution to denote an $a_{j,3}$ defining values and the interval boundary values the respective $a_{j,2}$ and $a_{j,4}$, the concomitant piecewise linear MFs are reported in Figure 2(right). Their labels, L, M and H, denote the linguistic terms, low, medium and high, for AFEE. Similar sets of MFs (linguistic variables) can be defined for the six continuous condition attributes, see Figure 3.

The series of linguistic variables (Figure 2 and 3) and the binary variables BIG and LOND are fundamental to the construction of a fuzzy decision tree for the audit fee model. The inductive fuzzy decision tree method is applied to the data on audit fees previously described, with a minimum "truth level" (β) of 0.80 required for a node to be a leaf (end) node, the complete tree is reported in Figure 4.

The fuzzy decision tree in Figure 4 indicates that a total of 21 leaf nodes (fuzzy if-then rules) were established. To illustrate, the rule labelled **R1** interprets to:

If SALES = L, CFEE = L and SUBS = M, then AFEE = M with truth level 0.9273

Or (equivalently):

For a company with low sales, low consultancy fees and a medium number of subsidiaries, then a low level of audit fees is expected with minimum truth level 0.9273

The fuzzy decision tree reported in Figure 4 as well as elucidating the relationship between audit fees (AFEE) and company characteristics can also be utilised to make predictions (matching) on the level of AFEE on future companies, not previously considered. The procedure (Wang et al., 2000), is as follows: *i*) Matching starts from the root node and ends at a leaf node along the branch of the maximum membership, *ii*) If the maximum membership at the node is not unique, matching proceeds along several branches, and *iii*) The decision class with the maximum degree of truth from the leaf nodes is then assigned the classification (e.g., L, M or H) for the associated rule.

FUTURE TRENDS

The ongoing characterization of data mining techniques in a fuzzy environment identifies the influence of its incorporation. The theoretical development of fuzzy set theory will, as well as explicit fuzzy techniques, continue to bring the findings from analysis nearer to the implicit human decision making.

Central to this is the linguistic interpretation associated with fuzzy related membership functions (MFs). There is no doubt their development will continue, including their structure and number of MFs to describe a linguistic variable. This is certainly true for the specific area of fuzzy decision trees, where the fuzzy if-then rules constructed offer a succinct elucidation to the data mining of large (and small) data sets.

The development of fuzzy decision trees will also include the alternative approaches to pruning, already considered in the non-fuzzy environment, whereby the branches of a decision tree may be reduced in size to offer even more general results. Recent attention has been towards the building of ensemble of classifiers. Here this relates to random forests (Breiman, 2001), whereby a number of different decision trees are constructed, subject to a random process. This can also include the use of techniques such as neural networks (Zhou & Jiang, 2003).

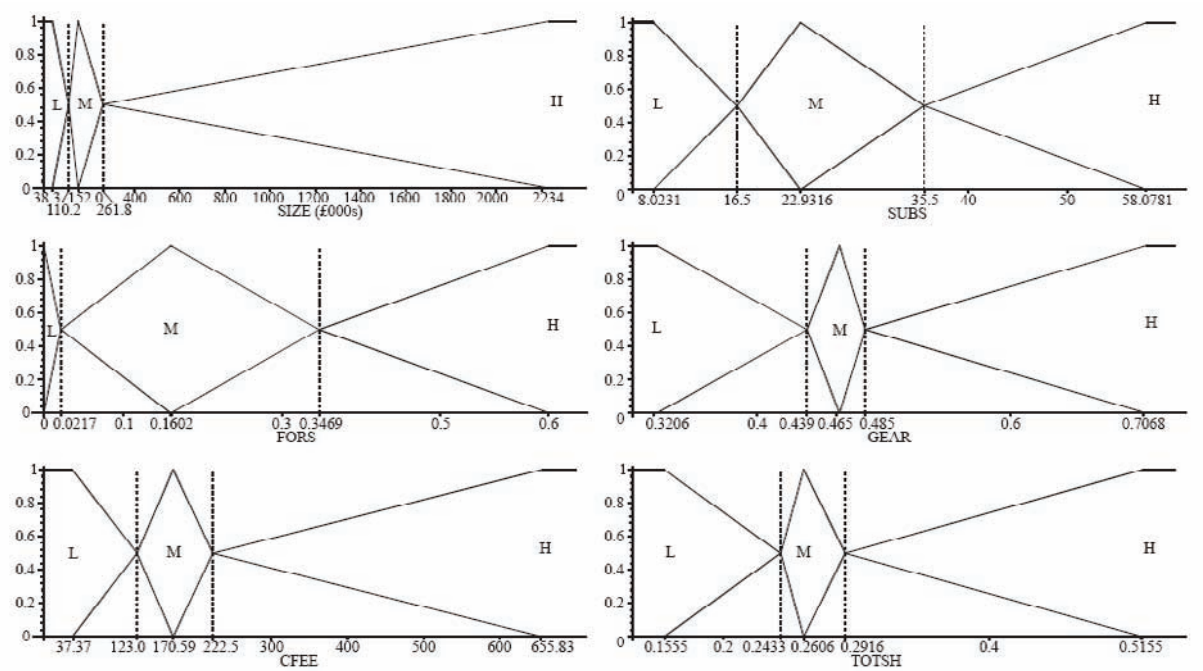

Figure 4. Complete fuzzy decision tree for audit fees problem

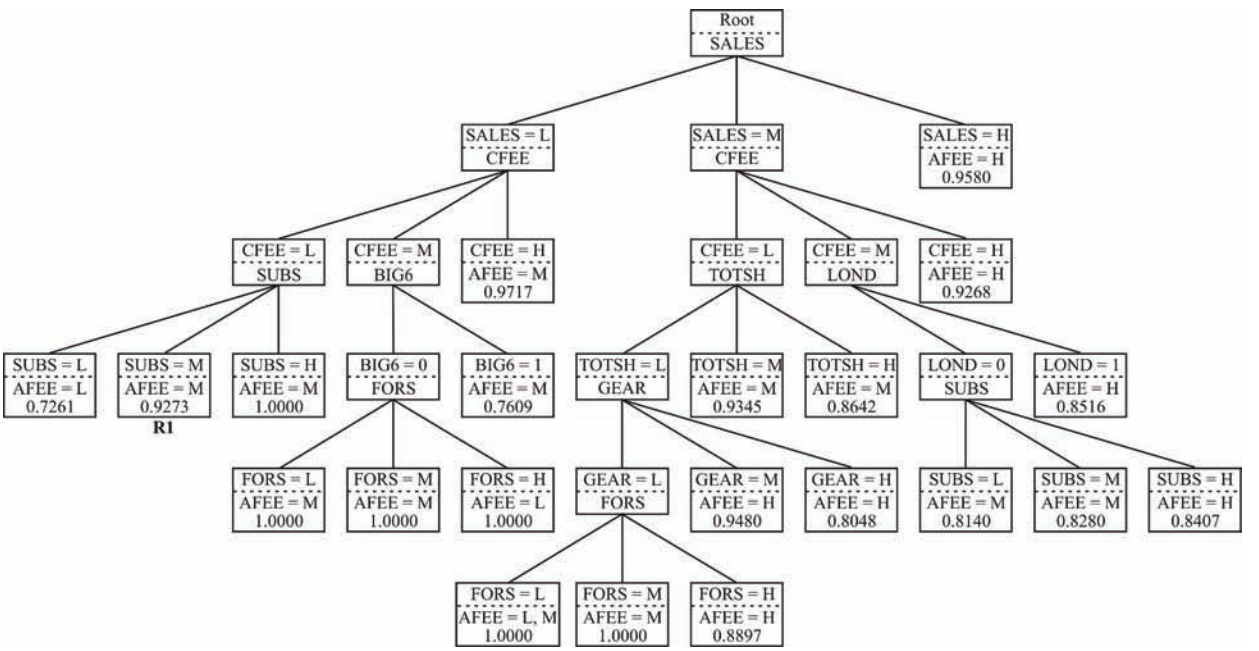

CONCLUSION

Within the area of data mining, the increased computational power (speed) available has reduced the perceived distance (relationship) between the original data and the communication of the antecedents and consequent to the relevant decision problem. As a tool for data mining, fuzzy decision trees exhibit the facets necessary for meaningful analysis. These include the construction of if-then decision rules to elucidate the warranted relationship. The fuzzy environment offers a linguistic interpretation to the derived relationship.

KEY TERMS

Antecedent: An antecedent is a driving factor in an event. For example, in the relationship "When it is hot, Mary buys an ice-scream", "it is hot" is the antecedent.

Branch: A single path down a decision tree, from root to a leaf node, denoting a single if-then rule.

Consequent: A consequent follows as a logical conclusion to an event. For example, in the relationship "When it is hot, Mary buys an ice-scream", "buys an ice-scream" is the consequent.

Decision Tree: A tree-like way of representing a collection of hierarchical rules that lead to a class or value.

Induction: A technique that infers generalizations from the information in the data.

Leaf: A node not further split – the terminal grouping – in a classification or decision tree.

Linguistic term: One of a set of linguistic terms which are subjective categories for a linguistic variable, each described by a membership function.

Linguistic variable: A variable made up of a number of words (linguistic terms) with associated degrees of membership towards them.

Node: A junction point in a decision tree, which describes a condition in an if-then rule.

Variable Length Markov Chains for Web Usage Mining

José Borges
School of Engineering, University of Porto, Portugal

Mark Levene
Birkbeck, University of London, UK

INTRODUCTION

Web usage mining is usually defined as the discipline that concentrates on developing techniques that model and study users' Web navigation behavior by means of analyzing data obtained from user interactions with Web resources; see (Mobasher, 2006; Liu, 2007) for recent reviews on web usage mining. When users access Web resources they leave a trace behind that is stored in log files, such traces are called *clickstream* records. Clickstream records can be preprocessed into time-ordered sessions of sequential clicks (Spiliopoulou et al., 2003), where a *user session* represents a *trail* the user followed through the Web space. The process of session reconstruction is called *sessionizing*.

Understanding user Web navigation behavior is a fundamental step in providing guidelines on how to improve users' Web experience. In this context, a model able to represent usage data can be used to induce frequent navigation patterns, to predict future user navigation intentions, and to provide a platform for adapting Web pages according to user specific information needs (Anand et al., 2005; Eirinaki et al., 2007). Techniques using association rules (Herlocker et al., 2004) or clustering methods (Mobasher et al., 2002) have been used in this context. Given a set of transactions clustering techniques can be used, for example, to find user segments, and association rule techniques can be used, for example, to find important relationships among pages based on the users navigational patterns. These methods have the limitation that the ordering of page views is not taken into consideration in the modeling of user sessions (Liu, 2007). Two methods that take into account the page view ordering are: tree based methods (Chen et al., 2003) used for prefetching Web resources, and Markov models (Borges et al., 2000; Deshpande et al., 2004) used for link prediction. Moreover, recent studies have been conducted on the use of visualization techniques for discovering navigational trends from usage data (Chen et al., 2007a; Chen et al., 2007b).

BACKGROUND

In (Mobasher, 2006) a review of Web usage mining methods was given and Markov models were discussed as one of the techniques used for the analysis of navigational patterns. In fact, *Markov models* provide an effective way of representing Web usage data, since they are based on a well established theory and provide a compact way of representing clickstream records. Markov models provide the means for predicting a user's next link choice based on his previous navigation trail (Dongshan et al., 2002; Deshpande et al., 2004), and as a platform for inducing user *frequent trails* (Borges et al., 2000).

In a first-order Markov model each Web page is represented by a state. In addition, a *transition probability* between two states represents the estimated probability (according to past usage) of viewing the two connected states in a sequence. Each user session is individually processed to count the number of times each page was visited and the number of times each pair of pages was viewed in a sequence, that is, the number of times a transition was followed. The model is built incrementally by processing the entire collection of user sessions. The transition probability between every pair of connected pages is estimated by the proportion of times the corresponding link was followed after viewing the anchor page. The ratio between the number of times a page was viewed and the total number of page views gives the probability estimate for a user choosing the corresponding page from the set of all pages in the site; we call this probability the *initial probability* of a state. The probability estimate of a trail is given by

the product of the initial probability of the first state in the trail and the probability of the traversed links, that is, the transition probabilities.

We note that, as an alternative for modeling a page as a state it is possible to group pages into categories, for example based on their content. In such a scenario each state corresponds to a Web page category, and state transitions model the user's navigation through page categories. In addition, in the case of Web sites composed of pages dynamically built from database queries, each state will correspond to a query. In this case the user's navigation through the content requests is being modeled rather than the navigation through the content that has been viewed. Finally, for Web sites in which page content changes frequently, mechanism that deal with concept drift, such as the use of a sliding window (Koychev, 2007), can be utilized in order to take into account the change of users' behavior over time.

MAIN FOCUS

Building a Variable Length Markov Chain

A first-order Markov model has the limitation of taking into account only the last viewed page when providing the next link choice prediction probability. Thus, it assumes that user navigation options are influenced only by the current page being viewed. To tackle this limitation a method based on building a sequence of higher-order Markov models and a technique to choose the best model to use in each case (Deshpande et al., 2004) has been proposed. However, we stress that the amount of navigation history a user takes into account when deciding which page to visit next, varies from site to site or even from page to page within a given site. Thus, a method that produces a single model representing the variable length history of pages is potentially valuable for studying user Web navigation behavior.

A Variable Length Markov Chain (VLMC) is a Markov model extension that allows variable length navigation history to be captured within a single model (Bejerano, 2004), and a method that transforms a first-order Markov model into a VLMC was presented in (Borges et al., 2005). The method makes use of a clustering-based *cloning* operation that duplicates states having in-paths inducing distinct conditional probabilities for subsequent link choices.

An n-order VLMC model is obtained by upgrading the corresponding previous-order model; for example, a second-order VLMC is obtained by upgrading a first-order model. The method evaluates one state at a time, measuring the accuracy with which n-order conditional probabilities are represented by the (n-1)-order model. From the input data, the n-order conditional probabilities are induced and compared to the (n-1)-order conditional probabilities represented by the model. If a state is shown to be inaccurate, its accuracy in representing the outlinks' transition probabilities can be increased by separating the in-paths to the state that correspond to different conditional probabilities. Thus, a state that is not accurately representing n-order conditional probabilities is cloned; the number of clones is determined by the required precision (set by a parameter) and a clustering technique that groups in-paths corresponding to similar conditional probabilities is used. As a result we obtain a model in which a transition probability between two states takes into account the path users followed to reach the anchor state prior to choosing the outlink corresponding to the transition.

We note that, when evaluating the accuracy of a state in a n-order model all n-length paths to that state are evaluated, thus, long sessions are pre-processed into (n+1)-grams whose corresponding conditional probabilities are evaluated in sequence. Sessions holding cycles are dealt with in the same way.

In Figure 1 we give a brief example to illustrate the method used to construct a first-order model from a collection of sessions and the resulting second-order model. On the left we present a collection of sessions and the corresponding frequency of occurrence, and, in the middle, we present the first-order model resulting from the sessions. Next to a link we show the number of times the link was followed and the corresponding estimated transition probability. According to the input data, the probability of the next link choice when viewing page D depends on the preceding page, thus, state D is set to be cloned. A clustering method identifies the estimated conditional probabilities from A and B to be closer, and therefore they are assigned to the same state; the conditional probabilities from C are kept separate. Transition probabilities from D and D' are more accurate in the resulting second-order model and in case higher accuracy is need more clones will be created.

EVALUATING VLMC MODELS

Several methods have been proposed and experiments conducted, to evaluate Variable Length Markov Chains in the context of Web usage mining. In (Borges et al., 2007a) two methods were presented that focus on testing the predictive power of a VLMC.

The first method is based on a $\chi 2$ (**Chi**-squared) statistical test that measures the distance between the probability distribution estimated by the model built from the full collection of sessions and the distribution estimated by the model induced from a subset of the collection. K-fold *cross validation* is used for building the two competing models: a model from (k-1) folds of the data set and a model from the full data set. The model obtained from the full data set represents the ground truth, the aim being to assess how well the model build from (k-1) folds can predict the unseen events in the remaining fold. A statistical test is used to compare the probability distributions of the predictions given by the two models concerned, and thus to evaluate a VLMC model's ability to generalize for unseen trails. Moreover, the result of the test can be used to evaluate the length of memory required to model users' navigation sessions.

The second method presented in (Borges et al., 2007a) evaluates a VLMC model's ability to predict the last page of a navigation session based on the preceding sequence of page views. The collection of input sessions is split into a training set and a test set, and a VLMC model is induced from the training set. Since results in previous experiments revealed a small variation among folds we decided to use a standard (70/30) training and test set split for this experiments. Then, for each session in the test set we use the VLMC model to estimate the probability of a user visiting the last page on the trail after having followed the preceding pages. The prediction accuracy is measured by the rank of the last page of the trail (the prediction target) among the ordered set of predictions given by the model; the higher the rank of the prediction target the better the prediction provided by the model. The average prediction ranking is returned as the overall metric.

In (Borges et al., 2007b) a technique is presented to measure the summarization ability of a VLMC model. The *Spearman footrule* metric (Fagin et al., 2003) is used to assess the accuracy with which a VLMC represents the information content of a collection of user sessions. For example, in order to measure how well a second-order VLMC model represents user trails having length four (i.e. a third-order model), the method collects from the input sessions all sequences of four pages ranked by frequency count. Then, an algorithm is used that gathers from the VLMC model the set of length-four trails ranked by the corresponding estimated traversal probability. The top-k elements of both rankings (where k is a parameter) are compared by means of the Spearman footrule metric, which is a metric used for comparing top-k ranked lists (Fagin et al., 2003).

We stress the importance of measuring both the summarization ability and the predictive power of a model. While a model that accurately summarizes the information content of a collection of user sessions can provide a potential platform for techniques focused on identifying users' frequent navigation patterns, a model showing strong predictive power provides the means to predict the next link choice of unseen navigation sessions and thus can be used for prefetching links or in adaptive Web site applications.

Results from extensive experiments conducted with real data sets were presented in (Borges et al., 2007a; Borges et al., 2007b) and show that, in general, a second or third-order model is sufficient to accurately represent a collection of user Web navigation sessions. The experimental results also provide evidence that there is a linear relationship between the predictive power and summarization ability of a VLMC model.

FUTURE TRENDS

Web usage mining research has focused on techniques that aim to deliver personalized, adaptive, effective and efficient Web services both from the point of view of the Web site owner and of the Web user. In the future, we expect methods to emerge that integrate Web usage mining techniques with Web content and Web structure mining techniques. For example, methods that are able to induce frequent patterns of users interested in a given topic or methods that are able to compare the induced navigation patterns with the underlying Web site topology in order to provide crucial insight to the Web site owner.

Another research direction that we expect to become very important in the near future is the problem of adapting the Web usage mining techniques to the context of Web 2.0, (Ankolekar et al., 2007). In fact, the way people use the Web is moving from that of taking a passive role, in which users access published content, to taking a more active role, in which users collaboratively produce and publish content. There are, for example, sites based on the Wiki concept, in which the content is dynamically kept up-to-date by a community of users, or sites in which users share and collaboratively tag multimedia material. These new paradigms of user interaction with Web resources pose fresh challenges to the Web usage mining community.

CONCLUSION

Web usage mining is an important topic within the more general field of web data mining. Several methods have been proposed to preprocess clickstream data into collections of user navigation sessions in a Web space as well as methods to model and analyze such data. Among the proposed methods we advocate the use of VLMC models because they provide a compact and powerful platform for Web usage analysis. An important property is the ability of a VLMC to take into account, for a given Web site, each page's amount of navigation history users consider when making the next link choice.

In this chapter we have reviewed recent research on methods that build VLMC models as well as methods devised to evaluate both the prediction power and the summarization ability of a VLMC model induced from a collection of navigation sessions. We believe that due to the well established concepts from Markov chain theory that underly VLMC models, they will be capable of providing support to cope with the new challenges in Web mining.

KEY TERMS

Clickstream: A recording of user clicks while browsing the Web.

Frequent Trail: A sequence of pages frequently followed by Web users.

Markov Model: A statistical model used to represent a stochastic process characterized by a set of states and a transition probability matrix.

Sessionizing: The process of reconstructing user sessions from clickstream data.

State Cloning: The process of duplicating selected states in order to accurately represent higher-order conditional probabilities.

Usage Mining: Automatic discovery of user navigation patterns from clickstream data.

User Session: A sequence of web page clicks followed by a user within a given time window.

Variable Length Markov Model: A Markov model extension that allows variable length navigation history to be captured.

Vertical Data Mining on Very Large Data Sets

William Perrizo
North Dakota State University, USA

Qin Ding
East Carolina University, USA

Taufik Abidin
North Dakota State University, USA

INTRODUCTION

Due to the rapid growth of the volume of data that are available, it is of importance and challenge to develop scalable methodologies and frameworks that can be used to perform efficient and effective data mining on large data sets. Vertical data mining strategy aims at addressing the scalability issues by organizing data in vertical layouts and conducting logical operations on vertical partitioned data instead of scanning the entire database horizontally in order to perform various data mining tasks.

BACKGROUND

The traditional horizontal database structure (files of horizontally structured records) and traditional scan-based data processing approaches (scanning files of horizontal records) are known to be inadequate for knowledge discovery in very large data repositories due to the problem of scalability. For this reason much effort has been put on sub-sampling and indexing as ways to address and solve the problem of scalability. However, sub-sampling requires that the sub-sampler know enough about the large dataset in the first place in order to sub-sample "representatively". That is, sub-sampling requires considerable knowledge about the data, which, for many large datasets, may be inadequate or non-existent. Index files are vertical structures. That is, they are vertical access paths to sets of horizontal records. Indexing files of horizontal data records does address the scalability problem in many cases, but it does so at the cost of creating and maintaining the index files separate from the data files themselves.

A new way to organize data is to organize them vertically, instead of horizontally. Data miners are typically interested in collective properties or predictions that can be expressed very briefly (e.g., a yes/no answer). Therefore, the result of a data mining query can be represented by a bitmap vector. This important property makes it possible to perform data mining directly on vertical data structures.

MAIN FOCUS

Vertical data structures, vertical mining approaches and multi-relational vertical mining will be explored in detail to show how vertical data mining works.

Vertical Data Structures

The concept of vertical partitioning has been studied within the context of both centralized and distributed database systems for a long time, yet much remains to be done (Winslett, 2002). There are great advantages of using vertical partitioning, for example, it makes hardware caching work really well; it makes compression easy to do; it may greatly increase the effectiveness of the I/O device since only participating fields are retrieved each time. The vertical decomposition of a relation also permits a number of transactions to be executed concurrently. Copeland & Khoshafian (1985) presented an attribute-level Decomposition Storage Model called DSM, similar to the Attribute Transposed File model (ATF) (Batory, 1979), that stores each column of a relational table into a separate table. DSM was shown to perform well. It utilizes surrogate keys to map individual attributes together, hence requiring a surrogate

key to be associated with each attribute of each record in the database. Attribute-level vertical decomposition is also used in Remotely Sensed Imagery (e.g., Landsat Thematic Mapper Imagery), where it is called Band Sequential (BSQ) format. Beyond attribute-level decomposition, Wong et al. (1985) presented the Bit Transposed File model (BTF), which took advantage of encoded attribute values using a small number of bits to reduce the storage space.

In addition to ATF, BTF, and DSM models, there has been other work on vertical data structuring, such as Bit-Sliced Indexes (BSI) (Chan & Ioannidis, 1998, O'Neil & Quass, 1997, Rinfret et al., 2001), Encoded Bitmap Indexes (EBI) (Wu & Buchmann, 1998; Wu, 1998), and Domain Vector Accelerator (DVA) (Perrizo et al., 1991).

A Bit-Sliced Index (BSI) is an ordered list of bitmaps used to represent values of a column or attribute. These bitmaps are called bit-slices, which provide binary representations of attribute's values for all the rows.

In the EBI approach, an encoding function on the attribute domain is applied and a binary-based bit-sliced index on the encoded domain is built. EBIs minimize the space requirement and show more potential optimization than binary bit-slices.

Both BSIs and EBIs are auxiliary index structures that need to be stored twice for particular data columns. As we know, even the simplest index structure used today incurs substantial increase in total storage requirements. The increased database size, in turn, translates into higher media and maintenance costs, and results in lower performance.

Domain Vector Accelerator (DVA) is a method to perform relational operations based on vertical bit-vectors. The DVA method performs particularly well for joins involving a primary key attribute and an associated foreign key attribute.

Vertical mining requires data to be organized vertically and be processed horizontally through fast, multi-operand logical operations, such as AND, OR, XOR, and complement. Predicate tree (P-tree[1]) (Ding et al., 2002) is one form of lossless vertical structure that meets this requirement. P-tree is suitable to represent numerical and categorical data and has been successfully used in various data mining applications, including classification (Khan et al., 2002; Ding et al., 2002; Perrizo et al., 2007), clustering (Denton et al., 2002), association rule mining (Ding et al., 2002; Imad et al., 2004), and outlier detection (Ren et al., 2004).

To convert a relational table of horizontal records to a set of vertical P-trees, the table has to be projected into columns, one for each attribute, retaining the original record order in each. Then each attribute column is further decomposed into separate bit vectors (called bit Sequential format, or bSQ format), one for each bit position of the values in that attribute. Each bit vector, i.e., bSQ file, is then compressed into a tree structure by recording the truth of the predicate "purely 1-bits" recursively on halves until purity is reached.

Figure 1 is an example of an 8×8 bSQ file and its corresponding P-tree (Ding et al., 2002). In this example, 36 is the number of 1's in the entire image, called root count. This root level is labeled level 0. The numbers 16, 7, 13, and 0 at the next level (level 1) are the 1-bit counts for the four major quadrants in raster order. Since the first and last level-1 quadrants are composed entirely of 1-bits (called pure-1 quadrants) and 0-bits (called pure-0 quadrants) respectively, sub-trees are not needed and these branches terminate. This pattern is continued recursively using the Peano or Z-ordering of the four sub-quadrants at each new level. Eventually, every branch terminates.

A variation of the P-tree data structure, the PM-tree, is a similar structure in which masks rather than counts

Figure 1. P-tree for a 8×8 bSQ file

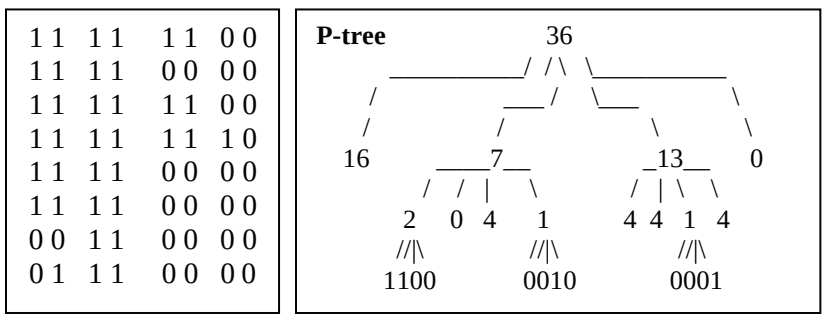

Figure 2. PM-tree

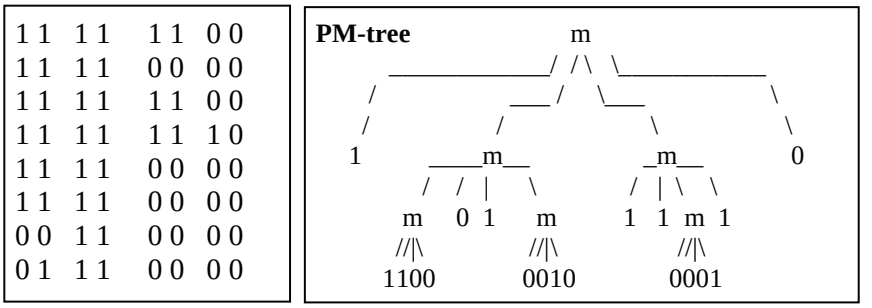


are used. In a PM-tree, a 3-value logic is used to represent pure-1, pure-0 and mixed quadrants (1 denotes pure-1, 0 denotes pure-0 and m denotes mixed). The PM-tree for the previous example is given in Figure 2.

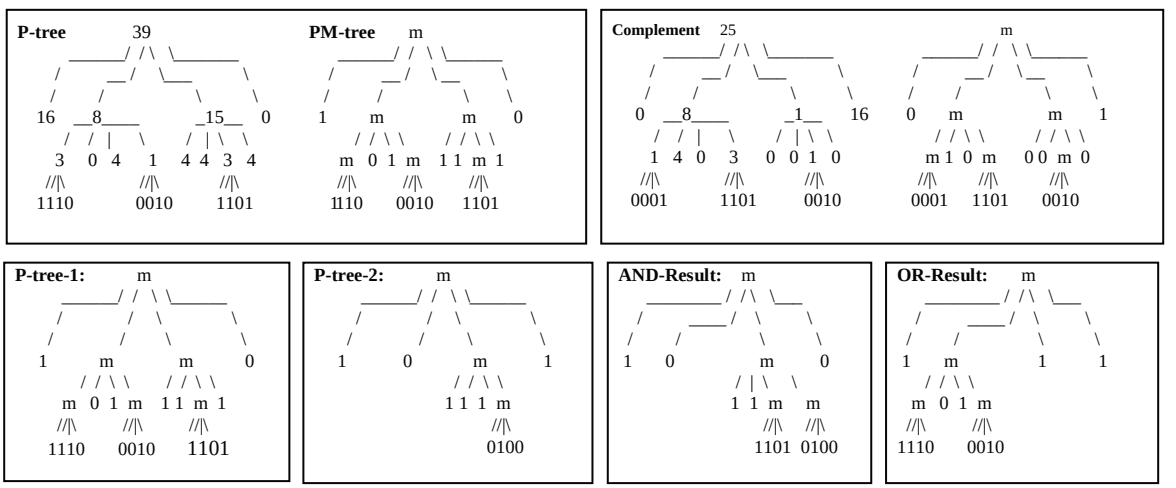
P-tree algebra includes three basic operations: complement, AND and OR. The complement of a P-tree can be constructed directly from the P-tree by simply complementing the counts at each level (subtracting from the pure-1 count at that level), as shown in the example below (Figure 3). The complement of a P-tree provides the 0-bit counts for each quadrant. P-tree AND/OR operations are also illustrated in Figure 3.

P-trees can be 1-dimensional, 2-dimensional, and multi-dimensional. If the data has a natural dimension (e.g., spatial data), the P-tree dimension is matched to the data dimension. Otherwise, the dimension can be chosen to optimize the compression ratio.

Vertical Mining Approaches

A number of vertical data mining algorithms have been proposed, especially in the area of association rule mining. Mining algorithms using the vertical format have been shown to outperform horizontal approaches in many cases. One example is the Frequent Pattern Growth algorithm using Frequent Pattern Trees introduced by Han in (Han et al., 2000). The advantages come from the fact that frequent patterns can be counted via the intersections of transaction_id sets, instead of using complex internal data structures. The horizontal approach, on the other hand, requires complex hash/search trees. Zaki & Hsiao (2002; 2003) introduced a vertical presentation called diffset, which keeps track of differences in the tidset of a candidate pattern from its generated frequent patterns. Diffset drastically reduces the memory required to store intermediate results; therefore, even in dense domains, the entire working

Figure 3. P-tree Algebra (Complement, AND and OR)



set of patterns of several vertical mining algorithms can be fit entirely in main-memory, facilitating the mining for very large database. Shenoy et al. (2000) proposes a vertical approach, called VIPER, for association rule mining of large databases. VIPER stores data in compressed bit-vectors and integrates a number of optimizations for efficient generation, intersection, counting, and storage of bit-vectors, which provides significant performance gains for large databases with a close to linear scale-up with database size.

P-trees have been applied to a wide variety of data mining areas. The efficient P-tree storage structure and the P-tree algebra provide a fast way to calculate various measurements for data mining task, such as support and confidence in association rule mining, information gain in decision tree classification, Bayesian probability values in Bayesian classification, etc.

P-trees have also been successfully used in many kinds of distance-based classification and clustering techniques. A computationally efficient distance metric called Higher Order Basic Bit Distance (HOBBit) (Khan et al., 2002) has been proposed based on P-trees. For one dimension, the HOBBit distance is defined as the number of digits by which the binary representation of an integer has to be right-shifted to make two numbers equal. For more than one dimension, the HOBBit distance is defined as the maximum of the HOBBit distances in the individual dimensions.

Since computers use binary systems to represent numbers in memory, bit-wise logical operations are much faster than ordinary arithmetic operations such as addition and multiplication of decimal numbers. Therefore, knowledge discovery algorithm utilizing vertical bit representation can accomplish its goals in a quick manner.

Multi-Relational Vertical Mining

Multi-Relational Data Mining (MRDM) is the process of knowledge discovery from relational databases consisting of multiple tables. The rise of several application areas in Knowledge Discovery in Databases (KDD) that is intrinsically relational has provided and continues to provide a strong motivation for the development of MRDM approaches. Since scalability has always been an important concern in the field of data mining, it is even more important in the multi-relational context, which is inherently more complex. From the perspective of database, multi-relational data mining usually involves one or more joins between tables, as is not the case for classical data mining methods. Until now, there is still lack of accurate, efficient, and scalable multi-relational data mining methods to handle large databases with complex schemas.

Databases are usually normalized for implementation reasons. However, for data mining workload, denormalizing the relations into a view may better represent the real world. In addition, if a view can be materialized by storing onto disks, it will be accessed much faster without being computed on the fly. Two alternative materialized view approaches, relational materialized view model and multidimensional materialized view model, can be utilized to model relational data (Ding, 2004).

In the relational model, a relational or extended-relational DBMS is used to store and manage data. A set of vertical materialized views can be created to encompass all the information necessary for data mining. Vertical materialized views can be generated directly from vertical representation of the original data. The transformation can be done in parallel by Boolean operations.

In the multidimensional materialized view model, multidimensional data are mapped directly to a data cube structure. The advantage of using a data cube is that it allows fast indexing by using offset calculation to precomputed data. The vertical materialized views of the data cube will require larger storage than that of the relational model. However, with the employment of the P-tree technology, there would not be much difference due to the compression inside the P-tree structure.

All the vertical materialized views can be easily stored in P-tree format. When encountering any data mining task, by relevance analysis and feature selection, all the relevant materialized view P-trees can be grabbed for data mining.

FUTURE TRENDS

Vertical data structure and vertical data mining will become more and more important. New vertical data structures will be needed for various types of data. There is great potential to combine vertical data mining with parallel mining as well as hardware. The scalability will become a very important issue in the area of data mining. The challenge of scalability is not just dealing with a large number of tuples but also handling with

high dimensionality (Fayyad, 1999, Han & Kamber, 2001).

CONCLUSION

Horizontal data structure has been proven to be inefficient for data mining on very large sets due to the large cost of scanning. It is of importance to develop vertical data structures and algorithms to solve the scalability issue. Various structures have been proposed, among which P-tree is a very promising vertical structure. P-trees have show great performance to process data containing large number of tuples due to the fast logical AND operation without scanning (Ding et al., 2002; Serazi et al., 2004)). Vertical structures, such as P-trees, also provide an efficient way for multi-relational data mining. In general, horizontal data structure is preferable for transactional data with intended output as a relation, and vertical data mining is more appropriate for knowledge discovery on very large data sets.

KEY TERMS

Association Rule Mining: The process of finding interesting association or correlation relationships among a large set of data items.

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns and relationships such as classification, prediction, estimation, or affinity grouping.

HOBBit Distance: A computationally efficient distance metric. In one dimension, it is the number of digits by which the binary representation of an integer has to be right-shifted to make two numbers equal. In other dimension, it is the maximum of the HOBBit distances in the individual dimensions.

Multi-Relational Data Mining: The process of knowledge discovery from relational databases consisting of multiple tables.

Multi-Relational Vertical Mining: The process of knowledge discovery from relational databases consisting of multiple tables using vertical data mining approaches.

Predicate Tree (P-Tree): A lossless tree that is vertically structured and horizontally processed through fast multi-operand logical operations.

Vertical Data Mining (Vertical Mining): The process of finding patterns and knowledge from data organized in vertical formats, which aims to address the scalability issues.

ENDNOTE

[1] P-tree technology is patented by North Dakota State University (William Perrizo, primary inventor of record); patent number 6,941,303 issued September 6, 2005.

INTRODUCTION

Data mining, which is defined as the process of extracting previously unknown knowledge and detecting interesting patterns from a massive set of data, has been an active research area. As a result, several commercial products and research prototypes are available nowadays. However, most of these studies have focused on corporate data — typically in an alpha-numeric database, and relatively less work has been pursued for the mining of multimedia data (Zaïane, Han, & Zhu, 2000). Digital multimedia differs from previous forms of combined media in that the bits representing texts, images, audios, and videos can be treated as data by computer programs (Simoff, Djeraba, & Zaïane, 2002). One facet of these diverse data in terms of underlying models and formats is that they are synchronized and integrated hence, can be treated as integrated data records. The collection of such integral data records constitutes a multimedia data set. The challenge of extracting meaningful patterns from such data sets has lead to research and development in the area of multimedia data mining. This is a challenging field due to the non-structured nature of multimedia data. Such ubiquitous data is required in many applications such as financial, medical, advertising and Command, Control, Communications and Intelligence (C3I) (Thuraisingham, Clifton, Maurer, & Ceruti, 2001). Multimedia databases are widespread and multimedia data sets are extremely large. There are tools for managing and searching within such collections, but the need for tools to extract hidden and useful knowledge embedded within multimedia data is becoming critical for many decision-making applications.

BACKGROUND

Multimedia data mining has been performed for different types of multimedia data: image, audio and video. Let us first consider image processing before discussing image and video data mining since they are related. Image processing has been around for some time. Images include maps, geological structures, biological structures, and many other entities. We have image processing applications in various domains including medical imaging for cancer detection, and processing satellite images for space and intelligence applications. Image processing has dealt with areas such as detecting abnormal patterns that deviate from the norm, and retrieving images by content (Thuraisingham, Clifton, Maurer, & Ceruti, 2001). The questions here are: *what* is image data mining and *how* does it differ from image processing? We can say that while image processing focuses on manipulating and analyzing images, image data mining is about finding useful patterns. Therefore, image data mining deals with making associations between different images from large image databases. One area of researches for image data mining is to detect unusual features. Its approach is to develop templates that generate several rules about the images, and apply the data mining tools to see if unusual patterns can be obtained. Note that detecting unusual patterns is not the only outcome of image mining; that is just the beginning. Since image data mining is an immature technology, researchers are continuing to develop techniques to classify, cluster, and associate images (Goh, Chang, & Cheng, 2001; Li, Li, Zhu, & Ogihara, 2002; Hsu, Dai, & Lee, 2003; Yanai, 2003; Müller & Pun, 2004). Image data mining is an area with applications in numerous domains including space, medicine, intelligence, and geoscience.

Mining video data is even more complicated than mining still image data. One can regard a video as a collection of related still images, but a video is a lot more than just an image collection. Video data management has been the subject of many studies. The important areas include developing query and retrieval techniques for video databases (Aref, Hammad, Catlin, Ilyas, Ghanem, Elmagarmid, & Marzouk, 2003). The question we ask yet again is what is the difference between video information retrieval and video mining? There is no clear-cut answer for this question yet. To be consistent with our terminology, we can say that finding correlations and patterns previously unknown from large video databases is video data mining.

MAIN THRUST

Even though we define video data mining as finding correlations and patterns previously unknown, the current status of video data mining remains mainly at the pre-processing stage, in which the preliminary issues such as video clustering, and video classification are being examined and studied for the actual mining. Only a very limited number of papers about finding any patterns from videos can be found. We discuss video clustering, video classification and pattern finding as follows.

Video Clustering

Clustering is a useful technique for the discovery of some knowledge from a dataset. It maps a data item into one of several clusters which are natural groupings for data items based on similarity metrics or probability density models (Mitra & Acharya, 2003). Clustering pertains to unsupervised learning, when data with class labels are not available. Clustering consists of partitioning data into homogeneous granules or groups, based on some objective function that maximizes the inter-cluster distances, while simultaneously minimizing the intra-cluster distances. Video clustering has some differences with conventional clustering algorithms. As mentioned earlier, due to the unstructured nature of video data, preprocessing of video data by using image processing or computer vision techniques is required to get structured format features. Another difference in video clustering is that the time factor should be considered while the video data is processed. Since video is a synchronized data of audio and visual data in terms of time, it is very important to consider the time factor. Traditional clustering algorithms can be categorized into two main types: partitional and hierarchical clustering (2003). Partitional clustering algorithms (i.e., *K-means* and *EM*) divide the patterns into a set of spherical clusters, while minimizing the objective function. Here the number of clusters is predefined. Hierarchical algorithms, on the other hand, can again be grouped as agglomerative and divisive. Here no assumption is made about the shape or number of clusters, and validity index is used to determine termination.

Two of the most popular partitional clustering algorithms are *K-means* and *Expectation Miximization (EM)*. In K-means, the initial centroids are selected, and each data item is classified to a cluster with the smallest distance. Based on the previous results, the cluster centroids are updated, and all corresponding data items are re-clustered until there is no centroid change. It is easily implemented, and provides a firm foundation of variances through the clusters. We can find the papers using the K-means algorithm for video clustering in the literature (Ngo, Pong, & Zhang, 2001). EM is a popular iterative refinement algorithm that belongs to the model-based clustering. It differs from the conventional K-means clustering algorithm in that each data point belongs to a cluster according to some weight or probability of membership. In other words, there are no strict boundaries between clusters. New means are computed based on weighted measures. It provides a statistical model for the data and is capable of handling the associated uncertainties. We can find the papers using the EM algorithm for video clustering in the literature (Lu, & Tan, 2002; Frey, & Jojic, 2003).

Hierarchical clustering methods create hierarchical nested partitions of the dataset, using a tree-structured dendogram and some termination criterion. Every cluster node contains child clusters; sibling clusters partition the points covered by their common parent. Such an approach allows exploring data on different levels of granularity. Hierarchical clustering methods are categorized into agglomerative (bottom-up) and divisive (top-down). An agglomerative clustering starts with one-point (singleton) clusters and recursively merges two or more of the most appropriate clusters. Divisive clustering starts with one cluster of all data points and recursively splits the most appropriate cluster. The process continues until a stopping criterion is achieved. The advantages of hierarchical clustering

include: embedded flexibility regarding the level of granularity, ease of handling of any forms of similarity or distance, and applicability to any attribute types. The disadvantages of hierarchical clustering are vagueness of termination criteria, and the fact that most hierarchical algorithms do not revisit constructed (intermediate) clusters for the purpose of their improvement. Hierarchical clustering is used in video clustering because it is easy to handle the similarity of extracted features from video, and it can represent the depth and granularity by the level of tree (Okamoto, Yasugi, Babaguchi, & Kitahashi, 2002).

Video Classification

While clustering is an unsupervised learning method, classification is a way to categorize or assign class labels to a pattern set under the supervision. Decision boundaries are generated to discriminate between patterns belonging to different classes. The data set is initially partitioned into training and test sets, and the classifier is trained on the former. A framework to enable semantic video classification and indexing in a specific video domain (medical video) was proposed (Fan, Luo, & Lin, 2003). VideoGraph, a tool for finding similar scenes in a video, was studied (Pan & Faloutsos, 2001). A method for classification of different kinds of videos that uses the output of a concise video summarization technique that forms a list of key frames was presented (Lu, Drew, & Au, 2001).

Pattern Finding

A general framework for video data mining was proposed to address the issue of how to extract previously unknown knowledge and detect interesting patterns (Oh, Lee, Kote, & Bandi, 2003). In the work, they develop how to segment the incoming raw video stream into meaningful pieces, and how to extract and represent some feature (i.e., motion) for characterizing the segmented pieces. Then, the motion in a video sequence is expressed as an accumulation of quantized pixel differences among all frames in the video segment. As a result, the accumulated motions of the segment are represented as a two dimensional matrix. Further, a method to capture the location of motions occurring in a segment is developed using the same matrix. How to cluster those segmented pieces using the features (the amount and the location of motion) extracted by the matrix above is studied. Also, an algorithm is investigated to determine whether a segment has normal or abnormal events by clustering and modeling normal events, which occur most frequently. In addition to deciding normal or abnormal, the algorithm computes a Degree of Abnormality of a segment, which represents the distance of a segment from the existing segments in relation to normal events.

A fast dominant motion extraction scheme called Integral Template Match (ITM), and a set of qualitative and quantitative description schemes were proposed (Lan, Ma, & Zhang, 2003). A video database management framework and its strategies for video content structure and events mining were introduced (Zhu, Aref, Fan, Catlin, & Elmagarmid, 2003). The methods of extracting editing rules from video stream were proposed by introducing a new data mining technique (Matsuo, Amano, & Uehara, 2002).

FUTURE TRENDS

As mentioned above, there have been a number of attempts to apply clustering methods to video data. However, these classical clustering techniques only create clusters but do not explain why a cluster has been established (Perner, 2002). The conceptual clustering method builds clusters and explains why a set of objects confirms a cluster. Thus, conceptual clustering is a type of learning by observations, and it is a way of summarizing data in an understandable manner. In contrast to hierarchical clustering methods, conceptual clustering methods build the classification hierarchy based on merging two groups. The algorithm properties are flexible in order to dynamically fit the hierarchy to the data. This allows incremental incorporation of new instances into the existing hierarchy and updating this hierarchy according to the new instance. A concept hierarchy is a directed graph in which the root node represents the set of all input instances and the terminal nodes represent individual instances. Internal nodes stand for the sets of instances attached to them and represent a super-concept. The super-concept can be represented by a generalized representation of this set of instances such as the prototype, the method or a user-selected instance. We can find a work applying this conceptual mining to image domain (Perner, 1998). However, we cannot find any papers related to conceptual clustering for video data. Since it is important to

understand what a created cluster means semantically, we need to study how to apply conceptual clustering to video data.

In fact, one of the most important techniques for data mining is association-rule mining since it is most efficient way to find unknown patterns and knowledge. Therefore, we need to investigate how to apply association-rule mining to video data. For association-rule mining, we need a set of transactions (*D*), a set of the literals (or items, *I*), and an itemset (*X*) (Zhang & Zhang, 2002). After video is segmented into the basic units such as shots, scenes, and events, each segmented unit can be modeled as a transaction, and the features from a unit can be considered as the items contained in the transaction. In this way, video association mining can be transformed into problems of association mining in traditional transactional databases. A work using some associations among video shots to create a video summary was proposed (Zhu & Wu, 2003). But they did not come up with the concepts of transaction and itemset. We need to further investigate the optimal unit for the concept of transaction, and the possible items in a transaction of video to characterize it.

Also, we need to study whether video can be considered as time-series data. It looks positive since the behavior of a time-series data item is very similar to that of video data. A time-series data item has a value at any given time, and the value is changing over time. Similarly a feature of video has a value at any given time, and the value is changing over time. If video can be considered as time-series data, we can get the advantages of the techniques already developed for time-series data mining. When the similarity between data items is computed, the ordinary distance metrics, such as Euclidean distance, may not be suitable, because of its high dimensionality and time factor. In order to address this problem, alternative ways are used to get a more accurate measure of similarity; for example, Dynamic Time Warping and Longest Common Subsequences.

Although most of data mining techniques are in batch processing, including video data mining as well as conventional data mining, some applications need to be processed in real time or near real time. For example, the anomaly detection system in a surveillance video using data mining should be processed in real time. Therefore, we also need to examine online video data mining.

CONCLUSION

V

Data mining describes a class of applications that look for hidden knowledge or patterns in large amounts of data. Most of data mining research has been dedicated to alpha-numeric databases, and relatively less work has been done for the multimedia data mining. The current status and the challenges of video data mining which is a very premature field of multimedia data mining, are discussed in this paper. The issues discussed should be dealt with in order to obtain valuable information from vast amounts of video data.

KEY TERMS

Classification: A method of categorizing or assigning class labels to a pattern set under the supervision.

Clustering: A process of mapping a data item into one of several clusters, where clusters are natural groupings for data items based on similarity metrics or probability density models.

Concept Hierarchy: A directed graph in which the root node represents the set of all input instances and the terminal nodes represent individual instances.

Conceptual Clustering: A type of learning by observations and a way of summarizing data in an understandable manner.

Degree of Abnormality: A probability that represents to what extent a segment is distant to the existing segments in relation with normal events.

Dendogram: It is a 'tree-like' diagram that summaries the process of clustering. Similar cases are joined by links whose position in the diagram is determined by the level of similarity between the cases.

Digital Multimedia: The bits that represent texts, images, audios, and videos, and are treated as data by computer programs.

Image Data Mining: A process of finding unusual patterns, and making associations between different images from large image databases. One could mine for associations between images, cluster images, classify images, as well as detect unusual patterns.

Image Processing: A research area analyzing and manipulating digital images for image enhancement, data compression, or pattern discovery.

Video Data Mining: A process of finding correlations and patterns previously unknown from large video databases.

View Selection in DW and OLAP: A Theoretical Review

Alfredo Cuzzocrea
University of Calabria, Italy

INTRODUCTION

Data Warehousing (DW) systems store *materialized views*, *data marts* and *data cubes*, and provide nicely data exploration and analysis interfaces via *OnLine Analytical Processing* (OLAP) (Gray et al., 1997) and *Data Mining* (DM) tools and algorithms. Also, *OnLine Analytical Mining* (OLAM) (Han, 1997) integrates the previous *knowledge discovery* methodologies and offers a meaningfully convergence between OLAP and DM, thus contributing to significantly augment the power of data exploration and analysis capabilities of knowledge workers. At the storage layer, the mentioned knowledge discovery methodologies share the problem of efficiently accessing, querying and processing multidimensional data, which in turn heavily affect the performance of knowledge discovery processes at the application layer. Due to the fact that OLAP and OLAM directly process data cubes/marts, and DM is more and more encompassing methodologies that are interested to multidimensional data, the problem of *efficiently representing data cubes by means of a meaningfully selected view set* is become of relevant interest for the Data Warehousing and OLAP research community.

This problem is directly related to the analogous problem of *efficiently computing the data cube* from a given relational data source (Harinarayan et al., 1996; Agarwal et al., 1996; Sarawagi et al., 1996; Zhao et al., 1997). Given a *relational data source* $\mathcal{R}$ and a target *data cube schema* $\mathcal{W}$, the *view selection problem* in OLAP deals with how to select and materialize views from $\mathcal{R}$ in order to compute the data cube $\mathcal{A}$ defined by the schema W by optimizing both the *query processing time*, denoted by $\mathcal{TQ}$, which models the amount of time required to answer a reference query-workload on the materialized view set, and the *view maintenance time*, denoted by $\mathcal{TM}$, which models the amount of time required to maintain the materialized view set when updates occur, under a given set of constraints $\mathcal{I}$ that, without any loss of generality, can be represented by a *space bound constraint* $\mathcal{B}$ limiting the overall occupancy of the views to be materialized (i.e., $\mathcal{I} = \langle \mathcal{B} \rangle$). It has been demonstrated (Gupta, 1997; Gupta & Mumick, 2005) that this problem is *NP-hard*, thus *heuristic schemes* are necessary. Heuristics are, in turn, implemented in the vest of *greedy algorithms* (Yang et al., 1997; Kalnis et al., 2002).

In this article, we focus the attention on state-of-the-art methods for the view selection problem in Data Warehousing and OLAP, and complete our analytical contribution with a theoretical analysis of these proposals under different selected properties that nicely model spatial and temporal complexity aspects of the investigated problem.

BACKGROUND

Before going into details, in this Section we provide the conceptual basis of our work, which is mainly related to the representation of multidimensional data cubes according to the ROLAP storage model. Let $\mathcal{R} = \langle \{R_0, R_1, \ldots, R_{M-1}\}, S \rangle$ be a relational data source, such that (*i*) R_i, with $0 \leq i \leq M-1$, is a relational table of form $R_i(A_{i,0}, A_{i,1}, \ldots, A_{i,|Ri|-1})$, such that $A_{i,j}$, with $0 \leq j \leq |R_i|-1$, is an *attribute* of R_i, and (*ii*) S it the *relational schema* that models associations among relational tables in $\{R_0, R_1, \ldots, R_{M-1}\}$. Let $\mathcal{W}$ be the goal data cube schema, which, without any loss of generality, can alternatively be modeled as a *star schema*, where a central *fact table* $\mathcal{F}$ is connected to multiple *dimensional tables* $\mathcal{T}_j$, or a *snowflake schema*, where dimensional tables are also *normalized* across multiple tables (Gray et al., 1997). At the conceptual level, the goal data cube A can also be modeled as a tuple $\mathcal{A} = \langle \mathcal{D}, \mathcal{H}, \mathcal{M} \rangle$, such that: (*i*) $\mathcal{D}$ is the set of *dimensions* of $\mathcal{A}$, (*ii*) $\mathcal{H}$ is the set of *hierarchies* associated to dimensions of $\mathcal{A}$, and (*iii*) $\mathcal{M}$ is the set of *measures* of $\mathcal{A}$. Dimensions model the *perspective of analysis* of the actual OLAP model. Hierarchies are hierarchical structures (e.g., *trees*) that capture hierarchical relationships among attributes of

dimensional tables. Measures model the *analysis goals* of the actual OLAP model.

Given an N-dimensional data cube $\mathcal{A}$, and the set of dimensions $\mathcal{D} = \{d_0, d_1, \ldots, d_{N-1}\}$ of $\mathcal{A}$, all the possible (simultaneous) combinations of sub-sets of $\mathcal{D}$ define a *lattice of cuboids* (Harinarayan et al., 1996), i.e. a set of hierarchically-organized multidimensional partitions of $\mathcal{A}$. Since real-life data cube have a large number of dimensions, the resulting number of cuboids N_C is large as well (Harinarayan et al., 1996). More precisely, this number is given by the following formula: $N_C = \prod_{k=0}^{N-1}\left(2^{L_k}+1\right)$, such that L_k denotes the depth of the hierarchy H_k associated to the dimension d_k, and the unary contribution is due to the aggregation ALL. Although N_C can became prohibitively large, the cuboid lattice offers several optimization opportunities for both the two complementary problems of computing the data cube (Harinarayan et al., 1996; Agarwal et al., 1996; Sarawagi et al., 1996; Zhao et al., 1997) and selecting the views to be materialized in order to efficiently representing the data cube.

VIEW SELECTION TECHNIQUES FOR DATA WAREHOUSING AND OLAP: THE STATE-OF-THE-ART

View selection is very related to the problem of computing the data cube (Harinarayan et al., 1996; Agarwal et al., 1996; Sarawagi et al., 1996; Zhao et al., 1997), as before to materialize data cube cells, views must be selected depending on spatial and (query) time constraints. Harynarayan *et al.* (1996) first consider the problem of efficiently computing a data cube starting from the relational source. The goal is that of optimizing the query processing time, under a given space bound. To this end, Harynarayan *et al.* (1996) develop a greedy algorithm working on the cuboid lattice that tries to optimize the so-called BPUS (*Benefit Per Unit Space*) that fine-grainy models the spatial cost needed to represent materialized views. Under an optimization-oriented view of the problem, this algorithm traverses the cuboid lattice and, at each step, materializes those cuboids that, overall, give the *greatest benefit* towards improving the query processing time while lowering the BPUS. Gupta (1997) first improves this methodology with the aim of specializing it towards the proper data cube model. The result consists in introducing an elegant graph-based notion to reason on views and their underlying base relations, called AND-/OR-DAG (*Direct Acyclic Graph*). An AND-/OR-DAG is a graph such that (*i*) leafs nodes represent the base relations stored in the relational data source, (*ii*) the root represents the view to be materialized, and (*iii*) internal nodes are classified in two classes, namely AND nodes and OR nodes. AND nodes model relational algebra operations like join, projection and selection, which apply on base relations or their combinations that, in turn, model operators. OR nodes model a set of *equivalence expressions* (in terms of SQL statements generating equivalent views and intermediate views) that can be alternatively used when a choice must be done. Based on this nice theoretical model, Gupta (1997) proposes a greedy algorithm that inspects the AND-/OR-DAG in order to determine the final view set via optimizing both query processing time and view maintenance time, under a given space bound. With respect to the previous work of Harynarayan *et al.* (1996), the most significant novelty carried out by (Gupta, 1997) is represented by the amenity of considering as parameter to be optimized the view maintenance time, beyond the query processing time. Gupta and Mumick further consolidate the theory of the view selection problem with maintenance time constraint in (Gupta & Mumick, 1999), where the *maintenance-cost view-selection problem* is formalized as an extension of the baseline view selection problem. All these research results have then been synthesized in (Gupta & Mumick, 2005).

Yang *et al.* (1997) propose a set of algorithms for the view selection problem that have the particular characteristic of finding, among all the possible ones, the sub-optimal solution capable of obtaining the best *combined benefit* between two critical factors, namely the *maximization* of query performance and the *minimization* of maintenance cost. Similarly to other proposals, the main idea of this approach consists in analyzing typical queries in order to detect *common intermediate results* that can be shared among queries with the aim of reducing computational overheads, thus improving the performance.

Agrawal *et al.* (2001) demonstrate the effectiveness and the reliability of view selection tools within commercial Data Warehousing and OLAP servers in the context of the *AutoAdmin* project (Agrawal et al., 2000; Agrawal et al., 2006). In more detail, (Agrawal et al., 2000; Agrawal et al., 2006) describe algorithms (implemented within the core layer of the related tool

called *AutoAdmin*) that allow us to select the optimal view set under a complex metrics involving query cost, maintenance cost and index construction cost. *AutoAdmin* is embedded within the well-know DBMS *Microsoft SQL Server 2000*.

DynaMat is a dynamic view management system proposed by Kotidis and Rossopulos (2001). The main idea underlying *DynaMat* is that of modeling the view selection problem in terms of a traditional *memory management problem*, which is typical of operating systems research. In *DynaMat*, a *pool* of materialized views is maintained in dependence on query monitoring reports and gathered statistics. Views are added to the pool on the basis of the frequency they are involved by input queries, or removed if they are no longer involved. Strategies for removing victim views, inspired from similar methods of operating systems, are presented and evaluated (Kotidis & Rossopulos, 2001).

Lee *et al.* (2001; 2007) propose a very interesting optimization to the view maintenance problem that can be reasonably regarded as a valuable contribution over state-of-the-art research. The resulting approach is called *Delta Propagation Strategy*. The underlying method deals with the issue of efficiently maintaining the materialized view set in the presence of updates that can occur in the reference relational source. The main intuition here is noticing that the performance of any view maintenance system is heavily affected by the amount of I/O disk accesses to the base relations from which views are derived (e.g., based on an AND-/OR-DAG). Inspired by this main intuition, Lee *et al.* (2001; 2007) rigorously model the cost needed to compute a *changed* materialized view V, denoted by ΔV, in dependence of updates that occur in the base relations R_i, being changed relations denoted by ΔR_i. Then, they introduce the so-called *delta expressions*, which are maintenance expressions derived from formulas and equivalences coming from *Relational Algebra*. Delta expressions allow us to minimize the cost of computing ΔV via reducing the overall number of I/O disk accesses to (changed) base relations. Finally, since computing optimal delta expressions from a given set of changed relations is still a combinatory problem, the so-called *delta propagation tree* is introduced, along with a *dynamic programming algorithm* that exploits the hierarchical model offered by this structure in order to efficiently accomplish the view maintenance task. The same approach has been then targeted to data cubes by the same authors (Lee & Kim, 2006) via introducing the concept of *delta cuboid* that, similarly to the relational case, effectively captures changes that can happen in a cuboid.

Mistry *et al.* (2001) attack the view selection problem under a different perspective of research, i.e. the issue of materializing *transient* views in Data Warehousing and OLAP systems. Transient views refer to views that are temporarily materialized, e.g. during the evaluation of complex OLAP queries against very large Data Warehouses, and are different from the materialized views considered until now, which should be more precisely referred as *permanent* views, i.e. views that are materialized permanently. The issue of materializing transient views is also known in literature under the term: *multi-query optimization problem* (Sellis, 1988). The novelty of the Mistry *et al.*'s approach (2001) relies in the fact that an integrated methodology taking into consideration the selection of both transient and permanent views in a combined manner is proposed. Indeed, this aspect can be reasonably intended as innovative with respect to previous research experiences. In this direction, Mistry *et al.* (2001) devise a quite complex methodology that encompasses the following aspects: (*i*) temporarily materialization of common sub-expressions in order to reduce the overall cost of different maintenance plans, (*ii*) selection of auxiliary expressions that further improve the overall view maintenance task, (*iii*) selection of the optimal maintenance plan (which can alternatively be incremental or with re-computation from the scratch) for each selected view, (*iv*) minimization of the overall maintenance cost by meaningfully combining all the previous aspects. The reasoning unit of the Mistry *et al.*'s approach (2001) approach still is the AND-/OR-DAG, and a greedy algorithm is again exploited to transient and permanent view selection and materialization purposes.

Kalnis *et al.* (2002) propose a novel perspective to face-off the annoying view selection and materialization problem. Starting from specific requirements of real-life Data Warehousing and OLAP systems, such as the need of analyzing multidimensional data according to numerous perspectives of analysis, they propose the application of *randomized local search algorithms*, and test the efficiency of these algorithms against several synthetic data sets and different query distributions shaping high-heterogeneous query-workloads that can be posed to the system. In (Kalnis et al., 2002), authors correctly assert that, for low-dimensional data cubes, state-of-the-art proposals are able to provide

efficiency within satisfactory space and maintenance time constraints, whereas when data cubes grow in dimension number and size this efficiency drastically decreases. In this context, and the application of randomized approaches seems to be the most pertinent one. Authors model the overall search space of the underlying optimization problem in terms of an *undirected graph* where: (*i*) nodes represent *candidate solutions* (i.e., set of views for the particular selection and materialization instance); (*ii*) arcs represent simple transformations among set of views activated by means of transactions, and capture the hierarchical relationships among such sets; (*iii*) a cost, depending on both the space and maintenance time constraints, is associated to each node, and the final goal is that of finding the solution that minimizes this cost. Authors also review state-of-the-art randomized algorithms, and develop a very comprehensive experimental study that shows the different trade-offs in terms of query performance and maintenance cost of classical methods and other more focused approaches such as (Gupta, 1997; Gupta & Mumick, 2005; Shukla et al., 1998), and also *EX*, a *branch-&-bound* algorithm that exhaustively searches the overall view space in order to avoid unnecessary checks thus speeding-up the execution time.

A *wavelet-based framework* for making flexible data cube views for OLAP is proposed by Smith *et al.* (2004). Wavelets have been extensively used in OLAP to obtain data cube compression in the context of *approximate query answering techniques* (Vitter et al., 1998; Chakrabarti et al., 2000). The framework proposed by Smith *et al.* (2004) asserts to decompose the input data cube into a set of the so-called *wavelet view elements*, which are obtained by means of *partial SQL aggregations* over the input data cube. Depending on the way of generating wavelet view elements, they can be of *aggregated*, *intermediate* or *residual* kinds. The main idea of this approach consists in adopting the well-known *wavelet decomposition hierarchy* (Stollnitz et al., 1996) to represent the dependencies among view elements instead of the widely-adopted view dependency hierarchy defined by the cuboid lattice (Harinarayan et al., 1996). This is meant to achieve more flexibility in several OLAP-oriented activities such as querying and analyzing data cubes. In this vest, the proposed wavelet-based framework can also be used for the view selection problem, as authors state in (Smith et al., 2004). According to this framework, an input data cube is represented by means of a view element set that satisfies the following properties: (*i*) *perfect reconstruction*, which asserts that the entire data cube can be fully-reconstructed from the view element set; (*ii*) *non-expansiveness*, which asserts that the generation of child view elements from ancestor ones does not augment the volume of the data cube; (*iii*) *distributivity*, which asserts that view elements can be computed from other ones in the wavelet decomposition hierarchy; (*iv*) *separability*, which asserts that a multidimensional view element can be obtained by applying partial SQL aggregations over each single dimension of the target data cube separately. Similarly to other approaches, wavelet view elements are handled by means of a hierarchical data structure, called *View Element Graph* (VEG). On top of VEG, authors propose two different greedy algorithms for the view selection problem. The first one is based on the assumption claiming that views of the view element set compose *a complete and non-redundant basis of the data cube*. The second one relaxes the previous assumption, and finds the optimal view set that minimizes the average throughput cost with respect to the spatial cost, i.e. the cost needed to represent the materialized views in secondary memory.

THEORETICAL ANALYSIS AND RESULTS

In this Section, we provide the theoretical analysis and related results of those techniques that we retain as the most "representative" ones among the state-of-the-art proposals. In our theoretical analysis, we introduce the following parameters:

- *Spatial Complexity*, which models the spatial complexity of a data cube obtained in terms of the total amount of tuples (in the case of the ROLAP storage organization) or cells (in the case of the MOLAP storage organization) that must be materialized to represent the cube.
- *Time Complexity*, which models the temporal complexity required to find the optimal view set to be materialized.
- *Update Complexity*, which models the temporal complexity of updating a data cube obtained in terms of the total amount of tuples (for ROLAP)

or cells (for MOLAP) that must be updated as the consequence of load or refresh operations at the relational data source.

Table 1 summarizes theoretical results for some representative state-of-the-art view selection and materialization techniques.

Note that for *all* the considered view selection and materialization techniques, the spatial complexity is obviously the same, as it only depends on the particular OLAP storage model used to represent the final data cube. In particular, for an N-dimensional data cube, if the ROLAP model is used, this complexity is $O\left(\sum_{j=0}^{P-1} |R_j|\right)$, such that $|R_j|$ denotes the cardinality of the relation R_j (i.e., the number of tuples of R_j). Explicitly note that P is such that $P \geq N$, as in a ROLAP schema dimensions can be mapped in single or normalized dimensional tables. Otherwise, if the MOLAP model is instead used, this complexity is $O\left(\prod_{k=0}^{N-1} |d_k|\right)$, such that $|d_k|$ denotes the cardinality of the dimension d_k (i.e., the number of members of d_k).

For what regards (Gupta, 1997; Gupta & Mumick, 2005), the time complexity of finding the optimal view set on the AND-/OR-DAG is $O(k \times n^2)$, such that k is the number of stages required by the greedy algorithm, and n is the number of nodes of the AND-/OR-DAG. The update complexity is instead exponential in the number of nodes of the AND-/OR-DAG.

Table 1. Theoretical analysis of some representative view selection and materialization techniques

Technique	Spatial Complexity		Time Complexity	Update Complexity
(Gupta, 1997; Gupta & Mumick, 2005)	ROLAP	$O\left(\sum_{j=0}^{P-1} \lvert R_j \rvert\right)$	$O(k \times n^2)$	EXPTIME(n)
	MOLAP	$O\left(\prod_{k=0}^{N-1} \lvert d_k \rvert\right)$		
(Lee et al., 2001; Lee et al., 2007)	ROLAP	$O\left(\sum_{j=0}^{P-1} \lvert R_j \rvert\right)$	$O(2^n \times n)$	EXPTIME(n)
	MOLAP	$O\left(\prod_{k=0}^{N-1} \lvert d_k \rvert\right)$		
(Mistry et al., 2001)	ROLAP	$O\left(\sum_{j=0}^{P-1} \lvert R_j \rvert\right)$	$O(k \times n^2)$	EXPTIME(n)
	MOLAP	$O\left(\prod_{k=0}^{N-1} \lvert d_k \rvert\right)$		
(Smith et al., 2004)	ROLAP	$O\left(\sum_{j=0}^{P-1} \lvert R_j \rvert\right)$	$O\left((N+1) \times \prod_{k=0}^{N-1} (2 \times \lvert d_k \rvert - 1)\right)$	EXPTIME(n)
	MOLAP	$O\left(\prod_{k=0}^{N-1} \lvert d_k \rvert\right)$		

For what regards (Lee et al., 2001; Lee et al., 2007), the time complexity of finding the optimal delta expression on the delta propagation tree is $O(2^n \times n)$, such that n is the number of base relations from which views are derived. The update complexity is instead exponential in the number of base relations.

For what regards (Mistry et al., 2001), the time complexity is the same of (Gupta, 1997; Gupta & Mumick, 2005), i.e. $O(2^n \times n)$, as the AND-/OR-DAG is still used as baseline computational model. Indeed, (Mistry et al., 2001) mostly focuses on the problem of maintaining the already-materialized view set. While the update complexity is still exponential in the number of nodes of the AND-/OR-DAG, Mistry *et al.* (2001) develop very useful closed formulas for estimating the maintenance cost of a materialized view set (see the paper for further details).

Finally, for what regards (Smith et al., 2004) the time complexity of extracting the non-redundant basis of the data cube modeling the optimal view set (i.e., the first of the two proposed view selection algorithms) is $O\left((N+1)\times\prod_{k=0}^{N-1}(2\times|d_k|-1)\right)$, such that N is the number of dimensions of the data cube and $|d_k|$ is the cardinality of the dimension d_k. The update complexity is instead exponential in the number of nodes of the VEG.

FUTURE TRENDS

Although of traditional nature, the problem of view selection and materialization in Data Warehousing and OLAP systems still plays a significant role today. Mostly, the research effort should be oriented towards novel applications contexts where this problem demands for specialized solutions, beyond the capabilities of state-of-the-art techniques. Some of these contexts are: (*i*) *high-dimensional data cubes*, (*ii*) *XML native database systems*, (*iii*) *sensor database systems*, (*iv*) *RFID database systems*, (*v*) *trajectory database systems*, (*vi*) *incomplete information bases*.

CONCLUSION

This article has presented and discussed in detail a comprehensive number of view selection and materialization techniques for Data Warehousing and OLAP systems, by also putting in evidence related benefits and limitations. Then, some of these techniques have been selected as the most representative ones, as fundamental issues of the investigated problem have been proposed just in these papers. For these techniques, a theoretical analysis under different parameters that nicely model spatial and temporal complexity aspects has completed the overall contribution of the article.

KEY TERMS

Cuboid: A multidimensional partition (or equally, sub-cube) of a data cube obtained by aggregating data along a given sub-set of the dimensions.

Cuboid Lattice: Hierarchical representation of the generation relationships among cuboids of a given data cube.

Data Cube: A multidimensional data structure storing OLAP data as measures (of interest) that are indexed in a multidimensional space defined by the dimensions of the cube.

Data Warehousing (DW): A methodology for integrating, representing and managing massive heterogeneous and distributed data sets.

Multidimensional View: A portion of a multidimensional database that stores data related to a specific subject of (OLAP) analysis.

On-Line Analytical Processing (OLAP): A methodology for exploring and querying massive DW data according to multidimensional and multi-resolution abstractions of them.

Relational View: A portion of a relational database that stores data related to a specific application-domain/process.

Visual Data Mining from Visualization to Visual Information Mining

INTRODUCTION

The current explosion of data and information, which are mainly caused by the continuous adoption of data warehouses and the extensive use of the Internet and its related technologies, has increased the urgent need for the development of techniques for intelligent data analysis. Data mining, which concerns the discovery and extraction of knowledge chunks from large data repositories, addresses this need. Data mining automates the discovery of hidden patterns and relationships that may not always be obvious. Data mining tools include classification techniques (such as decision trees, rule induction programs and neural networks) (Kou et al., 2007); clustering algorithms and association rule approaches, amongst others.

Data mining has been fruitfully used in many of domains, including marketing, medicine, finance, engineering and bioinformatics. There still are, however, a number of factors that militate against the widespread adoption and use of this new technology. This is mainly due to the fact that the results of many data mining techniques are often difficult to understand. For example, the results of a data mining effort producing 300 pages of rules will be difficult to analyze. The visual representation of the knowledge embedded in such rules will help to heighten the comprehensibility of the results. The visualization of the data itself, as well as the data mining process should go a long way towards increasing the user's understanding of and faith in the data mining process. That is, data and information visualization provide users with the ability to obtain new insights into the knowledge, as discovered from large repositories.

This paper describes a number of important visual data mining issues and introduces techniques employed to improve the understandability of the results of data mining. Firstly, the visualization of data prior to, and during, data mining is addressed. Through *data* visualization, the quality of the data can be assessed throughout the knowledge discovery process, which includes data preprocessing, data mining and reporting. We also discuss *information* visualization, i.e. how the knowledge, as discovered by a data mining tool, may be visualized throughout the data mining process. This aspect includes visualization of the results of data mining as well as the learning process. In addition, the paper shows how virtual reality and collaborative virtual environments may be used to obtain an immersive perspective of the data and the data mining process as well as how visual data mining can be used to directly mine functionality with specific applications in the emerging field of proteomics.

BACKGROUND

Human beings intuitively search for novel features, patterns, trends, outliers and relationships in data (Han and Kamber, 2006). Through visualizing the data and the concept descriptions obtained (e.g., in the form of rules), a qualitative overview of large and complex data sets can be obtained. In addition, data and rule visualization can assist in identifying regions of interest and appropriate parameters for more focused quantitative analysis. The user can thus get a "rough feeling" of the quality of the data, in terms of its correctness, adequacy, completeness, relevance, etc. The use of data and rule visualization thus greatly expands the range of models that can be understood by the user, thereby easing the so-called "accuracy versus understandability" tradeoff (Valdes and Barton, 2007).

Data mining techniques construct a model of the data through repetitive calculation to find statistically significant relationships within the data. However, the human visual perception system can detect patterns

within the data that are unknown to a data mining tool. This combination of the various strengths of the human visual system and data mining tools may subsequently lead to the discovery of novel insights and the improvement of the human's perspective of the problem at hand. Visual data mining harnesses the power of the human vision system, making it an effective tool to comprehend data distribution, patterns, clusters and outliers in data (Blanchard et al., 2007).

Visual data mining is currently an active area of research. Examples of related commercial data mining packages include the *MultiMediaMiner* data mining system, *See5* which forms part of the RuleQuest suite of data mining tools, *Clementine* developed by Integral Solutions Ltd (ISL), *Enterprise Miner* developed by SAS Institute, *Intelligent Miner* produced by IBM, and various other tools. Neural network tools such as *NeuroSolutions* and *SNNS* and Bayesian network tools including *Hugin*, *TETRAD*, and *Bayesware Discoverer*, also incorporates extensive visualization facilities. Examples of related research projects and visualization approaches include *MLC++*, *WEKA*, *AlgorithmMatrix*, *C4.5/See5* and NCBI GEO amongst others (Barret et al., 2007).

Visual data mining integrates data visualization and data mining and is closely related to computer graphics, multimedia systems, human computer interfaces, pattern recognition and high performance computing.

DATA AND INFORMATION VISUALIZATION

Data Visualization

Data visualization provides a powerful mechanism to aid the user during both data preprocessing and the actual data mining. Through the visualization of the original data, the user can browse to get a "feel" for the properties of that data. For example, large samples can be visualized and analyzed (Barret et al., 2007). In particular, visualization may be used for outlier detection, which highlights surprises in the data, i.e. data instances that do not comply with the general behavior or model of the data (Sun et al., 2007). In addition, the user is aided in selecting the appropriate data through a visual interface. Data transformation is an important data preprocessing step. During data transformation, visualizing the data can help the user to ensure the correctness of the transformation. That is, the user may determine whether the two views (original versus transformed) of the data are equivalent. Visualization may also be used to assist users when integrating data sources, assisting them to see relationships within the different formats.

Data visualization techniques are classified in respect of three aspects. Firstly, their focus, i.e. symbolic versus geometric; secondly their stimulus (2D versus 3D); and lastly, their display (static or dynamic). In addition, data in a data repository can be viewed as different levels of granularity or abstraction, or as different combinations of attributes or dimensions. The data can be presented in various visual formats, including box plots, scatter plots, 3D-cubes, data distribution charts, curves, volume visualization, surfaces or link graphs, amongst others (Gardia-Osorio and Fyfe, 2008).

For instance, 3D-cubes are used in relationship diagrams, where the data are compared as totals of different categories. In surface charts, the data points are visualized by drawing a line between them. The area defined by the line, together with the lower portion of the chart, is subsequently filled. Link or line graphs display the relationships between data points through fitting a connecting line (Guo et al., 2007). They are normally used for 2D data where the X value is not repeated.

Advanced visualization techniques may greatly expand the range of models that can be understood by domain experts, thereby easing the so-called accuracy-versus-understandability trade-off. However, due to the so-called "curse of dimensionality", which refers to the problems associated with working with numerous dimensions, highly accurate models are usually less understandable, and vice versa. In a data mining system, the aim of data visualization is to obtain an initial understanding of the data and the quality thereof. The actual accurate assessment of the data and the discovery of new knowledge are the tasks of the data mining tools. Therefore, the visual display should preferably be highly understandable, possibly at the cost of accuracy.

The use of one or more of the above-mentioned data visualization techniques thus helps the user to obtain an initial model of the data, in order to detect possible outliers and to obtain an intuitive assessment of the quality of the data used for data mining. The visualization of the data mining process and results is discussed next.

Information Visualization

It is crucial to be aware of what users require for exploring data sets, small and large. The driving force behind visualizing data mining models can be broken down into two key areas, namely understanding and trust. Understanding means more than just comprehension; it also involves context. If the user can understand what has been discovered in the context of the business issue, he will trust the data and the underlying model and thus put it to use. Visualizing a model also allows a user to discuss and explain the logic behind the model to others. In this way, the overall trust in the model increases and subsequent actions taken as a result are justifiable (Blanchard et al., 2007). Visualization thus aids us to determine whether the data mining process is of high economic utility, i.e. it is adding value especially when considering large-scale real-world data mining projects (Hilderman, 2006).

The art of information visualization can be seen as the combination of three well defined and understood disciplines, namely cognitive science, graphics art and information graphics. A number of important factors have to be kept in mind when visualizing both the execution of the data mining algorithm (process visualization), e.g. the construction of a decision tree, and displaying the results thereof (result visualization). The visualization approach should provide an easy understanding of the domain knowledge, explore visual parameters and produce useful outputs. Salient features should be encoded graphically and the interactive process should prove useful to the user (Jankun-Kelly et al., 2007).

The format of knowledge extracted during the mining process depends on the type of data mining task and its complexity. Examples include classification rules, association rules, temporal sequences, casual graphs and tail trees (Klemela, 2007). Visualization of these data mining results involves the presentation of the results or knowledge obtained from data mining in visual forms, such as decision trees, association rules, clusters, outliers and generalized rules (Hruschka et al., 2007). For example, the Silicon Graphics (SGI) MineSet (MLC++) and the Blue Martini Software toolsets use connectivity diagrams to visualize decision trees, and simple Bayesian and decision table classifiers (Erbacher and Teerling, 2006). Other examples include the Iris Explorer system that offers techniques ranging from simple graphs to multidimensional animation (NAG, 2007); and SpectraMiner, an interactive data mining and visualization software for single particle mass spectroscopy (Zelenyuk et. al., 2006).

Visual Data Mining and Virtual Reality

Three-dimensional visualization has the potential to show far more information than two-dimensional visualization, while retaining its simplicity. This visualization technique quickly reveals the quantity and relative strength of relationships between elements, helping to focus attention on important data entities and rules. It therefore aids both the data preprocessing and data mining processes.

Many techniques are available to visualize data in three dimensions. For example, it is very common to represent data by glyphs. A glyph can be defined as a three-dimensional object suitable for representing data or subsets of data. The object is chosen in order to facilitate both the visualization and the data mining process. The glyph must be self-explanatory and unambiguous.

Three-dimensional visualization can be made more efficient by the use of virtual reality (VR). A virtual environment (VE) is a three-dimensional environment characterized by the fact that it is immersive, interactive, illustrative and intuitive. The fact that the environment is immersive is of great importance in data mining. In traditional visualization, the human subject looks at the data from outside, while in a VR environment the user is part of the data world. This means that the user can utilize all his senses in order to navigate and understand the data. This also implies that the representation is more intuitive. VR is particularly well adapted to representing the scale and the topology of various sets of data. That becomes even more evident when stereo visualization is utilized, since stereo vision allows the analyst to have a real depth perception. This depth perception is important in order to estimate the relative distances and scales between the glyphs. Such estimation can be difficult without stereo vision if the scene does not correspond to the paradigms our brain is used to processing. In certain cases, the depth perception can be enhanced by the use of metaphors.

In addition, we mention some non standard visualization techniques; for example iconic displays, dense pixel displays and stacked displays (Keim, 2002). The iconic display maps the attributes of a multidimensional data set to the features or parameters of an iconic representation e.g. color icons, sick figure icons and star

icons. A dense pixel display maps each dimension value to a colored pixel and groups the pixels belonging to each dimensions into adjacent areas. Stack displays are utilized to represent data which have a hierarchical partition by embedding coordinate systems inside each other.

Irrespectively of the representation chosen, the data exploration is more efficient by making use of the interaction and distortion techniques. In the case of the interaction technique, one can modify in real time the visualization scheme. Also, we may combine, relate and group various visual elements in order to facilitate the exploration of the data. As of the case of the distortion technique, it is based on the concept of multiresolution: a subset of the data is shown at high resolution while others are shown at low level. Such a technique can be either manual or automatic and is called, accordingly, interactive or dynamic.

Collaborative Virtual Environments (CVEs) can be considered as a major breakthrough in data mining (Jamieson et al., 2007). By analogy, they can be considered as the equivalent of collaborative agents in visualization. Traditionally, one or more analysts perform visualization at a unique site. This operational model does not reflect the fact that many enterprises are distributed worldwide and so are their operations, data and specialists. It is consequently impossible for those enterprises to centralize all their data mining operations in a single center. Not only must they collaborate on the data mining process, which can be carried out automatically to a certain extent by distributed and collaborative agents, but they must also collaborate on the visualization and the visual data mining aspects.

FUTURE TRENDS

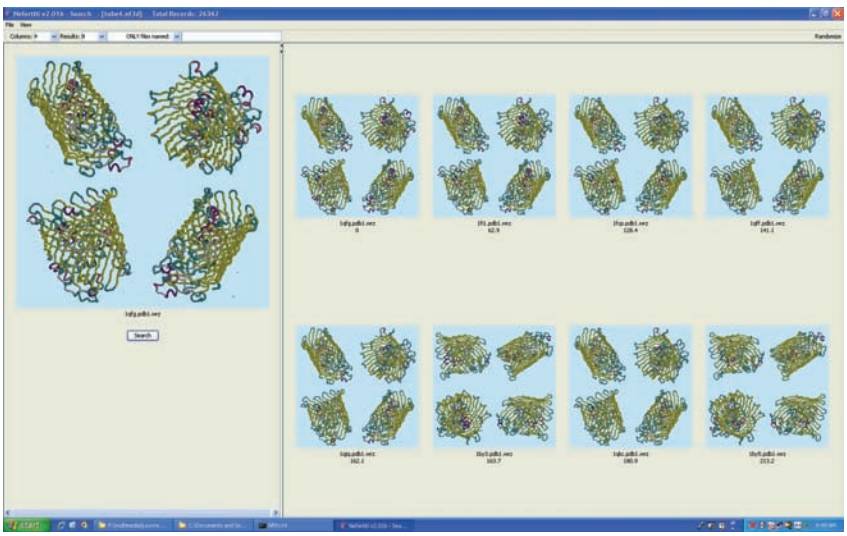
Visual Data Mining and Proteomics; when Visual Appearance Becomes Functionality

Visual data mining is not limited to data visualization per se. In some specific cases, the visual appearance of the data is related to their effective functionality and visual data mining becomes synonym of function mining; a highly attractive feature for many practical applications. In this section, such an approach is applied to the emerging field of proteomics and computer aided drug design.

Protein function analysis is an important research issue in molecular biology, bioinformatics and pharmaceutics. A protein's function is often dependent on the shape (visual appearance) and physical properties of the so-called active sites (local subparts) of the molecular surface. Current research suggests that, if two proteins have similar active sites, the function of the two proteins may be closely related. This observation is of importance for many reasons.

Consider a protein which has shown to be successful in a prescription drug developed to treat a

Figure 1.The CAPRI visual data mining system for proteins



terminal illness. However, this protein has serious contra-indications and causes severe adverse effects in a certain subset of the population. Suppose a protein with similar visual structure and functionality, but without these serious adverse effects, can be found. The subsequent modification of the harmful drug has obvious benefits.

For instance, the Content-based Analysis of Protein Structure for Retrieval and Indexing (CAPRI) visual data mining system addresses this issue (Paquet and Viktor, 2007). CAPRI is able to utilize the 3D structure of a protein, in order to find the *k* most similar structures.

The results against more than 26,000 protein structures as contained in the Protein Data Bank show that the system is able to accurately and efficiently retrieve similar protein structures with a very high precision-recall rate. For instance, figure 1 shows the retrieval of visually similar proteins based on their 3D shape. All proteins shown belong to the same family. Through the use of the CAPRI system, domain experts are able to find similar protein structures, using a "query by prototype" approach. In this way, they are aided in the task of labeling new structures effectively, finding the families of existing proteins, identifying mutations and unexpected evolutions.

The main benefit of 3D structural indexing is that the protein functionality is related to its 3D shape. 3D shape indexing is a natural way to index the functionality with all the foreseen applications in bioinformatics, genomic, as well as for the pharmaceutical industry.

CONCLUSION

The ability to visualize the results of a data mining effort aids the user to understand and trust the knowledge embedded in it. Data and information visualization provide the user with the ability to get an intuitive "feel" for the data and the results, e.g. in the form of rules, that is being created. This ability can be fruitfully used in many business areas, for example for fraud detection, diagnosis in medical domains and credit screening, amongst others.

Finally, the direct mining of visual information looks very promising in proteomics for the design of new drugs with fewer side effects.

KEY TERMS

Collaborative Virtual Environment: An environment that actively supports human-human communication in addition to human-machine communication and which uses a virtual environment as the user interface.

Curse of Dimensionality: The problems associated with information overload, when the number of dimensions is too high to visualize.

Data Visualization: The visualization of the data set through the use of a techniques such as scatter plots, 3D cubes, link graphs and surface charts.

Glyph: A three-dimensional object suitable for representing data or subsets of data.

Multimedia Data Mining: The application of data mining to data sets consisting of multimedia data, such as 2D images, 3D objects, video and audio. Multimedia data can be viewed as integral data records, which consist of relational data together with diverse multimedia content.

Visualization: The graphical expression of data or information.

Visual Data Mining: The integration of data visualization and data mining. Visual data mining is closely related to computer graphics, multimedia systems, human computer interfaces, pattern recognition and high performance computing.

Visualization of High-Dimensional Data with Polar Coordinates

Frank Rehm
German Aerospace Center, Germany

Frank Klawonn
University of Applied Sciences Braunschweig/Wolfenbuettel, Germany

Rudolf Kruse
University of Magdenburg, Germany

INTRODUCTION

Many applications in science and business such as signal analysis or costumer segmentation deal with large amounts of data which are usually high dimensional in the feature space. As a part of preprocessing and exploratory data analysis, visualization of the data helps to decide which kind of data mining method probably leads to good results or whether outliers or noisy data need to be treated before (Barnett & Lewis, 1994; Hawkins, 1980). Since the visual assessment of a feature space that has more than three dimensions is not possible, it becomes necessary to find an appropriate visualization scheme for such data sets.

Multidimensional scaling (MDS) is a family of methods that seek to present the important structure of the data in a reduced number of dimensions. Due to the approach of distance preservation that is followed by conventional MDS techniques, resource requirements regarding memory space and computation time are fairly high and prevent their application to large data sets. In this work we will present two methods that visualize high-dimensional data on the plane using a new approach. An algorithm will be presented that allows applying our method on larger data sets. We will also present some results on a benchmark data set.

BACKGROUND

Multidimensional scaling provides low-dimensional visualization of high-dimensional feature vectors (Kruskal & Wish, 1978; Borg & Groenen, 1997). MDS is a method that estimates the coordinates of a set of objects in a feature space of specified (low) dimensionality that come from data trying to preserve the distances between pairs of objects. In the recent years much research has been done (Chalmers, 1996; Faloutsos & Lin, 1995; Morrison, Ross, & Chalmers, 2003; Williams & Munzner, 2004; Naud, 2006). Different ways of computing distances and various functions relating the distances to the actual data are commonly used. These distances are usually stored in a distance matrix. The estimation of the coordinates will be carried out under the constraint, that the error between the distance matrix of the data set and the distance matrix of the corresponding transformed data set will be minimized. Thus, different error measures to be minimized were proposed, i.e. the absolute error, the relative error or a combination of both. A commonly used error measure is the so-called Sammon's mapping (Sammon, 1969). To determine the transformed data set by means of minimizing the error a gradient descent method is used.

Many modifications of MDS are published so far, but high computational costs prevent their application to large data sets (Tenenbaum, de Silva, & Langford, 2000). Besides the quadratic need of memory, MDS, as described above is solved by an iterative method, expensive with respect to computation time, which is quadratic in the size of the data set. Furthermore, a completely new solution must be calculated, if a new object is added to the data set.

MAIN FOCUS

With MDS_{polar} and POLARMAP we present two approaches to find a two-dimensional projection of a p-dimensional data set X. Both methods try to find a rep-

resentation in polar coordinates $Y = \{(l_1, \phi_1), \ldots, (l_n, \phi_n)\}$, where the length l_k of the original vector x_k is preserved and only the angle φ_k has to be optimized. Thus, our solution is defined to be optimal if all angles between pairs of data objects in the projected data set Y coincide as good as possible with the angles in the original feature space *X*. As we will show later, it is possible to transform new data objects without extra costs.

MDS$_{\text{polar}}$

A straight forward definition of an objective function to be minimized for this problem would be,

$$E = \sum_{k=2}^{n} \sum_{i=1}^{k-1} \left(\left| \phi_i - \phi_k \right| - \psi_{ik} \right)^2 \quad (1)$$

where φ_k is the angle of y_k, ψ_{ik} is the positive angle between x_i and x_k. The absolute value is chosen in equation (1) because the order of the minuends can have an influence on the sign of the resulting angle. The problem with this notation is that the functional *E* is not differentiable, exactly in those points we are interested in, namely, where the difference between angles φ_i and φ_k becomes zero.

We propose an efficient method that enables us to compute an approximate solution for a minimum of the objective function (1) and related ones. In a first step we ignore the absolute value in (1) and consider

$$E = \sum_{k=2}^{n} \sum_{i=1}^{k-1} \left(\phi_i - \phi_k - \psi_{ik} \right)^2. \quad (2)$$

When we simply minimize (2), the results will not be acceptable. Although the angle between y_i and y_k might perfectly match the angle ψ_{ik}, $\varphi_i - \varphi_k$ can either be ψ_{ik} or $-\psi_{ik}$. Since we assume that $0 \le \psi_{ik}$ holds, we always have $\left(\left| \phi_i - \phi_k \right| - \psi_{ik} \right)^2 \le \left(\phi_i - \phi_k - \psi_{ik} \right)^2$. Therefore, finding a minimum of (2) means that this is an upper bound for the minimum of (1). Therefore, when we minimize (2) in order to actually minimize (1), we can take the freedom to choose whether we want the term $\phi_i - \phi_k$ or the term $\phi_k - \phi_i$ to appear in (2). Since

$$\begin{aligned} &\left(\phi_i - \phi_k - \psi_{ik} \right)^2 \\ &= \left(-\left(\phi_i - \phi_k - \psi_{ik} \right) \right)^2 \\ &= \left(\phi_k - \phi_i + \psi_{ik} \right)^2 \end{aligned}$$

instead of exchanging the order of φ_i and φ_k, we can choose the sign of ψ_{ik}, leading to

$$E = \sum_{k=2}^{n} \sum_{i=1}^{k-1} \left(\phi_i - \phi_k - a_{ik} \psi_{ik} \right)^2 \quad (3)$$

with $a_{ik} \in \{-1, 1\}$.

In order to solve this optimization problem of equation (3) we take the partial derivatives of *E*, yielding

$$\frac{\partial E}{\phi_k} = -2 \sum_{i=1}^{k-1} \left(\phi_i - \phi_k - a_{ik} \psi_{ik} \right). \quad (4)$$

Thus, on the one hand, neglecting that we still have to choose a_{ik}, our solution is described by a system of linear equations which means its solution can be calculated directly without the need of any iteration procedure. On the other hand, as described above, we have to handle the problem of determining the sign of the ψ_{ik} in the form of the a_{ik}-values. To fulfill the necessary condition for a minimum we set equation (4) equal to zero and solve for the φ_k-values, which leads to

$$\phi_k = \frac{\sum_{i=1}^{k-1} \left(\phi_i - a_{ik} \psi_{ik} \right)}{k-1}. \quad (5)$$

Since we only want to preserve the angles between data vectors, it is obvious that any solution will be invariant with respect to rotation of the data set. Due to the representation in polar coordinates it is necessary to apply a preprocessing step in form of a translation that makes all components of data vectors non-negative. Reasons for that and further details are given in (Rehm, Klawonn, & Kruse, 2005).

A Greedy Algorithm for the Approximation of MDS$_{\text{polar}}$

As mentioned above, this solution describes a system of linear equations. Since the desired transformation is rotation invariant φ_1 can be set to any value, i.e. $\varphi_1 = 0$. By means of a greedy algorithm we choose $a_{ik} \in \{-1, 1\}$ such that for the resulting φ_k the error *E* of the objective function (3) is minimal. For φ_2 the exact solution can always be found, since a_{12} is the only parameter to optimize. For the remaining φ_k the greedy algorithm sets a_{ik} in turn either –1 or 1, verifying the validity of the result, setting a_{ik} the better value immediately and continuing with the next a_{ik} until all k–1 values for a_{ik} are set.

A Generalized MDS_{polar}

In certain cases the objective when transforming data is to preserve relations of feature vectors of the original feature space in the target feature space. Thus, feature vectors that form a cluster should be represented as exact as possible in the target feature space, too. The transformation of feature vectors with a large distance to the respective feature vector can have a lower accuracy. An approach to achieve this goal is the introduction of weights w_{ik} to our objective function

$$E = \sum_{k=2}^{n} \sum_{i=1}^{k-1} w_{ik} \left(\phi_i - \phi_k - a_{ik} \ \psi_{ik} \right)^2. \quad (6)$$

The main benefit of weights, indeed, is the ability to decrease the computational complexity of the algorithm. This is the case if weights are chosen in such a way, that for feature vectors with a certain (large) distance the respecting weights become zero. A weighting function can control this behavior automatically. For an efficient implementation it is useful to sort the feature vectors by means of their length. Note that sorting can be carried out in less than quadratic time. Weighting functions should be decreasing and should lead to zero weights for proper feature vectors. Different weighting functions and further details can be seen in (Rehm, Klawonn, & Kruse, 2005). In this way, feature vectors can be grouped into suitable bins, reducing the complexity of our algorithm to $O(n \cdot \log n)$.

POLARMAP

As an extension of MDS_{polar} we propose in this work a method that learns a function f that provides for any p-dimensional feature vector x_k the corresponding angle φ_k that is needed to map the feature vector to a 2-dimensional feature space. As for MDS_{polar} the length of vector x_k is preserved. With the obtained function also angles for new feature vectors can be computed. A 2-dimensional scatter plot might not be suitable, when visualizing mappings for large data sets. With the computed function it is simple to produce information murals, which allow more comprehensive visualizations (Jerding & Stasko, 1995).

Analogous to functional (1) we define our objective function E as follows:

$$E = \sum_{k=2}^{n} \sum_{i=1}^{k-1} \left(\left| f(x_i) - f(x_k) \right| - \psi_{ik} \right)^2. \quad (6)$$

Since functional (6) is not differentiable, we propose analogous to the procedure for MDS_{polar} to minimize the following differentiable objective function

$$E = \sum_{k=2}^{n} \sum_{i=1}^{k-1} \left(f(x_i) - f(x_k) - \psi_{ik} \right)^2. \quad (7)$$

Albeit, f might be any function, we discuss in this work the following type of function

$$f(x) = a^T \cdot \tilde{x} \quad (8)$$

where a is vector whose components are the parameters to be optimized and $\tilde{x}$ is the feature vector x itself or a modification of x. In the simplest case we use

$$\begin{aligned} \tilde{x} &= x \\ a &= (a_1, a_2, \ldots, a_p) \end{aligned} \quad (9)$$

where f describes in fact the linear combination of x. Other functions f are discussed in (Rehm, Klawonn, & Kruse, 2006).

Replacing term f by the respective function we obtain

$$E = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \left(a^T \tilde{x}_i - a^T \tilde{x}_j - \psi_{ik} \right)^2$$

$$= \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \left(a^T (\tilde{x}_i - \tilde{x}_j) - \psi_{ik} \right)^2. \quad (10)$$

For a better readability we replace $\tilde{x}_i - \tilde{x}_j$ by $\tilde{x}_{ij}$ and obtain

$$E = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \left(a^T \tilde{x}_{ij} - \psi_{ij} \right)^2. \quad (11)$$

The derivative of E w.r.t. a can by easily obtained

$$E = 2 \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \left(a^T \tilde{x}_{ij} - \psi_{ij} \right) \tilde{x}_{ij} \quad (12)$$

which results in a system of linear equations in $a = \left(a_1, a_2, \ldots, a_p \right)^T$. As mentioned already, angles computed by $f(x_i) - f(x_j)$, might be positive or negative, while ψ_{ik} is always positive by definition. Thus, in the case where $a^T \tilde{x}_{ij} < 0$ holds, E might be minimal, but our original objective function E might not be minimal.

Figure 1. Sammon's Mapping of the Wisconsin Breast Cancer Dataset

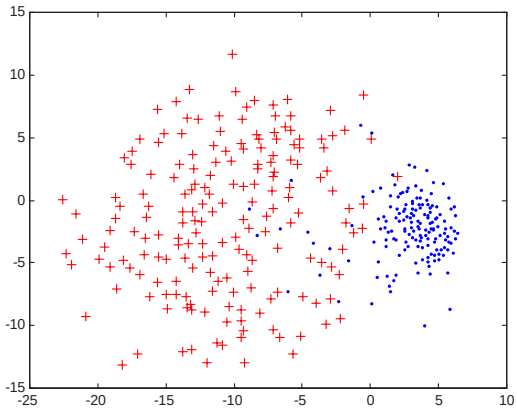

Figure 2. POLARMAP on the Wisconsin Breast Cancer Dataset

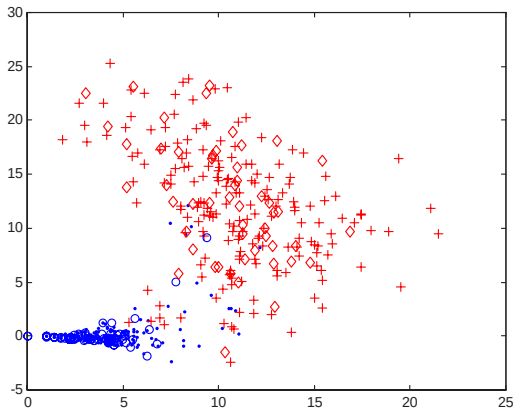

Hence, replacing $\tilde{x}_{ij}$ by $-\tilde{x}_{ij}$ in this case might lower the error. Consequently, finding the appropriate sign for $\tilde{x}_{ij}$ is a crucial step when minimizing E.

Determining the sign for each $\tilde{x}_{ij}$ requires exponential need of computation time in the number of feature vectors. For real-world data sets this is unacceptable. When relaxing the problem in favor to an approximation of the exact solution one can reduce the time complexity down to $O(n \cdot \log n)$. As for $\text{MDS}_{\text{polar}}$ this can be achieved by means of introducing weights which is discussed in detail in (Rehm, Klawonn, & Kruse, 2006).

Experimental Results

Since a function is learned by POLARMAP it becomes possible to map new vectors in the target space. To demonstrate the power of POLARMAP, we applied it on a UCI database, the well known Wisconsin breast cancer data set[1] (Mangasarian & Wolberg, 1990). Each patient in the database had a fine needle aspirate taken from her breast. Resultant, nine attributes where determined and analyzed to discriminate benign from malignant breast lumps. The original number of instances is about 699 that can be reduced to 481 data by removing redundant measurements or measurements that have missing values. Each instance in the data set is described by means of ten numerical attributes and one additional class attribute that classifies the measurement either benign or malignant accordingly.

Figure 1 shows the Sammon's mapping of the data set. The transformation of the Wisconsin breast cancer data set with POLARMAP is shown in figure 2. The different classes are represented by different symbols. Whereas the plus symbol corresponds to a benign

sample, does the dot symbol represent a malignant sample. Both transformations are similar regarding the scattering of the different classes. Patients with benign lumps and those with malignant lumps can be almost separated linearly in both transformations. Only few points can be found in regions where the opposite class mainly represented. Note, labeling of the axes is omitted intentionally in the figures. Since the discussed visualization techniques arrange some kind of non-trivial dimension reduction both axes represent the original attributes in a composite manner.

For the transformation with POLARMAP, the data set is split into a training data set and a test data set. The training data set consists of 80% of each class. This part of the data is used to learn the desired coefficients. The test data set, that contains the remaining 20% of the data, is mapped to the target space by means of the learned function. The mapping of the training data set is plotted with the different symbols again, each for the corresponding class. The mapped feature vectors of the test data set are marked with a small circle (for malignant samples) or a diamond (for benign samples), respectively. As the figure shows, the learned function maps the new feature vectors in an appropriate way.

FUTURE TRENDS

We presented two approaches that provide visualization of high-dimensional data. MDS_{polar} and POLARMAP find 2-dimensional representations of complex data trying to preserving angles between feature vectors. The bin-strategy that uses a weighting function to reduce the complexity of the algorithm, benefits from sorting the feature vectors by means of their length. Indeed, sorting guarantees that short feature vectors are quite similar. Nevertheless, longer feature vectors can be either similar or different, namely if they have different directions. Thus, another sorting criterion could improve the results of both proposed visualization methods. Appropriate techniques should be subject of future work.

CONCLUSION

In this paper we have described a powerful data visualization method. Under the constraint to preserve the length of feature vectors, it was our aim to find a mapping that projects feature vectors from a high-dimensional space to the plane in such a way that we minimize the errors in the angles between the mapped feature vectors. The solution is described by a system of linear equations. To overcome the problem in high-dimensional feature spaces, that no differentiation between positive and negative angles can be made as for a 2-dimensional feature space, an algorithm is provided to obtain the desired signs for the angles. With the bin-algorithm we presented an algorithm that lowers the computation complexity down to $O(n \cdot \log n)$. Experimental results on a benchmark data set have shown that the results of the proposed techniques are comparable to those of conventional MDS but fewer resources will be needed. In particular when additional instances have to be mapped, the proposed techniques can achieve this without extra costs.

KEY TERMS

Data Visualization: Presentation of data in human understandable graphics, images, or animation.

Information Mural: A technique that allows 2D visual representations of large information spaces to be created even when the number of informational elements greatly outnumbers the available resolution of the display device.

MDS_{polar}: A multidimensional scaling technique whose optimizations criterion is the minimization of the difference of angles between feature vectors.

Multidimensional Scaling: Provides low-dimensional visualization of high-dimensional feature vectors.

POLARMAP: A modification of MDS_{polar} in that point that a function is learned to map high-dimensional feature vectors on the plane. By means of this function even new feature vectors can be mapped without any extra costs.

Sammon's Mapping: An error measure of distances between feature vectors to be minimized for dimension reduction. A combination of both - the absolute error and the relative error - will be considered.

Visual Data Mining: Data mining process through data visualization. The fundamental concept of visual data mining is the interaction between data visual presentation, human graphics cognition, and problem solving.

INTRODUCTION

Decision support algorithms form an important part of the larger world of data mining. The purpose of a decision support system is to provide a human user with the context surrounding a complex decision to be based on computational analysis of the data at hand. Typically, the data to be considered cannot be adequately managed by a human decision maker because of its volume, complexity or both; data mining techniques are therefore used to discover patterns in the data and inform the user of their saliency in terms of a particular decision to be made.

Visualization plays an important role in decision support, as it is through visualization that we can most easily comprehend complex data relationships (Tufte, 1997, 2001, 2006; Wright, 1997). Visualization provides a means of interfacing computationally discovered patterns with the strong pattern recognition system of the human brain. As designers of visualization for decision support systems, our task is to present computational data in ways that make intuitive sense based on our knowledge of the brain's aptitudes and visual processing preferences.

Confidence, in the context of a decision support system, is an estimate of the value a user should place in the suggestion made by the system. System reliability is the measure of overall accuracy; confidence is an estimate of the accuracy of the suggestion currently being presented. The idea of an associated confidence or certainty value in decision support systems has been incorporated in systems as early as MYCIN (Shortliffe, 1976; Buchanan & Shortliffe, 1984).

BACKGROUND

A decision support system functions by taking a set of rules and evaluating the most preferable course of action. The most preferable of a set of possible actions is chosen based on an internal optimization of some form of objective function. This optimization may take one of several forms: a full cost-benefit analysis (Rajabi, Kilgour & Hipel, 1998; Hipel & Ben-Haim, 1999); a simple best-rule match; or that of a multi-rule evaluation using rules weighted by their expected contribution to decision accuracy (Hamilton-Wright, Stashuk & Tizhoosh, 2007).

The underlying rules forming the structure of a decision support system may be found using an automated rule discovery system, allowing a measure of the quality of the pattern to be produced through the analysis generating the patterns themselves (Becker, 1968); in other cases (such as rules produced through interview with experts), a measure of the quality of the patterns must be made based on separate study (Rajabi, Kilgour & Hipel, 1998; Kononenko & Bratko, 1999; Kukar, 2003; Gurov, 2004a,b).

The construction of a tool that will assist in choosing a course of action for human concerns demands a study of the confidence that may be placed in the accurate evaluation of each possible course. Many of the suggestions made by a decision-support system will have a high-risk potential (Aven, 2003; Crouhy, Galai & Mark, 2003; Friend & Hickling, 2005). Examples of such systems include those intended for clinical use through diagnostic inference (Shortliffe, 1976; Buchanan & Shortliffe, 1984; Berner, 1988; de Graaf, van den Eijkel, Vullings & de Mol, 1997; Innocent, 2000; Coiera, 2003; Colombet, Dart, Leneveut, Zunino, Ménard & Chatellier, 2003; Montani, Magni, Bellazzi,

Larizza, Roudari & Carson, 2003; Devadoss, Pan & Singh, 2005) and medical informatics (Bennett, Casebeer, Kristofco & Collins, 2005): other systems may have a lower immediate risk factor, but the long term public risk may be extensive, such as in environmental planning and negotiation (Rajabi, Kilgour & Hipel, 1998; Freyfogle, 2003; Randolph, 2004).

In such high-risk cases, a user cannot proceed through a decision process with a blind trust in a suggested algorithmic solution. This observation is further supported by the consideration that the possible solutions promoted by the algorithm will have a broad variability in confidence support themselves: some courses of action will be suggested based on only the thinnest degree of support; others may have a large margin of error. The disparity between these cases makes it obvious that one would clearly be unwise to treat the two suggestions in the same way when incorporating the suggested algorithmic decision into a larger course of action. Ideally, suggestions associated with a lower degree of confidence will be ratified through some other form of external evidence before being put into action. Such corroboration is certainly more desirable in the case of the less-confident decision than that of the more-confident one. The use of confidence based metrics for decision quality analysis has been discussed in the context of decision support since the inception of the field (Morton, 1971; Sage, 1991; Silver, 1991; Hipel & Ben-Haim, 1999). In order to trigger this ratification, it must be clear to the user what the relative and specific confidence values associated with a suggestion are.

The intent of this article is to discuss methods for conveying confidence to a human decision maker, and introduce ideas for clearly presenting such information in the context of a larger discussion of system design and usability (Norman, 1998; Tufte, 2001, 2006). The discussion will be based on decision support within a computationally supported visualization context (Wright, 1997; Brath, 1997; 2003; Mena, 1999).

MAIN FOCUS

Given that confidence in decision-making is a necessary and central concept to communicate to a human user, it is of interest to study how this concept may be conveyed. Counter-intuitively, although the concept of confidence is a central concept of decision support, an unambiguous formalism of confidence is lacking, due to the fact that different representations may or may not take into account a potential two-class labeling outcome in the confidence representation.

Confidence as Probability

In this representation, confidence is simply the perceived probability of a correct suggestion. The range of such a confidence measure is therefore [0…1], with the implication being that for a two-outcome case, a value of 0.5 will indicate "even odds", or a 50%-confidence solution. The value of this point will vary depending on the number of outcomes possible in the decision system at hand, and therefore the choice of this mechanism of confidence representation must be weighed against the system clarity of the number of outcomes for a decision will vary, especially if the number of outcomes may be substantially large.

The strongest reason to choose this representation of confidence is the direct relationship to probability; this clear relationship will aid decision makers with a strong statistical background, and will enable the confidence value to be integrated into a larger decision with greater ease and reliability.

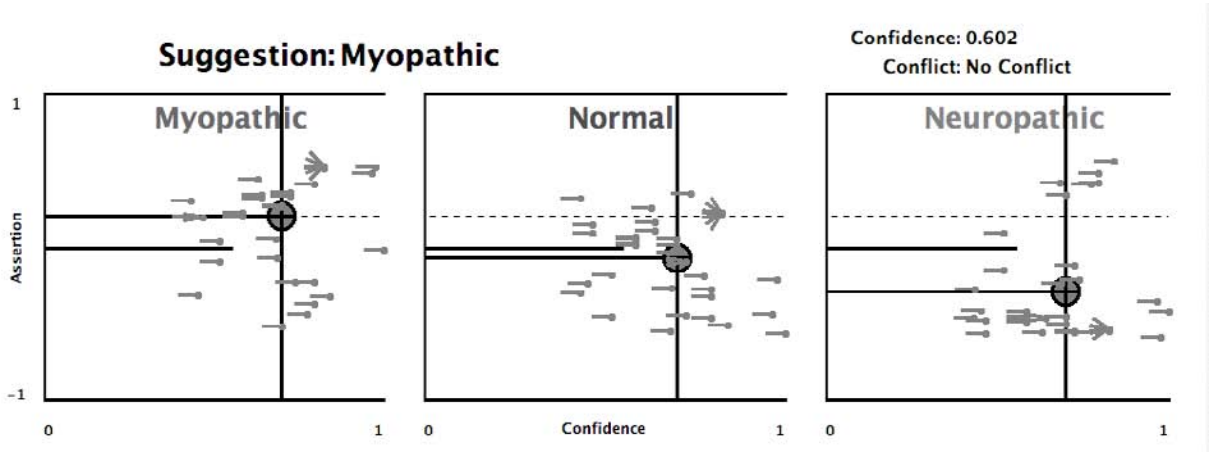
A further strength of this representational choice is the ability to have different probabilistic confidence values associated with different outcomes; these can be transparently calculated and clearly represented as part of the summary visualization for each case (see example below).

Confidence as Distance

This representation holds that confidence is a quality that has only a positive measure; that is the degree of confidence a system has in a given outcome is measured on a [0…1] scale where 0 indicates random chance and 1 indicates perfect certainty.

Figure 1 shows a sample visualization taken from a decision support tool (Hamilton-Wright & Stashuk, 2006; Hamilton-Wright, Stashuk & Tizhoosh, 2007). This tool produces "assertions" based on a rule weighting, and calculates a confidence value for each assertion produced. Suggested outcomes are proposed as aggregates of assertion weighting and confidence value. The location of the ticks shown in Figure 1 is therefore

Figure 1. Confidence visualization



important, as each of the three co-ordinate spaces relates aggregate decision support to both assertion weighting and confidence.

The figure shown here demonstrates the inclusion of all of these elements:

- each underlying data point is shown with a small tick; the *y* location of the tick indicates a degree of assertion associated with each point, and the *x* location indicates a confidence value in the [0…1] bounded range.
- an aggregate assertion is shown at a *y* location generated by an overall assertion value; these are shown by the larger circular marks.
- the overall confidence value is shown by the *x* location of *each* aggregate value.

By incorporating confidence and assertion weighting together, one may see at a glance to what degree the logic of the assertion weights are reinforced by their associated confidence values. It is clear in Figure 1 that the only high-confidence points are those whose assertion is significantly far from the zero line.

This display strategy brings up several points of note:

- the confidence display, being shown as a point along the *x*-axis of a bounded grid, accurately reflects the bounded nature of the confidence data; further, the lack of a central reference to the [0…1] number line reflects (accurately) that confidence in this sense is represented as a "degree of merit" associated with the indicated datum.
- the choice of *x* location reflects the continuous nature of the confidence data, as it is implied that all values between 0 and 1 are legal locations; the use of a linear color gradient would additionally support such a meaning.
- by using a one-dimensional representation for confidence, we are free to combine confidence values with another displacement-based data value – in this case, an assertion value was chosen. This allows the user to examine the relationship between confidence and assertion; as can be seen in the display, there is a general trend along the relation $x = |y|$ in each graph, which provides a useful insight by allowing a user to see a (desired) data dependency between confidence and assertion support.
- the strongest negative statement to be made about this display is the re-representation of confidence in each outcome domain; the display uses the same *x* location for all three confidence values. This is done as there is only a single confidence value available, however the obvious implication is the opposite: that there are three different confidence

values that are co-incidentally the same. Whether the strength of co-plotting confidence overcomes this undesired consequence will depend on the domain in question.

FUTURE TRENDS

Decision confidence is a necessary condition for intelligent decision support systems. The need for integration of confidence values into visual landscapes remains central to the requirements for decision support. Future visualization paradigms and tools will explore new ways to consistently and transparently integrate confidence visualization into the context of the data landscape supporting the decision to be made.

By moving to three-dimensional visualization (Wright, 1997; Mena, 1999) further degrees of freedom are introduced; providing further opportunities for the plotting of confidence values as supporting but independent data values. Obvious extensions of the above-mentioned ideas are to use the depth of a data bar for confidence while length and color may represent data values. Care must be taken to avoid overloading the decision maker with too much information, especially through displays containing redundant or extraneous information; Tufte (2001) urges designers to avoid "non-data" or "redundant data ink", and a consistent theme throughout his works asks for thought on the representation of data through clear use of strategically chosen representations (Tufte 1997, 2001, 2007).

Further papers regarding the representation of confidence and probabilistic error are being produced (Rossi, 2006; Sun, Kabán & Raychaudhury, 2007), as this study is central to the development of robust and understandable visual decision support systems.

CONCLUSIONS

Confidence values must accompany suggested courses of action in any decision support system. By achieving a coupled representation of confidence and suggestion, a system may provide insightful visualization that is easily understood by a decision-making user. Current visualization techniques provide a number of interesting tools to explore various methods of achieving this goal; one of the strongest remains the use of distance and position.

KEY TERMS

Confidence Measure: A metric produced by a data analysis system representing the likelihood of error in an associated calculated value. In a decision support

system, this is frequently related to the probability that the suggested course of action is in fact correct or the best.

Data Cleaning: A data mining task in which input data is examined to ensure that erroneous values are unlikely to be included. In terms of confidence estimation, an estimate of how "clean" a data set is will play a part in determining the confidence placed in any rules generated by analysis of such data.

Data Visualization: The construction of a two- or three-dimensional scene that represents relationships within a data set using relationships based on concepts used by the human visual system. Such concepts include geometric placement, relative scale, color and orientation.

Decision Exploration: A task related to decision support, decision exploration refers to the ability of a data analysis system to provide feedback on the consequences of, and rationale behind, a particular course of action. By exploring several courses of action, a human user will become more aware of the relative merits of each course.

Decision Support: The process of mining and presenting background data for the purposes of assisting in a complex decision. Typically, this is done by computational means to speed the process of data analysis, but may also be done through human collaboration. In all cases, the objective is to make clear to a decision maker the evidence in support of, or against, any particular course of action.

High-Risk Decision Making: An activity in which it is of greater than normal importance to ensure that poor outcomes are not chosen. In a high-risk environment, it is significantly preferable to determine the outcome of potential decisions by decision exploration using a model rather than direct experimentation. Many applications in civil engineering, public health and environmental management are considered to be "high risk" areas requiring special tools to avoid detrimental courses of action.

Risk Assessment: A protocol that will generate an estimate of the risk associated with a given course of action. This differs from confidence in that confidence is an estimate of the probability of an error being made; a risk is a probability that the outcome may be unfavorable in the case where all estimates are correct. A system may estimate a 7 in 10 chance of success with a 95% confidence interval; the risk in this case would be 3 in 10.

Visual Representation of Statistical Information: A mapping provided from a probabilistic data element into a visual representation. Statistical information is defined in terms of a (bounded) portion of a real-number line, and therefore a continuous-valued representation is preferred: typically this is done with a location-based metaphor with an associated axis, or color. Representations that imply enumeration, counts or other discrete phenomena are to be avoided.

Web Design Based on User Browsing Patterns

Yinghui Yang
University of California, Davis, USA

INTRODUCTION

It is hard to organize a website such that pages are located where users expect to find them. Consider a visitor to an e-Commerce website in searching for a scanner. There are two ways he could find information he is looking for. One is to use the search function provided by the website. The other one is to follow the links on the website. This chapter focuses on the second case. Will he click on the link "Electronics" or "Computers" to find the scanner? For the website designer, should the scanner page be put under Electronics, Computers or both? This problem occurs across all kinds of websites, including B2C shops, B2B marketplaces, corporate web-sites and content websites.

Through web usages mining, we can automatically discover pages in a website whose location is different from where users expect to find them. This problem of matching website organization with user expectations is pervasive across most websites. Since web users are heterogeneous, the question is essentially how to design a website so that majority of the users find it easy to navigate. Here, we focus on the problem of browsing within a single domain/web site (search engines are not involved since it's a totally different way of finding information on a web site.) There are numerous reasons why users fail to find the information they are looking for when browse on a web site. Here in this chapter, we focus on the following reason. Users follow links when browsing online. Information scent guides them to select certain links to follow in search for information. If the content is not located where the users expect it to be, the users will fail to find it. How we analyze web navigation data to identify such user browsing patterns and use them to improve web design is an important task.

BACKGROUND

There has been considerable amount of work on mining web logs – Web Usage Mining. Web usage mining is a viable framework for extracting useful access pattern information from massive amounts of web log data for the purpose of web site personalization and organization (Missaoui et al 2007; Srivastava 2000; Nasraoui et al. 2003; Mobasher & Anand 2005). Various tasks can be achieved via web usage mining (e.g., finding frequent and interesting navigation patterns, predicting future page requests and page recommendations). Spiliopoulou et al. (1998) and Spiliopoulou et al. (1999) propose a "web utilization miner" (WUM) to find interesting navigation patterns. The interestingness criteria for navigation patterns are dynamically specified by the human expert using WUM's mining language. Chen & Cook (2007) proposes a new data structure for mining contiguous sequential patterns from web log. Liu et al (2007) presents a study of the automatic classification of web user navigation patterns and propose an approach to classifying user navigation patterns and predicting users' future requests. The approach is based on the combined mining of web server logs and the contents of the retrieved web pages.

A small subset of the research in web usage mining uses the usage patterns observed from the web logs to improve web design. There is quite some research on link recommendations based on users' previous browsing patterns, mainly utilizing the sequence of pages visited. Perkowitz et al. (1998) and Perkowitz et al. (1999) investigate the problem of index page synthesis, which is the automatic creation of pages that facilitate a user's navigation of a website. By analyzing the web log, their cluster mining algorithm finds collections of pages that tend to co-occur in visits and puts them under one topic. They then generate index pages consisting of links to pages pertaining to a particular topic. Baraglia & Silvestri (2007) introduces a web personalization system that is online and incremental and it is designed to dynamically generate personalized contents of potential interest for users of large web sites made up of pages dynamically generated. It is based on an incremental personalization procedure tightly coupled with the web server. It is able to update incrementally and automatically the knowledge base

based on the ontology underlying the site. Data mining techniques can be applied to enriched web logs to extract knowledge that could be used to improve the navigational structure as well as exploited in recommender systems.

Another stream of related research is on Information foraging theory (Pirolli & Card 1995; Pirolli & Fu 2003). As mentioned in Juvina & Herder (2005), web sites generally are designed for a general audience with varying goals. As it is hard to satisfy all categories of users with one design, adaptive hypermedia systems try to better support the users by personalizing content or link structure. Traditional techniques in the latter category involve link hiding, sorting, annotation, direct guidance and hypertext map adaptation (Brusilovsky 2001). When trying to find information related to a task, users have to rely on proximal cues such as the link anchor text to decide what their next action will be. If the proximal cues are not clear enough, or if the users do not have sufficient insight on the structure of the site, they may become disoriented, i.e. they don't know their current position in a web site, how they came to that point or where to go next (Herder & Juvina 2004). Various studies have been carried out to infer user goals from their actions (e.g. Chi et al. 2003). Given these goals, the utility of the various navigation options on a web page can be estimated (Kitajima et al. 2000; Pirolli & Fu 2003) and communicated to the user by means of link relevancy indicators, or link suggestions.

Also, research on users' page revisit behavior has documented that users frequently visit pages already visited before. Earlier studies (Catledge & Pitkow 1995; Tauscher & Greenberg 1997; Cockburn & McKenzie 2001) have shown that the majority of page requests involve requests to pages visited before.) Tauscher & Greenberg (1997) identified the following main reasons for revisiting pages: (a) the information contained by them changes; (b) they wish to explore the page further; (c) the page has a special purpose; (d) they are authoring a page; (e) the page is on a path to another revisited page. When the revisited pages are home pages and index pages that serve to navigate users to a number of pages, the reason for backtracking can be also to search for information that's not found at the current location (Srikant & Yang 2001).

There is a great amount of research on locating documents via searching (Yeung et al 2007, Heflin et al 2003). Searching eventually becomes the dominating way of finding information when the web structure is too deep and complex to browse. Another stream of related research is automatic acquisition of taxonomies or concept hierarchies from a text corpus (Cimiano et al 2005). This can help organize documents automatically in a structure.

MAIN FOCUS OF THE CHAPTER

Our focus in this chapter is to address the gap between the web-site designer's expectations and the web users' expectations. The web designers' expectations are observed from the web site structure, and web users' expectations are observed from their usage patterns discovered for web logs. Through web usages mining, we can automatically discover users' traversal paths from which we can infer their expectation about how the web site should be structure.

We first briefly discuss several papers that address this problem and then focus more on one particular paper to illustrate a simple idea that can be used to improve the web design through users' behavioral patterns.

Nakayama et al. (2000) tries to discover the gap between the web-site designer's expectations and user behavior. Their approach uses the inter-page conceptual relevance to estimate the former, and the inter-page access co-occurrence to estimate the latter. They focus on website design improvement by using multiple regressions to predict hyperlink traversal frequency from page layout features. Paik et al (2002) describes the design and the implementation of a system through which existing on-line product catalogs can be integrated, and the resulting integrated catalogs can be continuously adapted and personalized within a dynamic environment. They propose a methodology for adaptation of integrated catalogs based on the observation of customers' interaction patterns. Gupta et al (2007) proposes a heuristic scheme based on simulated annealing that makes use of the aggregate user preference data to re-link the pages to improve navigability. Organizations maintain informational websites. The information content of such websites tends to change slowly with time, so a steady pattern of usage is soon established. User preferences, both at the individual and at the aggregate level, can then be gauged from user access log files. Their scheme is also applicable to the initial design of websites for wireless devices. Using the aggregate user preference data obtained from a parallel wired website, and given an upper bound on

the number of links per page, their methodology links the pages in the wireless website in a manner that is likely to enable the "typical" wireless user to navigate the site efficiently. Later, when a log file for the wireless website becomes available, the same approach can be used to refine the design further.

Srikant & Yang (2001) focuses on one type of web site structure, web sites with a top-down tree type of linkage structures, and looks at browsing activities within a web site. For this type of web sites, it is logical to consider the point from where the users backtrack the expected locations for the page they are looking for. Backtracking is the most common type of page revisitation and is both used for finding new information and relocating information visited before (Herder 2005). Under the assumption of backtracking browsing patterns, Srikant & Yang (2001) discusses the problem of automatically identifying pages in a website whose location is different from where users expect to find them and gives the algorithm for finding expected locations.

Search Strategies

When a user is looking for a single specific target page, we expect the user to execute the following search strategy:

1. Start from the root.
2. While (current location *C* is not the target page *T*) do
    a. If any of the links from *C* seem likely to lead to *T*, follow the link that appears most likely to lead to *T*.
    b. Else, either backtrack and go to the parent of *C* with some (unknown) probability, or give up with some probability.

The strategy the user takes when searching for set of targets is similar, except that after finding (or giving up on) one target, the user then starts looking for the next target.

Identify Target Pages

For some websites like Amazon and Ebay, there is a clear separation between content pages and index (or navigation) pages; product pages on these websites are content pages, and category pages are index or navigation pages. In such cases, we can consider the target pages for a visitor to be exactly the set of content pages requested by the visitor. Other websites such as information portals or corporate websites may not have a clear separation between content and index pages. For example, Yahoo! lists websites on the internal nodes of its hierarchy, not just on the leaf nodes. In this case, we can use a time threshold to distinguish whether or not a page is a target page. Pages where the visitor spent more time than the threshold are considered target pages. We can also combine these two methods, and have different time thresholds for different classes of pages.

Algorithm for Finding Expected Location

If there is no browser caching, it is conceptually trivial to find a backtrack point: it is simply the page where the previous and next pages in the web log (for this visitor) are the same. The HTTP standard states that the browser should not request the page again when using the browser's history mechanism. In practice, some browsers use the cached page when the visitor hits the "back" button, while others incorrectly request the page again. It is possible to disable caching by setting an expiration date (in the meta tag in the page), but this can significantly increase the load on the website. Rather than rely on disabling browser caching, we use the fact that if there is no link between pages P1 and P2, the visitor must have hit the "back" button in the browser to go from P1 to P2. Thus to find backtrack points, we need to check if there is a link between two successive pages in the web log. We build a hash table of the edges in the website to efficiently check if there is a link from one page to another.

In Step 1, we build the hash table. We partition the web log by visitor in Step 2. In Step 3, we split the sequence of accesses for each visitor by the target pages they visit. We assume that the website administrator either specifies the set of possible target pages, or specifies a time threshold to distinguish between target pages and other pages. In Step 4, we find all expected locations (if any) for that target page, and add it to a table for use by the next step of the algorithm. The detection of backtracks occurs in Step 4(b). In addition to checking for the absence of a link from the current to the next page, we also check if the previous and next pages are the same. The latter check takes

care of the case where visitors use a navigation link to go to the previous page instead of using the "back" button in the browser.

There are limitations to this approach. It can be hard to distinguish between target pages and other pages when the website does not have a clear separation between content and index pages. Hence the algorithm may generate false expected locations if it treats target pages as backtrack points, and may miss expected locations if it treats backtrack points as target pages. Increasing the time threshold will result in fewer missed expected locations at the cost of more false expected locations, while decreasing the threshold will have the opposite effect. Hence for websites without a clear separation between content and navigation, the administrator will have to spend some time to determine a good value for the time threshold, as well as sift through the discovered expected locations to drop any false patterns. Another limitation is that only people who successfully find a target page will generate an expected location for that page. We cannot track people who tried the expected location and gave up after not finding the target page.

Srikant & Yang (2001) also discussed several link recommendation strategies. (a) FirstOnly: Recommend all the pages whose frequency of occurrence in the first expected location is above an administrator-specified threshold. (b) OptimizeBenefit: Recommendthe set of pages that optimize benefit to the website, where benefit is estimated based on the fraction of people who might give up on not finding a page. (c) OptimizeTime: Recommend the set of pages that minimize the number of times the visitor has to backtrack, i.e., the number of times the visitor does not find the page in an expected location. The algorithm is applied to a university website, and we found many pages that were located differently from where users expected to fine them.

FUTURE TRENDS

An interesting problem for future research is that in websites without a clear separation of content and navigation, it can be hard to differentiate between users who backtrack because they are browsing a set of target pages, and users who backtrack because they are searching for a single target page. While Srikant & Yang (2001) has proposed using a time threshold to distinguish between the two activities, it will be interesting to explore if there are better approaches to solve this problem. Moreover, the web access patterns on a web site are very dynamic in nature, due not only to the dynamics of web site content and structure, but also to changes in the user's interests, and thus their navigation patterns. This is a huge challenge and needs to be carefully studied in the future.

CONCLUSION

In this chapter, research on using web usage mining to close the gap between the web designers' expectation and web users' expectation is surveyed. Through web usages mining, we can automatically discover pages in a website whose location is different from where users expect to find them. This problem of matching website organization with user expectations is pervasive across most websites.

KEY TERMS

Adaptive Hypermedia System: It is an alternative to the traditional "one-size-fits-all" approach in the

development of hypermedia systems. Adaptive hypermedia systems build a model of the goals, preferences and knowledge of each individual user, and use this model throughout the interaction with the user, in order to adapt the hypertext to the needs of that user.

Information Foraging Theory: A general term for modeling a human searching for and using information in terms of biological models of animals foraging for food.

Information Scent: Information scent is a term used to describe how people evaluate the options they have when they are looking for information on a site. When presented with a list of options users will choose the option that gives them the clearest indication (or strongest scent) that it will step them closer to the information they require.

Link Recommendation: Based on users' previous browsing history, web links that the users may be interested in next are recommended.

Ontology: specification of a conceptualization of a knowledge domain. An ontology is a controlled vocabulary that describes objects and the relations between them in a formal way, and has a grammar for using the vocabulary terms to express something meaningful within a specified domain of interest.

Web Server Log: A file (or several files) automatically created and maintained by a web server recording all the requests for files made to the server and the result of that request.

Web Usage Mining: Extract useful access pattern information from massive amounts of web log data for the purpose of web site personalization and organization.

Web Mining in Thematic Search Engines

Massimiliano Caramia
University of Rome "Tor Vergata," Italy

Giovanni Felici
Istituto di Analisi dei Sistemi ed Informatica IASI-CNR, Italy

INTRODUCTION

In the present chapter we report on some extensions on the work presented in the first edition of the Encyclopedia of Data Mining. In Caramia and Felici (2005) we have described a method based on clustering and a heuristic search method- based on a genetic algorithm - to extract pages with relevant information for a specific user query in a thematic search engine. Starting from these results we have extended the research work trying to match some issues related to the semantic aspects of the search, focusing on the keywords that are used to establish the similarity among the pages that result from the query. Complete details on this method, here omitted for brevity, can be found in Caramia and Felici (2006).

Search engines technologies remain a strong research topic, as new problems and new demands from the market and the users arise. The process of switching from *quantity* (maintaining and indexing large databases of web pages and quickly select pages matching some criterion) to *quality* (identifying pages with a high quality for the user), already highlighted in Caramia and Felici (2005), has not been interrupted, but has gained further energy, being motivated by the natural evolution of the internet users, more selective in their choice of the search tool and willing to pay the price of providing extra feedback to the system and wait more time to have their queries better matched. In this framework, several have considered the use of data mining and optimization techniques, that are often referred to as *web mining* (for a recent bibliography on this topic see, e.g., Getoor, Senator, Domingos, and Faloutsos, 2003 and Zaïane, Srivastava, Spiliopoulou, and Masand, 2002).

The work described in this chapter is bases on clustering techniques to identify, in the set of pages resulting from a simple query, subsets that are homogeneous with respect to a vectorization based on *context* or *profile*; then, a number of small and potentially good subsets of pages is constructed, extracting from each cluster the pages with higher scores. Operating on these subsets with a genetic algorithm, a subset with a good overall score and a high internal dissimilarity is identified. A related problem is then considered: the selection of a subset of pages that are compliant with the search keywords, but that also are characterized by the fact that they share a large subset of words different from the search keywords. This characteristic represents a sort of semantic connection of these pages that may be of use to spot some particular aspects of the information present in the pages. Such a task is accomplished by the construction of a special graph, whose maximum-weight clique and k-densest subgraph should represent the page subsets with the desired properties.

In the following we summarize the main background topics and provide a synthetic description of the methods. Interested readers may find additional information in Caramia and Felici (2004), Caramia and Felici (2005), and Caramia and Felici (2006).

BACKGROUND

Let P be a set of web pages, and indicate with $p \in P$ a page in that set. Now assume that P is the result of a standard query to a database of pages, and thus represents a set of pages that satisfy some conditions expressed by the user. Each page $p \in P$ is associated with a score, based on the query that generated P, that would determine the order by which the pages are presented to the user who submits the query. The role of this ordering is crucial for the quality of the search: in fact, if the dimension of P is relevant, the probability that the user considers a page p strongly decreases as the position of p in the order increases. This may lead to two major drawbacks: the pages in the first positions may be very similar (or even equal) to each other; pages that do not have a very high score but are representative of some aspect of set P may appear in

a very low position in the ordering, with a negligible chance of being looked at by the user.

Our method tries to overcome both drawbacks, focusing on the selection, from the initial set *P*, of a small set of pages with a high score and sufficiently different one from each other. A condition needed to apply our approach is the availability of additional information from the user, who indicates a search context (a general topic to which the search is referred to, that is not necessarily linked with the search keywords that generated the set *P*), and a user profile (a subjective identification of the user, that may be either provided directly by choosing amongst a set of predefined profiles, or extracted from the pages that have been visited more recently by that user).

MAIN THRUST OF THE CHAPTER

The basic idea of the method is to use the information conveyed by the search context or the user profile to analyze the structure of *P* and determine in it an optimal small subset that better represents all the information available. This is done in three steps. First, the search context and the user profile are used to extract a finite set of significant words or page characteristics that is used to create, from all pages in *P*, a vector of characteristics (page vectorization). Such vectorization represents a particular way of "looking" at the page, specific of each context/profile, and will constitute the ground on which the following steps are based.

Second, the vectorized pages are analyzed by a *clustering algorithm* that partitions them into subsets of similar pages. This induces a two-dimensional ordering on the pages, as each page *p* can now be ordered according to the original score within its cluster. At this point the objective is to provide the user with a reduced list that takes into account the structure identified by the clusters and the original score function.

This is done in the third step, where a *genetic algorithm* works on the pages that have higher score in each cluster to produce a subset of them that are sufficiently heterogeneous and of good values for the original score. In the following we describe the three steps in detail.

We then report on the technique proposed to select pages that, beside being relevant for the search, are induced by a set of strongly connected words, with a proper definition of connection; in addition, we are inclined to select in this set those words that have a high degree of similarity with the search keywords, to enhance the significance of the induced pages. This problem is formulated as a maximum-weight clique problem on a graph whose nodes are associated with the initial set of words and whose arcs convey a weight based on the cardinality of page subsets associated with the word nodes.

Page Vectorization

The first step of the method is the representation of each page that has been acquired by a vector of finite dimension *m*, where each component represents a measure of some characteristic of the page (page vectorization). Clearly, such representation is crucial for the success of the method; all the information of a page that is not maintained in this step will be lost for further treatment. For this reason it is very important to stress the thematic nature of the vectorization process, where only the information that appears to be relevant for a context or a profile is effectively kept for future use. In the most plain setting, each component of the vector is the number of occurrences of a particular word; one may also consider other measurable characteristics that are not specifically linked with the words that are contained in the page, such as the presence of pictures, tables, banners and so on. As mentioned above, the vectorization is based on one context, or one profile, chosen by the user. One may then assume that, for each of the contextes/profiles that have been implemented in the search engine, a list of words that are relevant to that context/profile is available and a related vectorization of the page is stored. In Caramia and Felici (2005) we propose two methods to determine the initial list of words.

Page Clustering

There has been extensive research on how to improve retrieval results by employing clustering techniques. In several studies the strategy was to build a clustering of the entire document collection and then match the query to the cluster centroids (see, e.g., Willet, 1988). More recently, clustering has been used for helping the user in browsing a collection of documents and in organizing the results returned by a search engine (Leuski, 2001, and Zamir, Etzioni, Madani, and Karp, 1997), or by a metasearch engine (Zamir and Etzioni, 1999) in

response to a user query. In Koller and Sahami (1997) document clustering has also been used to automatically generate hierarchical clusters of documents.

Document clustering in information retrieval is usually dealt with agglomerative hierarchical clustering algorithms (see, e.g., Jain, Murty and Flynn, 1999) or *k*-means algorithm (see, e.g., Dubes and Jain, 1998). While agglomerative hierarchical clustering algorithms are very slow when applied to large document databases (Zamir and Etzioni, 1998) (single link and group average methods take $O(|P|^2)$ time, complete link method take $O(|P|^3)$ time), *k*-means is much faster (its execution time is $O(k \cdot |P|)$). We have tested different methods and confirm that *k*-means clustering performs well in limited computing times – a must for this type of applications, where both the number of pages and the dimension of the vectors may be large.

The Genetic Algorithm

Genetic algorithms have been implemented efficiently in information retrieval by several researchers. Chen (1995) used genetic algorithms to optimize keywords that were used to suggest relevant documents. Amongst others, Kraft, Petry, Buckles and Sadavisan (1997), Sanchez and Pierre (1994), presented several approaches to enhance the query description based on genetic algorithms. In Boughanem, Chrisment and Tamine (1999) a genetic algorithm was deployed to find an optimal set of documents that best match the user's need. In Horng and Yeh (2000) a method for extracting keywords from documents and assigning them weights was proposed.

Our aim is to select a small subset *P'* of the original set of pages *P* for which the sum of the scores is large but also where the similarity amongst the selected page is restrained. We select such a subset using a genetic algorithm (GA). Several reasons motivate this choice. First, the use of metaheuristic techniques is well established in optimization problems where the objective function and the constraints do not have a simple mathematical formulation. Second, we have to determine a good solution in a small computing time, where the dimension of the problem may be significantly large. Third, the structure of our problem is straightforward representable by the data structure commonly used by a GA (see, e.g., Goldberg, 1989).

Starting from the clusters obtained, we define the chromosomes of the initial population as subsets of pages of bounded cardinality (in the GA terminology, a page is a *gene*). The genetic algorithm works on the initial population ending up with a representative subset of pages to present to the user. The idea is to start the genetic evolution with a population that is already smaller than the initial set of pages *P*. Each chromosome is created by picking a page from each cluster, starting with the ones with higher score. Thus, the first chromosome created will contain the pages with the highest score in each cluster, the second chromosome will contain the second best, and so on. If the cardinality of a cluster is smaller than the number of chromosomes to be created, then that cluster will not be represented in each chromosome, while other clusters with higher cardinality may have more that one page representing them in some chromosome. We indicate with *dc* the number of pages included in each chromosome in the initial population, and with *nc* the number of chromosomes. The population will thus contain $np = dc \cdot nc$ pages.

The fitness function computed for each chromosome is expressed as a positive value that is higher for "better" chromosome, and is thus to be maximized. It is composed of three terms. The first is the sum of the score of the pages in chromosome *C*, i.e.,

$$t_1(C) = \sum_{p_i \in C} score(p_i)$$

where $score(p_i)$ is the original score given to page p_i as previously described. This term considers the positive effect of having as many pages with high score as possible in a chromosome, but would also reward chromosomes with many pages regardless of their. This drawback is balanced with the second term of the fitness function. Let *ID* be such ideal dimension; the ratio $t_2(C) = np / \text{abs}(|C|-ID)+1$ constitutes the second term of the fitness function: it reaches its maximum *np* when the dimension of *C* is exactly equal to the ideal dimension *ID*, and rapidly decreases when the number of pages contained in chromosome *C* is smaller or greater than *ID*.

The chromosomes that are present in the initial population are characterized by the highest possible variability as far as the clusters to which the pages belong are concerned. The evolution of the population may alter this characteristic, creating chromosomes with high fitness where the pages belong to the same cluster and are very similar to each other. Moreover, the fact that pages belonging to different clusters are

different in the vectorized space may not be guaranteed, as it depends both on the nature of the data and on the quality of the initial clustering process. For this reason, we introduce in the fitness function a third term, that measures directly the overall dissimilarity of the pages in the chromosome. Let $D(p_i, p_j)$ be the Euclidean distance of the vectors representing pages p_i and p_j. Then, $t_3(C)=\sum_{p_i,p_j\in C, p_i\neq p_j} D(p_i, p_j)$ is the sum of the distances between the pairs of pages in chromosome C and measures the total variability expressed by C. The final form of the fitness function for chromosome C is then $ff(C)=\alpha\cdot t_1(C)+\beta\cdot t_2(C)+\gamma\cdot t_3(C)$ where α, β and γ are parameters that depend on the magnitude of the initial score and of the vectors that represent the pages. In particular, α, β and γ are chosen so as the contributions given by $t_1(C)$, $t_2(C)$ and $t_3(C)$ are balanced. Additionally, they may be tuned to express the relevance attributed to the different aspects represented by the three terms. The goal of the GA is to find, by means of the genetic operators, a chromosome C^* such that $ff(C^*)=\max_{C=1,\ldots,nc} ff(C)$.

The Search for Semantically Connected Pages

The identification of semantically connected subsets of pages intends to overcome the typical drawbacks that a user encounters when he/she is submitted a set of pages selected according to some score function that is added on the single pages of the set rather than computed on the sets as a whole.

The main computational step to solve the problem is the identification of subgraphs of a given graph G with certain properties, namely some variants of two strongly related problems: the maximum-weight clique and the k-densest subgraph. A clique in a graph is a node induced subgraph where each couple of nodes is connected by an edge. The maximum-weight clique problem consists in finding a clique of largest weight in a graph. The densest k-subgraph problem amounts to the selection of the subgraph of dimension k with the minimum number of edges. Graph G is such that there is a node v for each word w with weight $a_v=\Sigma_{p\in P} M_{w,p}$, $M_{i,j}$ represents the number of times word w_j appears in page p_i, and an edge is present between each pair of nodes (u,v) with weight a_{uv} proportional to the inverse of the similarity between the words associated with u and v. In Caramia and Felici (2006) we proposed an original solution algorithm that is able to guarantee good performance in very little time and can find the optimal solution to the problem when the graph is of reasonable dimension.

FUTURE TRENDS

The application of sophisticated data analysis and data mining techniques to the search of information on the web is a field that receives increasing interest from both research and industry. The strategic importance of such tools should not be underestimated, as the amount of information keeps increasing while the user time available for searching is not increasing. Such trend motivates the effort of research to produce tools that help in improving web search results.

CONCLUSION

Experimental results conducted with the above described method have shown its effectiveness in the selection of small subsets of pages of good quality, where quality is not considered as a simple sum of the scores of each page but as a global characteristic of the subset. The current implementations of the GA and of the clustering algorithm converge fast to good solutions for data sets of realistic dimensions. Future research in the search for semantic connected pages will include the tuning of the parameters in the algorithms used to identify the subset of words, and a deeper analysis of the interactions between computational time and solution quality to possibly improve the quality of the method with ad-hoc heuristic strategies.

KEY TERMS

Clustering: partitioning a data set into subsets (clusters), so that the data in each subset share some common trait.

Genetic Algorithm: heuristic optimization algorithm based on the concept of biological evolution.

Page Score: numeric value that measures how well a single page matches a given query. Higher score would imply a better matching.

Search Engine: software that builds a database of web pages, applies queries to it and returns results.

Thematic Search Engine: search engine devoted to the construction and management of a database of web pages that pertain to a limited subset of the knowledge or of the web users.

Vectorization: the representation of objects in a class by a finite set of measures defined on the objects.

Web Page: basic unit of information that is visualized on the web

Web Mining Overview

Bamshad Mobasher
DePaul University, USA

INTRODUCTION

In the span of a decade, the World Wide Web has been transformed from a tool for information sharing among researchers into an indispensable part of everyday activities. This transformation has been characterized by an explosion of heterogeneous data and information available electronically, as well as increasingly complex applications driving a variety of systems for content management, e-commerce, e-learning, collaboration, and other Web services. This tremendous growth, in turn, has necessitated the development of more intelligent tools for end users as well as information providers in order to more effectively extract relevant information or to discover actionable knowledge.

From its very beginning, the potential of extracting valuable knowledge from the Web has been quite evident. Web mining (i.e. the application of data mining techniques to extract knowledge from Web content, structure, and usage) is the collection of technologies to fulfill this potential.

In this article, we will summarize briefly each of the three primary areas of Web mining—Web usage mining, Web content mining, and Web structure mining—and discuss some of the primary applications in each area.

BACKGROUND

Knowledge discovery on and from the Web has been characterized by four different but related types of activities (Kosala & Blockeel, 2000):

1. **Resource Discovery:** Locating unfamiliar documents and services on the Web.
2. **Information Extraction:** Extracting automatically specific information from newly discovered Web resources.
3. **Generalization:** Uncovering general patterns at individual Web sites or across multiple sites.
4. **Personalization:** Presentation of the information requested by an end user of the Web.

The goal of Web mining is to discover global as well as local structures, models, patterns, or relations within and between Web pages. The research and practice in Web mining has evolved over the years from a process-centric view, which defined Web mining as a sequence of tasks (Etzioni, 1996), to a data-centric view, which defined Web mining in terms of the types of Web data that were being used in the mining process (Cooley et al., 1997).

MAIN THRUST

The evolution of Web mining as a discipline has been characterized by a number of efforts to define and expand its underlying components and processes (Cooley et al., 1997; Kosla & Blockeel, 2000; Madria et al., 1999; Srivastava et al., 2002). These efforts have led to three commonly distinguished areas of Web mining: Web usage mining, Web content mining, and Web structure mining.

Web Content Mining

Web content mining is the process of extracting useful information from the content of Web documents. Content data correspond to the collection of facts a Web page was designed to convey to the users. Web content mining can take advantage of the semi-structured nature of Web page text. The HTML tags or XML markup within Web pages bear information that concerns not only layout but also the logical structure and semantic content of documents.

Text mining and its application to Web content have been widely researched (Berry, 2003; Chakrabarti, 2000). Some of the research issues addressed in text mining are topic discovery, extracting association patterns, clustering of Web documents, and classification of Web pages. Research activities in this field generally

involve using techniques from other disciplines, such as information retrieval (IR), information extraction (IE), and natural language processing (NLP).

Web content mining can be used to detect co-occurrences of terms in texts (Chang et al., 2000). For example, co-occurrences of terms in newswire articles may show that gold frequently is mentioned together with copper when articles concern Canada, but together with silver when articles concern the US. Trends over time also may be discovered, indicating a surge or decline in interest in certain topics, such as programming languages like Java. Another application area is event detection, the identification of stories in continuous news streams that correspond to new or previously unidentified events.

A growing application of Web content mining is the automatic extraction of semantic relations and structures from the Web. This application is closely related to information extraction and ontology learning. Efforts in this area have included the use of hierarchical clustering algorithms on terms in order to create concept hierarchies (Clerkin et al., 2001), the use of formal concept analysis and association rule mining to learn generalized conceptual relations (Maedche & Staab, 2000; Stumme et al., 2000), and the automatic extraction of structured data records from semi-structured HTML pages (Liu, Chin & Ng, 2003). Often, the primary goal of such algorithms is to create a set of formally defined domain ontologies that represent precisely the Web site content and to allow for further reasoning. Common representation approaches are vector-space model (Loh et al., 2000), descriptive logics (i.e., DAML+OIL) (Horrocks, 2002), first order logic (Craven et al., 2000), relational models (Dai & Mobasher, 2002), and probabilistic relational models (Getoor et al., 2001).

Web Structure Mining

The structure of a typical Web graph consists of Web pages as nodes and hyperlinks as edges connecting between two related pages. Web structure mining can be regarded as the process of discovering structure information from the Web. This type of mining can be divided further into two kinds, based on the kind of structural data used (Srivastava et al., 2002); namely, hyperlinks or document structure. There has been a significant body of work on hyperlink analysis, of which Desikan et al. (2002) provide an up-to-date survey. The content within a Web page also can be organized in a tree-structured format, based on the various HTML and XML tags within the page. Mining efforts here have focused on automatically extracting document object model (DOM) structures out of documents (Moh et al., 2000) or on using the document structure to extract data records or semantic relations and concepts (Liu, Chin & Ng, 2003; Liu, Grossman & Zhai, 2003).

By far, the most prominent and widely accepted application of Web structure mining has been in Web information retrieval. For example, the Hyperlink Induced Topic Search (HITS) algorithm (Klienberg, 1998) analyzes hyperlink topology of the Web in order to discover authoritative information sources for a broad search topic. This information is found in authority pages, which are defined in relation to hubs as their counterparts: Hubs are Web pages that link to many related authorities; authorities are those pages that are linked by many good hubs. The hub and authority scores computed for each Web page indicate the extent to which the Web page serves as a hub pointing to good authority pages or as an authority on a topic pointed to by good hubs.

The search engine Google also owes its success to the PageRank algorithm, which is predicated on the assumption that the relevance of a page increases with the number of hyperlinks pointing to it from other pages and, in particular, of other relevant pages (Brin & Page, 1998). The key idea is that a page has a high rank, if it is pointed to by many highly ranked pages. So, the rank of a page depends upon the ranks of the pages pointing to it. This process is performed iteratively until the rank of all the pages is determined.

The hyperlink structure of the Web also has been used to automatically identify Web communities (Flake et al., 2000; Gibson et al., 1998). A Web community can be described as a collection of Web pages, such that each member node has more hyperlinks (in either direction) within the community than outside of the community.

An excellent overview of techniques, issues, and applications related to Web mining, in general, and to Web structure mining, in particular, is provided in Chakrabarti (2003).

Web Usage Mining

Web usage mining (Cooley et al., 1999; Srivastava et al., 2000) refers to the automatic discovery and analysis

of patterns in clickstream and associated data collected or generated as a result of user interactions with Web resources on one or more Web sites. The goal of Web usage mining is to capture, model, and analyze the behavioral patterns and profiles of users interacting with a Web site. The discovered patterns are usually represented as collections of pages, objects, or resources that are frequently accessed by groups of users with common needs or interests.

The primary data sources used in Web usage mining are log files automatically generated by Web and application servers. Additional data sources that also are essential for both data preparation and pattern discovery include the site files and meta-data, operational databases, application templates, and domain knowledge.

The overall Web usage mining process can be divided into three interdependent tasks: data preprocessing, pattern discovery, and pattern analysis or application. In the preprocessing stage, the clickstream data is cleaned and partitioned into a set of user transactions representing the activities of each user during different visits to the site. In the pattern discovery stage, statistical, database, and machine learning operations are performed to obtain possibly hidden patterns reflecting the typical behavior of users, as well as summary statistics on Web resources, sessions, and users. In the final stage of the process, the discovered patterns and statistics are further processed, filtered, and used as input to applications such as recommendation engines, visualization tools, and Web analytics and report generation tools.

For a full discussion of Web usage mining and its applications, see the article "Web Usage Mining" in the current volume (Mobasher, 2005).

FUTURE TRENDS

An important emerging area that holds particular promise is Semantic Web Mining (Berendt et al., 2002). Semantic Web mining aims at combining the two research areas: semantic Web and Web mining. The primary goal is to improve the results of Web mining by exploiting the new semantic structures on the Web. Furthermore, Web mining techniques can help to automatically build essential components of the Semantic Web by extracting useful patterns, structures, and semantic relations from existing Web resources (Berendt et al., 2004).

Other areas in which Web mining research and practice is likely to make substantial gains are Web information extraction, question-answering systems, and personalized search. Progress in the applications of natural language processing as well as increasing sophistication of machine learning and data mining techniques applied to Web content are likely to lead to the development of more effective tools for information foraging on the Web. Some recent advances in these areas have been highlighted in recent research activities (Mobasher et al. 2004; Muslea et al. 2004).

CONCLUSION

Web mining is the application of data mining techniques to extract knowledge from the content, structure, and usage of Web resources. With the continued growth of the Web as an information sources and as a medium for providing Web services, Web mining will continue to play an ever expanding and important role. The development and application of Web mining techniques in the context of Web content, Web usage, and Web structure data already have resulted in dramatic improvements in a variety of Web applications, from search engines, Web agents, and content managements systems to Web analytics and personalization services. A focus on techniques and architectures for more effective integration and mining of content, usage, and structure data from different sources is likely to lead to the next generation of more useful and more intelligent applications.

KEY TERMS

Hubs and Authorities: Hubs and authorities are Web pages defined by a mutually reinforcing relationship with respect to their hyperlink structure. Hubs are Web pages that link to many related authorities; authorities are those pages that are linked to by many good hubs.

Hyperlink: A hyperlink is a structural unit that connects a Web page to a different location, either within the same Web page or to a different Web page. A hyperlink that connects to a different part of the same page is called an intra-document hyperlink, and a hyperlink that connects two different pages is called an inter-document hyperlink.

Web Community: A Web community can be described as a collection of Web pages, such that each member node has more hyperlinks (in either direction) within the community than outside of the community.

Web Content Mining: The process of extracting useful information from the contents of Web documents. Content data corresponds to the collection of facts that a Web page was designed to convey to users. It may consist of unstructured or semi-structured text, images, audio, video, or structured records, such as lists and tables.

Web Mining: The application of data-mining techniques to extract knowledge from the content, structure, and usage of Web resources. It is generally subdivided into three independent but related areas: Web usage mining, Web content mining, and Web structure mining.

Web Structure Mining: Web structure mining can be regarded as the process of discovering structure information from the Web. This type of mining can be divided further into two kinds, based on the kind of structural data used: hyperlinks connecting Web pages and the document structure in semi-structured Web pages.

Web Usage Mining: The automatic discovery and analysis of patterns in clickstream and associated data collected or generated as a result of user interactions with Web resources on one or more Web sites.

Web Page Extension of Data Warehouses

Anthony Scime
State University of New York College Brockport, USA

INTRODUCTION

Data warehouses are constructed to provide valuable and current information for decision-making. Typically this information is derived from the organization's functional databases. The data warehouse is then providing a consolidated, convenient source of data for the decision-maker. However, the available organizational information may not be sufficient to come to a decision. Information external to the organization is also often necessary for management to arrive at strategic decisions. Such external information may be available on the World Wide Web; and when added to the data warehouse extends decision-making power.

The Web can be considered as a large repository of data. This data is on the whole unstructured and must be gathered and extracted to be made into something valuable for the organizational decision maker. To gather this data and place it into the organization's data warehouse requires an understanding of the data warehouse metadata and the use of Web mining techniques (Laware, 2005).

Typically when conducting a search on the Web, a user initiates the search by using a search engine to find documents that refer to the desired subject. This requires the user to define the domain of interest as a keyword or a collection of keywords that can be processed by the search engine. The searcher may not know how to break the domain down, thus limiting the search to the domain name. However, even given the ability to break down the domain and conduct a search, the search results have two significant problems. One, Web searches return information about a very large number of documents. Two, much of the returned information may be marginally relevant or completely irrelevant to the domain. The decision maker may not have time to sift through results to find the meaningful information.

A data warehouse that has already found domain relevant Web pages can relieve the decision maker from having to decide on search keywords and having to determine the relevant documents from those found in a search. Such a data warehouse requires previously conducted searches to add Web information.

BACKGROUND

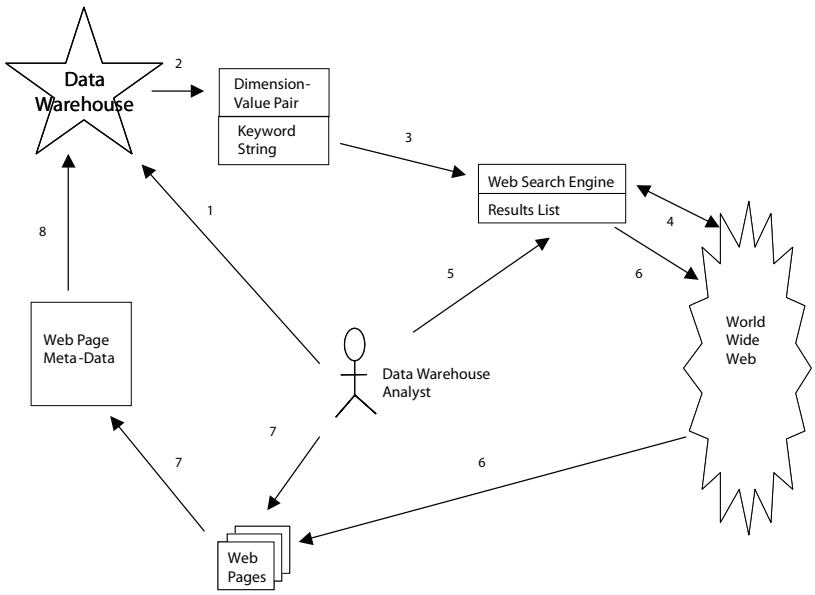
To provide an information source within an organization's knowledge management system, database structure has been overlaid on documents (Liongosari, Dempski, & Swaminathan, 1999). This knowledge base provides a source for obtaining organizational knowledge. Data warehouses also can be populated in Web-based interoperational environments created between companies (Triantafillakis, Kanellis & Martakos, 2004). This extends knowledge between cooperating businesses. However, these systems do not explore the public documents available on the Web.

Systems have been designed to extract relevant information from unstructured sources such as the Web. The Topicshop system allows users to gather, evaluate, and organize collections of Web sites (Amento, Terveen, Hill, Hix, & Schulman, 2003). Using topic discovery techniques Usenet news searching can be personalized to categorize contents and optimise delivery contents for review (Manco, Ortale & Tagarelli, 2005). Specialized search engines and indexes have been developed for many domains (Leake & Scherle, 2001). Search engines have been developed to combine the efforts of other engines and select the best search engine for a domain (Meng, Wu, Yu, & Li, 2001). However, these approaches do not organize the search results into accessible, meaningful, searchable data.

Web search queries can be related to each other by the results returned (Wu & Crestani, 2004; Glance, 2000). This knowledge of common results to different queries can assist a new searcher in finding desired information. However, it assumes domain knowledge sufficient to develop a query with keywords, and does not provide corresponding organizational knowledge.

Some Web search engines find information by categorizing the pages in their indexes. One of the first to create a structure as part of their Web index was

Figure 1. Data warehouse Web extension architecture



Yahoo! (http://www.yahoo.com). Yahoo! has developed a hierarchy of documents, which is designed to help users find information faster. This hierarchy acts as a taxonomy of the domain. Yahoo! helps by directing the searcher through the domain. Again, there is no organizational knowledge to put the Web pages into a local context, so the documents must be accessed and assimilated by the searcher.

DynaCat provides knowledge-based, dynamic categorization of search results in the medical domain (Pratt, 1999). The domain of medical topics is established and matched to predefined query types. Retrieved documents from a medical database are then categorized according to the topics. Such systems use the domain as a starting point, but do not catalog the information and add it to an existing organized body of domain knowledge such as a data warehouse.

Web pages that contain multiple semi-structured records can be parsed and used to populate a relational database. Multiple semi-structured records are data about a subject that is typically composed of separate information instances organized individually, but generally in the same format. For example, a Web page of want ads or obituaries. The first step is to create an ontology of the general structure of the semi-structured data. The ontology is expressed as an Object-Relationship Model. This ontology is then used to define the parsing of the Web page. Parsing into records uses the HTML tags to determine the structure of the Web page, determining when a record starts and ends. The relational database structure is derived from the ontology. The system requires multiple records in the domain, with the Web page having a defined structure to delimit records. However, the Web pages must be given to the system, it cannot find Web pages, or determine if they belong to the domain (Embley et al., 1999).

The Web Ontology Extraction (WebOntEx) project semi-automatically determines ontologies that exist on the Web. These ontologies are domain specific and placed in a relational database schema. Using the belief that HTML tags typically highlight a Web page's concepts, concepts are extracted, by selecting some number of words after the tag as concepts. They are reviewed and may be selected to become entity sets, attributes or relationships in a domain relational database. The determination is based on the idea that nouns are possible entity and attribute types and verbs are possible relationship types. By analyzing a number of pages in a domain an ontology is developed within the relational database structure (Han & Elmasri, 2004). This system creates the database from Web page input, whereas an existing data warehouse needs only to be extended with Web available knowledge.

Web based catalogs are typically taxonomy-directed. A taxonomy-directed Web site has its contents organized in a searchable taxonomy, presenting the instances of a category in an established manner. DataRover is a system that automatically finds and extracts products from taxonomy-directed, online catalogs. It utilizes heuristics to turn the online catalogs into a database of categorized products (Davulcu, Koduri & Nagarajan, 2003). This system is good for structured data, but is not effective on unstructured, text data.

To find domain knowledge in large databases domain experts are queried as to the topics and subtopics of a domain creating an expert level taxonomy (Scime, 2000, 2003). This domain knowledge can be used to assist in restricting the search space. The results found are attached to the taxonomy and evaluated for validity; and create and extend the searchable data repository.

WEB SEARCH FOR WAREHOUSING

Experts within a domain of knowledge are familiar with the facts and the organization of the domain. In the warehouse design process, the analyst extracts from the expert the domain organization. This organization is the foundation for the warehouse structure and specifically the dimensions that represent the characteristics of the domain.

In the Web search process; the data warehouse analyst can use the warehouse dimensions as a starting point for finding more information on the World Wide Web. These dimensions are based on the needs of decision makers and the purpose of the warehouse. They represent the domain organization. The values that populate the dimensions are pieces of the knowledge about the warehouse's domain. These organizational and knowledge faucets can be combined to create a dimension-value pair, which is a special case of a taxonomy tree (Kerschberg, Kim & Scime, 2003; Scime & Kerschberg, 2003). This pair is then used as keywords to search the Web for additional information about the domain and this particular dimension value.

The pages retrieved as a result of dimension-value pair based Web searches are analyzed to determine relevancy. The meta-data of the relevant pages is added to the data warehouse as an extension of the dimension. Keeping the warehouse current with frequent Web searches keeps the knowledge fresh and allows decision makers access to the warehouse and Web knowledge in the domain.

WEB PAGE COLLECTION AND WAREHOUSE EXTENSION

The Data Warehouse Web Extension Architecture (Figure 1) shows the process for adding Web pages to a data warehouse.

1. **Select Dimensions:** The data warehouse analyst selects the dimension attributes that are likely to have relevant data about their values on the Web. For example, the dimension *city* would be chosen; as most cities have Web sites.
2. **Extract Dimension Value Pair:** As values are added to the selected dimensions the dimension label and value are extracted as a dimension-value pair and converted into a keyword string. The value *Buffalo* for the dimension *city* becomes the keyword string *city Buffalo*.
3. **Keyword String Query:** The keyword string is sent to a search engine (for example, Google).
4. **Search the World Wide Web:** The keyword string is used as a search engine query and the resulting hit lists containing Web page meta-data are returned. This meta-data typically includes page URL, title, and some summary information. In our example, the first result is the Home Page for the City of Buffalo in New York State. On the second page of results is the City of Buffalo, Minnesota.
5. **Review Results Lists:** The data warehouse analyst reviews the resulting hit list for possible relevant pages. Given that large number of hits (over 5 million for *city Buffalo*) the analyst must limit consideration of pages to a reasonable amount.
6. **Select Web Documents:** Web pages selected are those that may add knowledge to the data warehouse. This may be new knowledge or extensional knowledge to the warehouse. Because the analyst knows that the city of interest to the data warehouse is Buffalo, New York, he only considers the appropriate pages.
7. **Relevancy Review:** The analyst reviews the selected pages to ensure they are relevant to the intent of the warehouse attribute. The meta-data of the relevant Web pages is extracted during this

relevancy review. The meta-data includes the Web page URL, title, date retrieved, date created, and summary. This meta-data may come from the search engine results list. For the Buffalo home page this meta-data is found in Figure 2.

8. **Add Meta-Data:** The meta-data for the page is added as an extension to the data warehouse. This addition is added as an extension to the *city* dimension creating a snowflake-like schema for the data warehouse.

FUTURE TRENDS

There are two trends in data repositories that when combined will greatly enhance the ability to extend data warehouses with Web based information. The first is the movement to object-oriented databases (Ravat, Teste & Zurfluh, 1999). The other is the movement to the semantic Web (Engels & Lech, 2003).

Currently, modeling and implementation of databases uses the Entity-Relationship model. This model has difficulty in representing multidimensional data views common in today's data warehouses. The object-oriented paradigm provides increased modeling capabilities in the multidimensional environment (Trujillo, Palomar & Gómez, 2000). Furthermore, the object-oriented data warehouse can be organized as an ontology.

In the search engine of the future the linear index of Web pages will be replaced by an ontology. This ontology will be a semantic representation of the Web. Within the ontology the pages may be represented by keywords and will also have connections to other pages. These connections will be the relationships between the pages and may also be weighted. Investigation of an individual page's content, the inter-page hypertext links, the position of the page on its server, and search engine discovered relationships would create the ontology (Guha, McCool & Miller, 2003).

Matches will no longer be query keyword to index keyword, but a match of the data warehouse ontology to the search engine ontology. Rather than point-to-point matching, the query is the best fit of one multi-dimensional space upon another (Doan, Madhavan, Dhamankar, Domingos, & Halevy, 2003). The returned page locations are then more specific to the information need of the data warehouse.

CONCLUSION

The use of the Web to extend data warehouse knowledge about a domain provides the decision maker with more information than may otherwise be available from the organizational data sources used to populate the data warehouse. The Web pages referenced in the warehouse are derived from the currently available data and knowledge of the data warehouse structure.

The Web search process and the data warehouse analyst sifts through the external, distributed Web to find relevant pages. This Web generated knowledge is added to the data warehouse for decision maker consideration.

KEY TERMS

Dimension: A category of information relevant to the decision making purpose of the data warehouse.

Domain: The area of interest for which a data warehouse was created.

Meta-Data: Data about data. In a database the attributes, relations, files, etc. have labels or names indicating the purpose of the attribute, relation, file, etc. These labels or names are meta-data.

Search Engine: A Web service that allows a user to find Web pages matching the user's selection of keywords.

Star Schema: The typical logical topology of a data warehouse; where a fact table occupies the center of the data warehouse and dimension tables are related to most fact table attributes.

Taxonomy Tree: A collection of related concepts organized in a tree structure where higher-level concepts are decomposed into lower-level concepts.

URL: The Uniform Resource Locator (URL) is the address of all Web pages, images, and other resources on the World Wide Web.

Web Page: A file that is on the Web and is accessible by its URL.

Web Site: A collection of Web pages located together on a Web server. Typically the pages of a Web site have a common focus and are connected by hyperlinks.

Web Usage Mining with Web Logs

INTRODUCTION

With the rapid growth of the World Wide Web, the use of automated Web-mining techniques to discover useful and relevant information has become increasingly important. One challenging direction is Web usage mining, wherein one attempts to discover user navigation patterns of Web usage from Web access logs. Properly exploited, the information obtained from Web usage log can assist us to improve the design of a Web site, refine queries for effective Web search, and build personalized search engines.

However, Web log data are usually large in size and extremely detailed, because they are likely to record every aspect of a user request to a Web server. It is thus of great importance to process the raw Web log data in an appropriate way, and identify the target information intelligently. In this chapter, we first briefly review the concept of Web Usage Mining and discuss its difference from classic Knowledge Discovery techniques, and then focus on exploiting Web log sessions, defined as a group of requests made by a single user for a single navigation purpose, in Web usage mining. We also compare some of the state-of-the-art techniques in identifying log sessions from Web servers, and present some popular Web mining techniques, including *Association Rule Mining, Clustering, Classification, Collaborative Filtering, and Sequential Pattern Learning*, that can be exploited on the Web log data for different research and application purposes.

BACKGROUND

Web Usage Mining (WUM), defined as the discovery and analysis of useful information from the World Wide Web, has been an active area of research and commercialization in the recent years (Cooley, Srivastava, & Mobasher, 1997). In general, as shown in Fig1, the WUM process can be considered as a three-phase process, which consists of data preparation, pattern discovery, and pattern analysis (Srivastava, Cooley, Deshpande, & Tan, 2000).

This process implicitly covers the standard process of Knowledge Discovery in the Databases (KDD), and WUM therefore can be regarded as an application of KDD to the Web domain. Nevertheless, it is distinct from standard KDD methods by facing the unique challenge to dealing with the overwhelming resources on the Internet. To assist Web users in browsing the Internet more efficiently, it is widely accepted that the easiest way to find knowledge about user navigations is to explore the Web server logs. Generally, Web logs record all user requests to a Web server. A request is recorded in a log file entry, which contains different types of information, including the IP address of the computer making the request, the user access timestamp, the document or image requested, etc. The following is an example extracted from the *Livelink* Web server log (Huang, An, Cercone & Promhouse, 2002).[1]

Livelink is a database driven web-based knowledge management system developed by Open Text Corporation (http://www.opentext.com). It provides a web-based environment (such as an intranet or extranet) to facilitate collaborations between cross-functional employees within an organization. In this example, a user using the computer with the IP 24.148.27.239 has requested a query with object ID 12856199 on April 10th, at 7:22pm.

However, when statistical methods are applied to such log data, we tend to get results that are too refined or too specific than they should be. In addition, it is very likely that user browsing behaviour is highly uncertain. Different users may visit the same page for

different purposes, spend various amount of time on the same page, or even access the same page from different sources. Hence, Web usage mining with original entry/ request-based logs may induce erroneous and worthless results. To solve this problem, Web usage session is introduced as a group of requests made by a single user for a single navigation purpose. A user may have a single session or multiple sessions during a period of time, and each session may include one or more requests accomplishing a single task.

MAIN FOCUS OF THE CHAPTER

Session identification method traditionally suffers from the problem of time threshold setting. Different users may have different browsing behaviours, and their

time intervals between sessions may be significantly different. Even for the same user, intervals between sessions may vary. There are several session identification methods reported in the literature.

Timeout

The most commonly used session identification method is called *Timeout*, in which a user session is defined as a sequence of requests from the same user such that no two consecutive requests are separated by an interval more than a predefined threshold. He and Goker (2000) reported the results of experiments that used the timeout method on two different sets of Web logs. By initially selecting a large value, and then gradually decreasing to smaller thresholds, the authors concluded that a time range of 10-15 minutes was an optimal session interval threshold. Catledge and Pitkow (1995) also reported their experimental results where a Web browser was modified to record the time interval between user actions on the browser's interface. One result indicated that the average time interval between two consecutive events by a user was 9.3 minutes, and 25.5 minutes was subsequently recommended as the threshold for session identification. However, the optimal timeout threshold is obviously problem dependent. As an example, Anick (2003) believed that his algorithm favours longer information seeking sessions, and took the time threshold as 60 minutes. Despite the application dependence of the optimal interval length, most commercial products use 30 minutes as a default threshold.

Reference Length

This method assumes that the time a user spends on a page is associated with whether it is an "auxiliary" or "content" page for that user (Cooley, Mobasher & Srivastava, 1999). By analyzing the histogram of page reference lengths, it is found that the time spent on auxiliary pages is usually shorter than that spent on a content page, and the variance of the times spent on auxiliary pages is also smaller. If an assumption is made about the percentage of auxiliary references in a log file, a reference length can be calculated by estimating the optimal cut-off between auxiliary and content references. Once pages are classified as either auxiliary or content pages, a session boundary will be detected whenever a content page is met. However, the potential problem of this method could be that the assumption is valid if only one content page is included in each session. This hypothesis thus may not apply when users visit more than one content page for a single retrieval purpose.

As an extension of the reference length method, a heuristic method, which integrates the reference-oriented method with the timeout strategy, has also been developed (Spilioupoulou, Mobasher, Berendt & Nakagawa, 2003). Nonetheless, the improvement is still limited due to the inherent problems that associate with the two methods.

Maximal Forward Reference

In the method of maximal forward reference, a usage session is defined as the set of pages from the first page in a request sequence to the last page before a backward reference is made (Chen, Park & Yu, 1998). In this approach, a backward reference is naturally defined as a page that has already occurred in the current session. The advantage of this method is that it is not necessary to set any parameters that make assumptions about the characteristics of a particular dataset. Nonetheless, a serious problem could be the backward references will not be recorded on the server if the caching function is enabled at the client side.

Statistical Language Model

Statistical language-model-based approach exploits information theory in the session boundary identification process by measuring the information change in the request sequence (Huang, Peng, An & Schuurmans, 2004). Its objective is to group sequential log entries that are related to a common topic and segment those that are unrelated. They first show that the entropy (or perplexity) of the sequence is always low, when the objects in the sequence are on a common topic and frequently accessed one after another. Also, when a new object that is not relevant to the original topic is observed in the sequence, the new occurrence of this object will induce an increase in entropy, and this new object actually indicates a shift to a new topic. If such changes in entropy pass a threshold, there is reason to claim that the user is currently changing to another topic, and a session boundary can thus be placed before this new object. Through empirical studies, this approach demonstrates favourable results compared with other methods.

Web Mining Methods and Applications of Web Log Data

In order to extract useful user navigation patterns, various data mining techniques, including *Association Rule Mining, clustering, Classification, Collaborative Filtering, and Sequential Pattern Discovery*, have been successfully applied to the pre-processed Web usage session.

1. *Association Rule Mining* - In Web usage mining, association rule mining seeks for a group of objects or pages that are accessed together with a support value exceeding some predefined threshold (Agrawal & Srikant, 1994). For example, it might be interesting to know the correlation between users who view a page containing electronic products and those users who visit the page about sporting equipment in an on-line purchase. As another example, with the assist of association rule mining, page pre-fetching can be applied to reduce the overhead of retrieving documents when loading a page outside memory (Yang, Zhang, & Li, 2001).
2. *Clustering* - Clustering in the Web domain allows us to group together Web users or Web pages or request objects that have similar session characteristics. Current clustering techniques can be classified into two categorizes: discriminative (distance/ similarity-based) approaches and generative (model-based) approaches (Zhong & Ghosh, 2003). Similarity-based clustering determines the distance or (dis) similarity between pair-wise data. As an example, Fu (1999) suggested using URLs to construct a page hierarchy by making use of the directory structure of a web site. The requested sessions of a user was represented with feature vectors by merging access time of visited pages at the same generalized hierarchy level. With the measure of Euclidean distance, the similarities between Web usage sessions were finally calculated for clustering. Model-based clustering places cluster analysis on a principled statistical support. It is based on probability models in which objects are assumed to follow a mixture of probability distributions such that each component distribution stands for a unique cluster (Fraley & Raftery, 2002). The information discovered with clustering algorithms is one of the most important types that have a wide range of applications from real-time personalization to link prediction (Cadez, Heckerman, Meek, Smyth, & White, 2000).
3. *Classification* - Classification is a supervised learning technique that maps Web pages or users into one or more predefined classes. Classification techniques, such as decision tree classifier (Du & Zhan, 2002), naive Bayesian classifier (Geiger & Goldszmidt, 1997), K-nearest-neighbour classifier (Masand, Linoff & Waltz, 1992), neural networks (Ng, Goh, & Low, 1997), language modeling (Mcmahon, Smith 1996), maximum entropy (Nigam, Lafferty & McCallum, 1999), and support vector machines have been widely studied in Web usage mining by taking the advantage of various log data. They can generally be used to categorize visitors or Web pages by selecting features that best describe the properties of their characteristics. For example, a classification rule might be in a format of: 25% of visitors who buy fiction books from Ontario, are aged between 18 and 35, and visit after 5:00pm. Such rules can be applied to categorize future data samples, as well as provide a better understanding of the whole Web data.
4. *Collaborative Filtering* - When a user is navigating on the Web, it is practically infeasible for him/her to find reliable experts that can give advice on which options to choose whenever there is a need. Instead of consulting from a single individual, CF-based methods tend to find opinions of those people having similar interests by measuring the overlaps between their request objects in Web usage sessions (Breese, Heckerman, & Kadie, 1998; Ding & Li, 2005; Kawamae & Takahashi, 2005). To achieve this, the basic idea behind the collaborative filtering technique can be described as follows:
    1. A large group of users' preferences are registered;
    2. With some similarity metric, a subgroup of people that share similar preference of the person who is seeking for advice are selected;
    3. An (weighted) average of the preferences of that subgroup is calculated;

4. A prediction function is applied to recommend options on which the advice seeker has expressed.
   The most commonly used similarity metric is the *Pearson Correlation Coefficients* between the users' preference functions.
5. *Sequential Pattern Mining* - In Web server logs, user click streams are sequentially recorded. Each Web usage session is a sequence of pages or objects that a user requests during a visit to the Web site. The discovery of sequential patterns in Web server logs allows for predicting user navigation patterns (Gunduz& Ozsu, 2003; Mobasher, Dai, Luo, & Nakagawa, 2002). By analyzing the sequential patterns, the Web mining system can determine temporal relationships among data items.

FUTURE TRENDS

Some questions involving both session boundary identification and Web usage mining applications are still open for further investigations. For example, although the language-model-based session identification approach demonstrates the best performance compared with other methods, it is still sensitive to the setting of entropy threshold. An inappropriate threshold value may yield non-optimal results. An automatic parameter estimation method therefore should be investigated. Some future trends also include combining Web usage mining approaches with the Web content learning. For example, the information gained through discovering the Web user/page patterns can be used to refine queries of a personalized search engine, or construct an adaptive information system.

CONCLUSION

To better satisfy the requirements of various Web-based applications, Web usage mining exploits data mining methods to discover useful patterns from Web log data. In this chapter, we first reviewed the concept of Web usage mining, and discussed its difference from standard KDD methods. To make a better understanding of the unique characteristics in Web data, we then explained the need of introducing Web usage sessions, and focused on describing different state-of-the-art session identification techniques. We finally presented some popular Web usage mining techniques, and displayed their applications in recent research.

ENDNOTE

[1] For security reasons, some of the lines are removed.

KEY TERMS

Session Identification: The application of determining the boundaries of Web usage sessions.

Statistic Language Model: The probability distributions defined on sequences of words, $P(w_1 \ldots w_n)$. In

speech recognition, such models refer to a probabilistic distribution capturing the statistics of the generation of a language, and attempt to predict the next word in a speech sequence.

Web Log Mining: The application of discovering Web usage patterns from the records of Web server logs.

Web Usage Mining: The application of data mining techniques to discover usage patterns from Web data.

Web Usage Session: A group of requests made by a single user for a single navigation purpose.

Wrapper Feature Selection

INTRODUCTION

It is well known that the performance of most data mining algorithms can be deteriorated by features that do not add any value to learning tasks. Feature selection can be used to limit the effects of such features by seeking only the relevant subset from the original features (de Souza et al., 2006). This subset of the relevant features is discovered by removing those that are considered as irrelevant or redundant. By reducing the number of features in this way, the time taken to perform classification is significantly reduced; the reduced dataset is easier to handle as fewer training instances are needed (because fewer features are present), subsequently resulting in simpler classifiers which are often more accurate.

Due to the abovementioned benefits, feature selection has been widely applied to reduce the number of features in many data mining applications where data have hundreds or even thousands of features. A large number of approaches exist for performing feature selection including filters (Kira & Rendell, 1992), wrappers (Kohavi & John, 1997), and embedded methods (Quinlan, 1993). Among these approaches, the wrapper appears to be the most popularly used approach. Wrappers have proven popular in many research areas, including Bioinformatics (Ni & Liu, 2004), image classification (Puig & Garcia, 2006) and web page classification (Piramuthu, 2003). One of the reasons for the popularity of wrappers is that they make use of a classifier to help in the selection of the most relevant feature subset (John et al., 1994). On the other hand, the remaining methods, especially filters, evaluate the merit of a feature subset based on the characteristics of the data and statistical measures, e.g., chi-square, rather than the classifiers intended for use (Huang et al., 2007). Discarding the classifier when performing feature selection can subsequently result in poor classification performance. This is because the relevant feature subset will not reflect the classifier's specific characteristics. In this way, the resulting subset may not contain those features that are most relevant to the classifier and learning task. The wrapper is therefore superior to other feature selection methods like filters since it finds feature subsets that are more suited to the data mining problem.

These differences between wrappers and other existing feature selection techniques have been reviewed by a number of studies (e.g. Huan & Lei, 2005). However, such studies have primarily focussed on providing a holistic view of all the different types of techniques. Although these works provide comprehensive information, there has yet to appear a deep review that solely focuses on the most popular feature selection technique; the wrapper. To this end, this paper aims to present an in-depth survey of the wrapper. In particular, attention will be given to improvements made to the wrapper since they are known for being much slower than other existing feature selection techniques. This is primarily because wrappers are required to repeatedly run the classifier when determining feature accuracy and perform feature selection again each time a different classifier is used. To overcome such problems, researchers in this area have spent considerable effort in improving the performance of wrappers (Yu & Cho, 2006). Basically, improvements can be divided into two trends. One focuses on reducing the time taken to do feature selection and the other emphasises on improv-

ing the accuracy of the selected subset of features. In fact, there are close relationships between these two trends because one can potentially influence the other. In other words, decreasing the time taken to perform feature selection with wrappers may potentially affect the accuracy of the final output. This relationship has been investigated by several studies and will be reviewed in this paper.

The paper will first formally define the feature selection process, with an emphasis on the wrapper approach. Subsequently, improvements made to the wrapper for reducing the time taken to do feature selection and increasing the overall accuracy of the selected subset of features will be discussed. It then moves to discuss future directions for wrapper feature selection approaches. Finally, conclusions are drawn at the end of the paper.

BACKGROUND

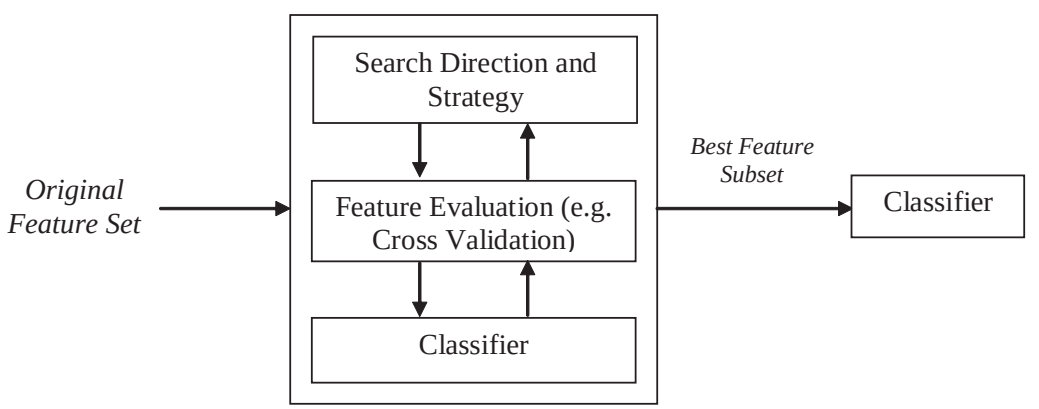
Typically, feature selection can be formally defined in the following manner. Suppose F is the given set of original features with cardinality n (where n symbolises the number of features in set F), and $\overline{F}$ is the selected feature subset with cardinality $\overline{n}$ (where $\overline{n}$ symbolises the number of features in set $\overline{F}$), then $\overline{F} \subseteq F$. Also, let $J(\overline{F})$ be the selection criterion for selecting feature set $\overline{F}$. We assume that a higher value of J indicates a better feature subset. Thus, the goal is to maximise $J()$. The problem of feature selection is to find a subset of features $\overline{F} \subseteq F$ such that,

$$J(\overline{F}) = \max_{Z \subseteq F, |Z|=n} J(Z)$$

Deriving a feature subset that maximises $J(\ )$ typically consists of four key steps namely, search direction, search strategy, subset evaluation and stopping criterion (Huan & Lei, 2005). Search direction defines the point at which the search for the most relevant subset will begin. Complimentary to the direction of the search is the search strategy. The search strategy outlines the way in which feature subsets are searched within the feature space. Each of the feature subsets found is then evaluated according to some evaluation criteria. Finally, a stopping criterion is used for halting the search through feature subsets.

As indicated in the Introduction, this paper will focus on the wrapper approach, where a classifier is used as the evaluation criterion for maximising $J(\ )$. Basically, the wrapper uses the classifier as a black box. The classifier is repeatedly run on the dataset using various subsets of the original features. These feature subsets are found through the use of a search strategy. The classifier's performance and some accuracy estimation method like cross validation are then used to evaluate the accuracy of each subset (John et al., 1994). The feature subset with the highest accuracy is chosen as the final set on which to run the classifier.

Figure 1. Wrapper feature selection



To have a better understanding of the wrapper approach, this paper will use a decision tree as an example to explain the aforementioned process. The decision tree classifier initially seeks and generates different feature subsets with some search strategies, one of which is forward selection. The forward selection strategy begins with no features and successively adds more features that are deemed relevant by the decision tree classifier. The feature subsets found using this strategy may then be evaluated using the decision tree's performance and 10-fold cross validation, where the subset with the highest accuracy is determined as the most relevant. This relevant subset is subsequently fed as input to the decision tree classifier. The entire procedure for performing wrapper feature selection is illustrated in Figure 1.

DECREASE IN TIME

Although the wrapper is able to find accurate feature subsets, the main criticism of the approach is the amount of time needed to perform feature selection. Typically, the wrapper will require considerably more time to examine feature subsets compared to any other feature selection approaches. This is because of two issues. The first issue concerns the use of a classifier. By using a classifier, more time is needed in examining each potential feature subset searched in the feature space. The second issue regards the use of cross validation. Cross validation is used in conjunction with the classifier to determine the level of accuracy of feature subsets. When both the classifier and cross validation are used together, the wrapper runs prohibitively slow. These drawbacks have led researchers to investigate ways of reducing the time of the wrapper process.

As stated above, the classifier is one of the main reasons why the wrapper performs slower than other feature selection approaches. To alleviate the effects of using a classifier, Caruana & Freitag (1994) developed a new method for speeding up the wrapper approach when specifically used with decision tree classifiers. The method functions by reducing the number of decision trees grown during feature selection by recording the features that were used to construct the trees. By doing so, less time is needed to analyze the features used in tree formation. In addition to two well known decision tree classifiers, ID3 and C4.5, five different search strategies were used to test the effectiveness of the method, including forward selection, backward elimination, forward stepwise selection, backward stepwise elimination, and backward stepwise elimination-SLASH, which is a bi-directional version of backward stepwise elimination. Empirical analysis revealed that, irrespective of the search strategy and decision tree classifier used, the time taken to perform feature selection decreased.

Furthermore, Kohavi & Sommerfield (1995) introduced the concept of 'compound' operators in an attempt to make the wrapper perform in less time. The purpose of using compound operators is to direct the search strategy more quickly toward the most relevant features. In this way, the classifier will need to spend less time evaluating all the features. Experiments using the compound operators were carried out using two classifiers: ID3 and Naïve Bayes. Results showed a significant decrease in the amount of time needed to perform feature selection when either classifier was used. Improvements in classification accuracy for ID3 and Naïve Bayes were also found when compound operators were implemented.

Besides the classifiers, cross validation is another factor that can decrease the speed at which the wrapper performs features selection. A strategy for reducing the wrapper's time complexity when used in conjunction with cross validation was presented by Moore & Lee (1994). The strategy reduces the number of instances used during the evaluation stage of feature selection so the cost of fully evaluating each feature subset is also decreased. They showed that the new strategy successfully reduced the number of feature subsets evaluated during feature selection. This led to a drop in the amount of time needed to perform wrapper feature selection. It was also found that the reliability of the chosen feature subset was unaffected by the fall in the number of instances.

Hashemi (2005) also investigated the effects of reducing the number of instances used for feature selection. Hashemi presented a new wrapper approach that performs feature selection roughly 75 times faster than traditional wrapper approaches. The new wrapper approach does this by using an algorithm called Atypical Sequential Removing (ASR). The ASR algorithm finds and removes those instances in the data, which do not influence classifier performance. By decreasing the number of instances, the process of feature selection can be speeded up as there will be less data to deal with. Experiments were carried out using the proposed

wrapper approach with different classifiers, including Support Vector Machines (SVM), *k*-Nearest Neighbour and C4.5. Overall, findings showed that although the accuracy of some classifiers did not improve when compared to the use of all instances, the new wrapper method performed much faster.

INCREASE OF ACCURACY

The aforementioned studies have so far shown that it is possible to reduce the time needed to perform wrapper feature selection. Although time complexity is a major issue, especially when many features are involved, the accuracy of the chosen feature subset is also very important. The idea of accuracy and time is interrelated because improving one may affect the other. Numerous studies have investigated this relationship by using evolutionary search strategies called Genetic Algorithms (GA) (e.g. Ni & Liu, 2004) because GA possess powerful search capabilities (Sikora & Piramuthu, 2007). Rhitoff, et al. (2002) is an example of works using GA. They incorporate GA with the wrapper to form a feature selection technique that avoids a suboptimal solution without sacrificing much in speed. Specifically, the GA wrapper uses a SVM as the classifier when performing feature selection. Results showed that accuracy significantly improved when compared to using no feature selection. Their approach was also tested against the well known sequential forward selection wrapper with similar findings.

Another framework combining the uses of GA and feature selection approaches can be found in Sikora & Piramuthu (2007). This framework uses GA with the Hausdorff distance measure for wrapper feature selection. Experimental results comparing this framework to a GA-based wrapper approach without the Hausdorff distance measure showed that it provided superior performance. The GA and Hausdorff wrapper feature selection approach was not only able to improve classification accuracy by 10% but also reduce the amount of time by 60%. This goes to show that the accuracy of the wrapper approach can be improved no matter if time taken is lowered.

Furthermore, Ruiz et al. (2006) developed a new gene selection method called Best Incremental Ranked Subset (BIRS) based on the wrapper approach. The method aims to improve classification accuracy of cancer data without affecting the time taken to do feature selection. BIRS does this by first ranking the genes. A small subset of genes with the highest rank is then fed as input to the wrapper. The method was tested using three different classifiers, i.e., Naïve Bayes, Nearest Neighbour, and C4.5, on four DNA microarray datasets. Experimental results on these datasets showed that BIRS is a very fast feature selection approach when compared to a wrapper that uses all the genes. In addition, BIRS was found to produce good classification accuracy.

The abovementioned studies have clearly shown that the wrapper's time complexity can significantly be reduced. In addition, we have seen that the accuracy of the wrapper can be improved. However, improving time and accuracy only present the first step towards developing more robust wrapper approaches. Further research is needed to identify alternative ways of improving the way in which the wrapper performs feature selection. Other directions for further research are presented in the next section.

FUTURE TRENDS

The reviewed studies demonstrate that feature selection, more specifically the wrapper, is a very popular data analysis tool. However, there are some limitations that need to be further investigated.

Combined Feature Selection

As described in the previous section, the classifier is used by the wrapper to select the most relevant feature subset. In this way, the biases specific to the classifier are included in the feature selection process, which often lead to subsets that are better suited to the classifier. However, each classifier has its own limitations and current research mainly uses a single classifier when selecting the most relevant features. There exists little work that considers combining several different classifiers and deriving a consensus from the features selected from these different classifiers. Such a combined approach can be used to overcome the limitations of each individual classifier.

Search Techniques

The wrapper approach is not only influenced by the classifier used, but also by the strategy applied to

search through the vast number of feature subsets. Often, selecting the right strategy can be difficult as there are many to choose from. In addition, wrongly chosen search strategies can influence the accuracy of the output feature subset. To alleviate the task of choosing a search strategy, it would be interesting to investigate search strategies that use concepts from Soft Computing, such as Fuzzy Logic and Rough Set Theory. This is because Soft Computing methods are very good at handling ill-defined learning tasks. However, very little work has been done to implement these strategies in feature selection, so more empirical studies are needed to identify their true usefulness and effectiveness.

Parallelization of Feature Selection

In recent years, the notion of parallelization for improving the performance of data mining techniques has received much interest from researchers. Such parallelization is conducted by running data mining techniques over several computers to output results in less time. However, not many attempts have been made to apply parallelization to feature selection (de Souza et al., 2006). Feature selection approaches, specifically the wrapper, could benefit from such an approach. More specifically, parallelization can reduce the amount of time needed to perform feature selection by distributing the workload among different computers and their processors. In this way, much larger datasets can be analyzed in much less time. Due to such advantages, further investigation is certainly needed to evaluate the effectiveness of applying parallelization for the wrapper or any other feature selection approach.

CONCLUSION

In summary, feature selection is a very useful approach for choosing a small subset of features that is most relevant to a learning task. Reducing the number of features in this way leads to many benefits, including more concise results with better comprehensibility. The most popular feature selection approach used to reduce the number of features is the wrapper. In this paper, we provided a review of the wrapper feature selection process. Particular attention was given to survey current works that reduce the time complexity and increase the accuracy of the wrapper. However, these works apply the wrapper, and its improved variants, to solve different data mining problems. Since each problem will be different in nature, it would be beneficial to collectively integrate these works into a generic guide to help researchers decide the most suitable way for applying the wrapper to a particular data mining problem. By doing so, researchers can exploit the full potential of the wrapper approach to gain a relevant feature subset that is more accurate and suitable.

KEY TERMS

Classification: Prediction of the class label of a new instance using a set of already labelled data instances.

Classifier: Categorises instances based on a labelled dataset and outputs a classification model.

Cross Validation: An accuracy estimation technique typically used for classification and feature selection, which estimates generalisation error and prevents overfitting of the data. Cross validation is extremely useful when a separate validation or test set is unavailable.

Decision Tree: A top-down hierarchical structure constructed by repeatedly splitting the entire dataset into two or more nodes according to some target variable.

Genetic Algorithm: A powerful search technique that uses concepts from biological evolution. It is initiated with a population of individual solutions called chromosomes. Genetic operators such as crossover and mutation are then used to select the best solution.

***k*-Nearest Neighbour:** A technique that uses a distance metric to select the *k* closest instance(s) to a new instance. The class label of the closest instance will be assigned to the new instance. This technique can be applied to both classification and regression problems.

Support Vector Machine (SVM): The mapping of the original feature space onto a higher dimensional space to find an optimal hyperplane that correctly classifies instances in a dataset by maximising the margin between instances and minimising the chance of errors.

XML Warehousing and OLAP

Hadj Mahboubi

University of Lyon (ERIC Lyon 2), France

INTRODUCTION

With the eXtensible Markup Language (XML) becoming a standard for representing business data (Beyer et al., 2005), a new trend toward XML data warehousing has been emerging for a couple of years, as well as efforts for extending the XQuery language with near On-Line Analytical Processing (OLAP) capabilities (grouping, aggregation, etc.). Though this is not an easy task, these new approaches, techniques and architectures aim at taking specificities of XML into account (e.g., heterogeneous number and order of dimensions or complex measures in facts, ragged dimension hierarchies…) that would be intricate to handle in a relational environment.

The aim of this article is to present an overview of the major XML warehousing approaches from the literature, as well as the existing approaches for performing OLAP analyses over XML data (which is termed XML-OLAP or XOLAP; Wang et al., 2005). We also discuss the issues and future trends in this area and illustrate this topic by presenting the design of a unified, XML data warehouse architecture and a set of XOLAP operators expressed in an XML algebra.

BACKGROUND

XML warehousing research may be subdivided into three families. The first family focuses on Web data integration for decision-support purposes. However, actual XML warehouse models are not very elaborate. The second family of approaches is explicitly based on classical warehouse logical models (star-like schemas). The third family we identify relates to document warehousing. In addition, recent efforts aim at performing OLAP analyses over XML data.

XML Web Warehouses

The objective of these approaches is to gather XML Web sources and integrate them into a data warehouse. For instance, Xyleme (2001) is a dynamic warehouse for XML data from the Web that supports query evaluation, change control and data integration. No particular warehouse model is proposed, though.

Golfarelli et al. (2001) propose a semi-automatic approach for building a data mart's conceptual schema from XML sources. The authors show how multidimensional design may be carried out starting directly from XML sources and propose an algorithm for correctly inferring the information needed for data warehousing.

Finally, Vrdoljak et al. (2003) introduce the design of a Web warehouse that originates from XML Schemas describing operational sources. This method consists in preprocessing XML Schemas, in creating and transforming the schema graph, in selecting facts and in creating a logical schema that validates a data warehouse.

XML Data Warehouses

In his XML-star schema, Pokorný (2002) models a star schema in XML by defining dimension hierarchies as sets of logically connected collections of XML data, and facts as XML data elements.

Hümmer et al. (2003) propose a family of templates enabling the description of a multidimensional structure for integrating several data warehouses into a virtual

or federated warehouse. These templates, collectively named XCube, consist of three kinds of XML documents with respect to specific schemas: XCubeSchema stores metadata; XCubeDimension describes dimensions and their hierarchy levels; and XCubeFact stores facts, i.e., measures and the corresponding dimensions.

Rusu et al. (2005) propose a methodology, based on the XQuery technology, for building XML data warehouses, which covers processes such as data cleaning, summarization, intermediating XML documents, updating/linking existing documents and creating fact tables. Facts and dimensions are represented by XML documents built with XQueries.

Park et al. (2005) introduce an XML warehousing framework where every fact and dimension is stored as an XML document. The proposed model features a single repository of XML documents for facts and multiple repositories for dimensions (one per dimension).

Eventually, Boussaïd et al. (2006) propose an XML-based methodology, X-Warehousing, for warehousing complex data (Darmont et al., 2005). They use XML Schema as a modeling language to represent users' analysis needs, which are compared to complex data stored in heterogeneous XML sources. Information needed for building an XML cube is then extracted from these sources.

XML DOCUMENT WAREHOUSES

Baril and Bellahsène (2003) envisage XML data warehouses as collections of materialized views represented by XML documents. Views allow filtering and restructuring XML sources, and provide a mediated schema that constitutes a uniform interface for querying the XML data warehouse. Following this approach, the authors have developed the DAWAX system.

Nassis et al. (2005) propose a conceptual approach for designing and building an XML repository, named xFACT. They exploit object-oriented concepts and propose to select dimensions based on user requirements. To enhance the XML data warehouse's expressiveness, these dimensions are represented by XML virtual views. In this approach, the authors assume that all dimensions are part of fact data and that each fact is described in a single XML document.

Rajugan et al. (2005) also propose a view-driven approach for modeling and designing an XML fact repository, named GxFact. GxFact gathers xFACTs (distributed XML warehouses and datamarts) in a global company setting. The authors also provide three design strategies for building and managing GxFact to model further hierarchical dimensions and/or global document warehouses.

Finally, Zhang et al. (2005) propose an approach to materialize XML data warehouses based on frequent query patterns discovered from historical queries. The authors apply a hierarchical clustering technique to merge queries and therefore build the warehouse.

OLAP ANALYSES OVER XML DATA

Chronologically, the first proposals for performing OLAP analyses over XML data mainly rely on the power of relational implementations of OLAP, while more recent research directly relates to XOLAP.

Jensen et al. (2001) propose an integration architecture and a multidimensional UML model for relational and XML data. They also discuss the design of XML databases supporting OLAP analyses. The output of this process is a unified relational representation of data, which are queried with the OQL language. Niemi et al. (2002) follow the same logic, but propose a dedicated language named MDX. In both these approaches, XML data are mapped into a relational database and exploited with relational query languages. Hence, no XML-specific OLAP operator is defined.

Pedersen et al. (2004) also advocate for federating XML data and existing OLAP cubes, but in addition, they propose an algebra composed of three operators. The most fundamental operator in an OLAP-XML federation, decoration, attaches a new dimension to a cube with respect to linked XML elements. Selection and generalized projection help filter and aggregate fact measures, respectively. They more or less correspond to the classical OLAP slice and dice operators. These three operators are implemented with an extension of the SQL_M language, SQL_{XM}, which helps associate XPath queries to SQL_M queries. SQL_M is itself an extension of SQL for processing multidimensional data.

Eventually, Park et al. (2005) propose an OLAP framework for XML documents called XML-OLAP and introduce the notion of XML cube (XQ-Cube). A specific multidimensional language (XML-MDX) is applied on XQ-Cubes. Wang et al. (2005) also propose a general aggregation operator for XML, GXaggrega-

tion, which forms the base of XCube, an extension of the traditional cube operator for XML data. These two operators have been implemented as an extension of XQuery. In opposition, Wiwatwattana et al. (2007) argue that such an extension from the relational model cannot address the specific issues posed by the flexibility of XML. Hence, they propose an XML warehouse-specific cube lattice definition, a cube operator named X^3, and a generalized specification mechanism. They also discuss the issue of cube computation and compare several alternative algorithms. X^3 has been implemented in C++ within the TIMBER XML-native Database Management System (DBMS).

UNIFIED XML WAREHOUSING AND XOLAP MODELS

XML Warehouse Architecture

Previous XML warehousing approaches assume that the warehouse is composed of XML documents that represent both facts and dimensions. All these studies more or less converge toward a unified XML warehouse model. They mostly differ in the way dimensions are handled and the number of XML documents that are used to store facts and dimensions.

A performance evaluation study of these different representations has been performed by Boukraa et al. (2006). It showed that representing facts in one single XML document and each dimension in one XML document allowed the best performance.

Moreover, this representation also allows to model constellation schemas without duplicating dimension information. Several fact documents can indeed share the same dimensions. Also, since each dimension and its hierarchy levels are stored in one XML document, dimension updates are more easily and efficiently performed than if dimensions were either embedded with the facts or all stored in one single document.

Hence, we propose to adopt this architecture model to represent XML data warehouses. It is actually the translation of a classical snowflake schema into XML. More precisely, our reference data warehouse is composed of the following XML documents:

1. *dw-model.xml* represents the warehouse metadata (basically the warehouse schema);
2. *facts.xml* helps store the facts, i.e., dimension identifiers and measure values;
3. *dimension$_d$.xml* helps store a given dimension *d*'s attribute values.

Figure 1 represents the *dw-model.xml* document's graph structure. *dw-model.xml* defines the multidimensional structure of the warehouse. Its root node, *DW-model*, is composed of two types of nodes: *dimension* and *FactDoc*. A *dimension* node defines one dimension, its possible hierarchical levels (*Level* elements) and attributes (including their types), as well as the

Figure 1. Dw-model.xml graph structure

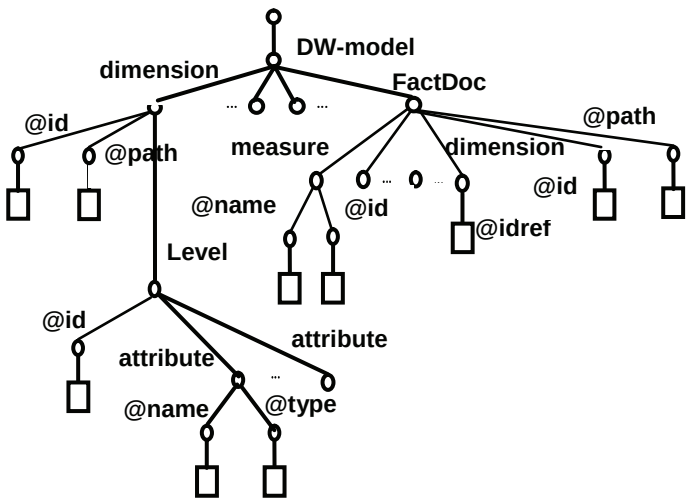

Figure 2. Facts.xml graph structure

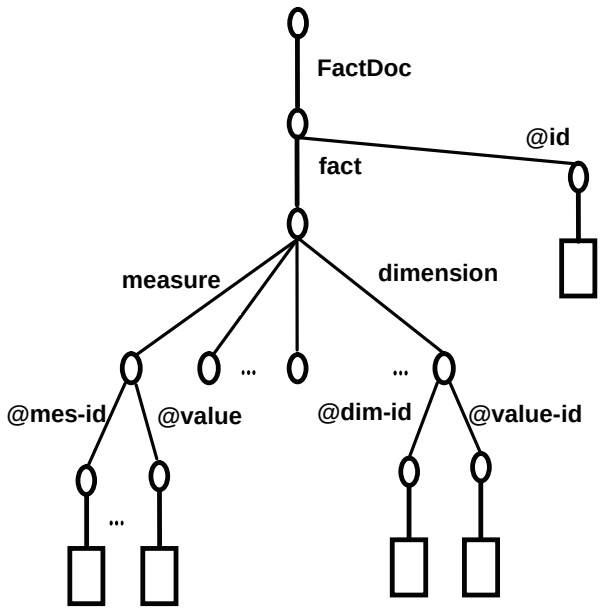

Figure 3. Dimension$_d$.xml graph structure

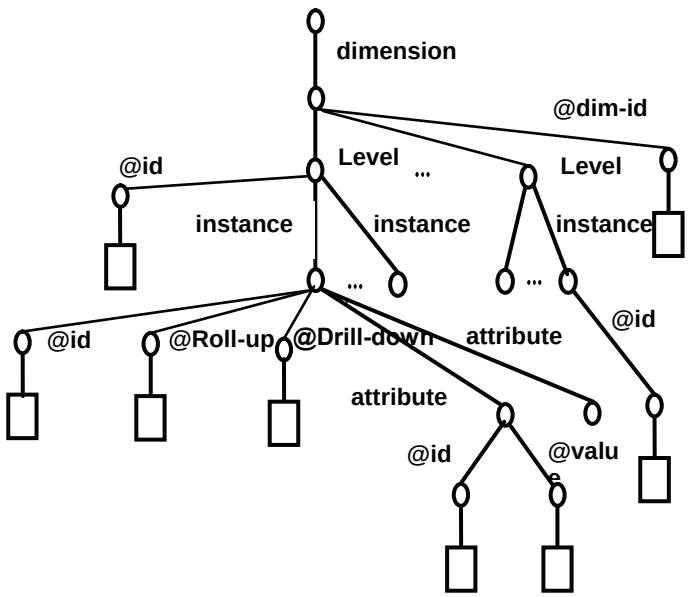

path to the corresponding *dimension$_d$.xml* document. A *FactDoc* element defines a fact, i.e., its measures, internal references to the corresponding dimensions, and the path to the *facts.xml* document. Note that several *FactDoc* elements are possible, thus enabling constellation schemas.

Figure 2 represents the *facts.xml* document's graph structure. *facts.xml* stores the facts and is composed of *fact* nodes defining measures and dimension references. The document root node, *FactDoc*, is composed of *fact* sub-elements, each of whose instantiates a fact, i.e., measure values and dimension references. These

identifier-based references support the fact-to-dimension relationship.

Finally, Figure 3 represents the *dimension$_d$.xml* document's graph structure. *dimension$_d$.xml* helps instantiate dimension *d,* including any hierarchy level. Its root node, *dimension,* is composed of *Level* nodes. Each one defines a hierarchy level composed of *instance* nodes that each defines the level's attribute values. In addition, an *instance* element contains *Roll-up* and *Drill-down* attributes that define the hierarchical relationship within dimension *d*.

Algebraic Expression of XOLAP Operators

These last decade's efforts for formalizing OLAP algebras (Agrawal et al., 1997; Gyssens and Lakshmanan, 1997; Thomas and Datta, 2001; Ravat et al., 2006) have helped design a formal framework and well-identified operators. Existing OLAP operators being defined in either a relational or multidimensional context, they must now be adapted to the data model of XML documents (namely trees or, more generally, graphs) and enriched with XML-specific operators.

Existing approaches that aim at XOLAP do not fully satisfy these objectives. Some favor the translation of XML data cubes in relational, and query them with extensions of the SQL language. Others tend toward multidimensional solutions that exploit XML query languages such as XQuery or XML-MDX. However, in terms of algebra, these works only propose a fairly limited number of operators.

As Wiwatwattana et al. (2007), we aim at a native-XML solution that exploits XQuery. As a first step toward an XOLAP platform, we initiated a previously inexistent formal framework in the XML context by demonstrating how the TAX Tree Algebra for XML (Jagadish et al., 2001) could support OLAP operators. Among the many XML algebras from the literature, we selected TAX for its richness. TAX indeed includes, under its logical and physical forms, more than twenty operators, which allows us many combinations for expressing XOLAP operators. Furthermore, TAX's expressivity is widely acknowledged, since this algebra can be expressed with most XML query languages, and especially XQuery, which we particularly target because of its standard status. Finally, TAX and its derived algebra TLC (Paparizos et al., 2004) provide a query optimization framework that we can exploit in the future, since performance is a major concern when designing decision-support applications that are integrally based on XML and XQuery.

We expressed in TAX the main usual OLAP operators: cube, rotate, switch, roll-up, drill-down, slice, dice, pull and push. By doing so, we significantly expanded the number of available XOLAP operators, since up to now, related papers only proposed at most three operators each (always including the cube operator). We have also implemented these XOLAP operators into a software prototype that helps generate the corresponding XQuery code. This querying interface is currently coupled to TIMBER XML-native DBMS, but it is actually independent and could operate onto any other DBMS supporting XQuery.

FUTURE TRENDS

Historically, XML data warehousing and OLAP approaches very often adapted existing, efficient relational solutions to the XML context. This was a sensible first step, but new approaches must now (and have definitely started to) take the specificities of XML data into account. More specifically, XML warehousing approaches now have to handle heterogeneous facts that may be described each by different dimension sets and/or hierarchy levels. Moreover, because of the variety of data sources, some fact and dimension data may also be missing. Finally, and especially when dealing with complex data such as multimedia data, measures may be non-numerical. For instance, if the observed fact is the health status of a patient, a radiography could be a measure.

Regarding XOLAP, let us take on an algorithmic metaphor. Most authors, and especially Wiwatwattana et al. (2007) and their excellent X^3 operator, have adopted a depth-first approach by fully developing one operator only, which is arguably of little use alone. On the other hand, we have adopted a breadth-first approach by proposing a wider range of operators that, however, only apply onto quite "regular" XML data. Both approaches should aim at completion, in breadth and depth, respectively, to achieve a full XOLAP environment; and are in our opinion complementary. In the next step of our work, we will indeed take inspiration from X^3's principle to enhance the rest of our XOLAP operators and truly make them XML-specific. For instance, we are actually currently working on performing roll-up

and drill-down operations onto the ragged hierarchies defined by Beyer et al. (2005).

CONCLUSION

More than a mere fashion related to XML's popularity, XML data warehousing and OLAP come from a true need. The complexity of data warehousing and OLAP technologies indeed makes them unattractive to many potential users and there is a growing need in the industry for simple, user-friendly Web-based interfaces, which is acknowledged by decision support system vendors (Lawton, 2006). Hence, though obvious and important difficulties do exist, including the maturity of XML-native DBMSs, especially regarding performance, we think that XML data warehousing and OLAP are promising approaches, and the best able to handle the numerous, so-called complex data (Darmont et al., 2005) that flourish on the Web, in a decision-support context.

KEY TERMS

Complex Data: Data that present several axes of complexity for analysis, e.g., data represented in various formats, diversely structured, from several sources, described through several points of view, and/or versioned.

Web Warehouse: "A shared information repository. A web warehouse acts as an information server that supports information gathering and provides value added services, such as transcoding, personalization." (Cheng et al., 2000)

XML Data Warehouse: A data warehouse managing multidimensionally modeled XML data.

XML Document Warehouse: An XML document repository dedicated to e-business and Web data analysis.

XML Graph: Data model representing the hierarchical nature of XML data. In an XML graph, nodes represent elements or attributes.

XML-OLAP or XOLAP: OLAP for XML; approaches and operators providing answers to analytical queries that are multidimensional in nature and applied to XML data.

XML-Enabled Association Analysis

Ling Feng
Tsinghua University, China

INTRODUCTION

The discovery of association rules from large amounts of structured or semi-structured data is an important data mining problem [Agrawal et al. 1993, Agrawal and Srikant 1994, Miyahara et al. 2001, Termier et al. 2002, Braga et al. 2002, Cong et al. 2002, Braga et al. 2003, Xiao et al. 2003, Maruyama and Uehara 2000, Wang and Liu 2000]. It has crucial applications in decision support and marketing strategy. The most prototypical application of association rules is market basket analysis using transaction databases from supermarkets. These databases contain sales transaction records, each of which details items bought by a customer in the transaction. Mining association rules is the process of discovering knowledge such as "*80% of customers who bought diapers also bought beer, and 35% of customers bought both diapers and beer*", which can be expressed as "*diaper* $\Rightarrow$ *beer*" (35%, 80%), where 80% is the *confidence* level of the rule, and 35% is the *support* level of the rule indicating how frequently the customers bought both diapers and beer. In general, an association rule takes the form $X \Rightarrow Y$ (s, c), where X and Y are sets of items, and s and c are support and confidence, respectively.

In the XML Era, mining association rules is confronted with more challenges than in the traditional well-structured world due to the inherent flexibilities of XML in both structure and semantics [Feng and Dillon 2005]. First, XML data has a more complex hierarchical structure than a database record. Second, elements in XML data have contextual positions, which thus carry the order notion. Third, XML data appears to be much bigger than traditional data. To address these challenges, the classic association rule mining framework originating with transactional databases needs to be re-examined.

BACKGROUND

In the literature, there exist techniques proposed to mine frequent patterns from complex tress and graphs databases. One of the most popular approaches is to use graph matching, which employs data structures like adjacency matrix [Inokuchi et al. 2000] or adjacency list [Kuramochi and Karypis 2001]. Another approach represents semi-structured tree-like structures using a string representation, which is more space efficient and relatively easy for manipulation [Zaki 2002]. This work concentrated on mining frequent tree structures within a forest, which can be extended to for mining frequent tree structures in XML documents. [Zhang et al. 2004, Zhang et al. 2005] proposed a framework, called XAR-Miner, which is directly applicable to mining association rules from XML data. Raw data in the XML document are preprocessed to transform to either an Indexed Content Tree (IX-tree) or Multi-relational databases (Multi-DB), depending on the size of XML document and memory constraint of the system, for efficient data selection and association rule mining. Task-relevant concepts are generalized to produce generalized meta-patterns, based on which the large association rules that meet the support and confidence levels are generated. Recently, Confronted with huge volume of XML data, [Tan, et al. 2005] proposed to generate candidates by model-validating, so that there is no time wasted in deriving invalid candidates which will be discarded at later stages. The algorithm processes an XML document directly taking into account the values of the nodes present in the XML tree, so the frequent item-sets generated contain both node names and values in comparison to the TreeMiner approach, which only generates frequent tree structures. The experiments with both synthetic and real life data sets demonstrate the efficiency of this approach.

MAIN FOCUS

The Framework

Under the traditional association rule framework, the basic unit of data to look at is database *record*, and the construct unit of a discovered association rule is *item* which has an *atomic value*. These lead us to the following two questions: 1) *what is the counterpart of record* and 2) *what is the counterpart of item* in mining association relationships from XML data? [Feng et al. 2003, Feng and Dillon 2004]. This investigation focuses on rule detection from a collection of XML documents, which describe the same type of information (e.g., customer order, etc.). Hence, each of XML documents corresponds to a database record, and possesses a tree-like structure. Accordingly, we extend the notion of associated item to an XML fragment (i.e., tree), and build up associations among trees rather than simple-structured items of atomic values. For consistency, we call each such kind of trees a **tree-structured item** to distinguish it from the traditional counterpart item. With the above extended notions, we propose an **XML-enabled association rule framework**. From both structural and semantic aspects, XML-enabled association rules are more powerful and flexible than the traditional ones.

Definition 1 *Let T denote a set of trees (tree-structured items). An* **XML-enabled association rule** *is an implication of the form $X \Rightarrow Y$, which satisfies the following two conditions:*

1. $X \subset T$, $Y \subset T$, *and* $X \cap Y = \phi$;
2. *for* $\forall T, T' \in (X \cup Y)$, *there exists no such tree* T''' *where* T'' *is a subtree of* T *and* T'.

Different from classical association rules where associated items are usually denoted using simple structured data from the domains of basic data types, the items in XML-enabled association rules can have a hierarchical tree structure, as indicated by the first clause of the definition. Here, it is worth pointing out that when each of the tree-structured items contains only one basic root node, the XML-enabled association rules will degrade to the traditional association rules. The second clause of the definition requires that in an XML-enabled association rule, no common sub-trees exist within any two item trees in order to avoid redundant expression.

Figure 1 illustrates some XML-enabled association rule examples. Thanks to XML, XML-enabled association rules are more powerful than traditional association rules in capturing and describing association relationships. Such enhanced capabilities can be reflected from both a structural as well as a semantic point of view:

- Association items have hierarchical tree structures, which are more natural, informative and understandable (e.g., Rule 1 & 2 in Figure 1).
- Associated items inherently carry the *order* notion, enabling a uniform description of association and sequence patterns within one mining framework (e.g., Rule 1 states the sequence of books to be ordered, i.e., "*Star War I*" proceeding "*Star War II* " on a customer's order).
- Associated items can further be constrained by their context positions, hierarchical levels, and weak/strong adhesion in the corresponding XML data to be mined. (e.g., Rule 1 indicates the contextual appearances of BOOKs on the order).
- Association relationships among structures and structured-values can also be captured and described (e.g., Rule 2 states that a student orders some flowers from a shop, and leaves detailed content of FLOWER element such as the kind of flowers and quantity, etc. aside).
- Auxiliary information which states the occurrence context of association relationships can be uniformly self-described in the mining framework (e.g., Rule 1 indicates that only male people have such as order pattern).

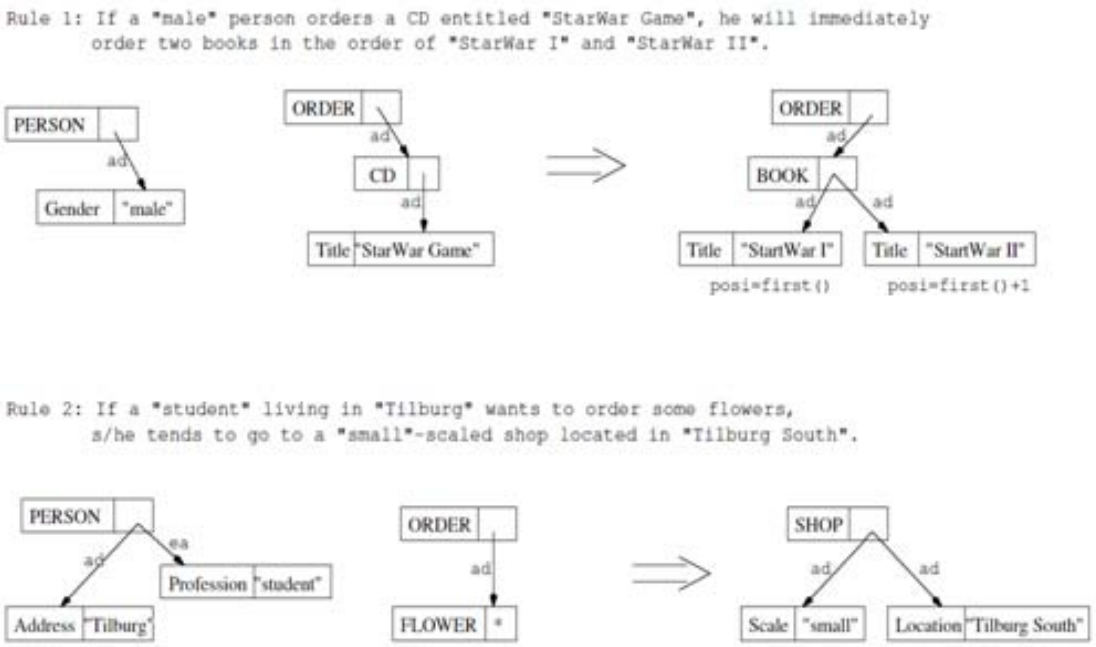
Similar to traditional association rules, we use support and confidence as two major measurements for XML-enabled association rules.

Definition 2 *Let D be a set of XML documents. The* **support** *and* **confidence** *of an XML-enabled association rule $X \Rightarrow Y$ are defined as follows:*

$$\text{support}(X \Rightarrow Y) = \frac{|D_{xy}|}{|\mathrm{D}|}, \quad \text{confidence}(X \Rightarrow Y) = \frac{|D_{xy}|}{|D_x|}$$

where $D_{xy} = \{doc | \forall T \in (X \cup Y)(T \in_{tree} doc)\}$, and $D_x = \{doc | \forall T \in X(T \in_{tree} doc)\}$.

Figure 1. XML-enabled association rule examples



The merit of such a support and confidence measurement definition in the context of XML association mining is that it sticks to the main stream of association analysis, where the counter part of "atomic item" concept in the classical association analysis is "tree-structured item", and that of the classical "transaction" concept corresponds to an XML document. This could help extend traditional methods and facilitate the development of new techniques in the newly emerging XML domain.

Template-Guided Mining of XML-Enabled Association Rules

The template-guided mining of XML-enabled association rules proceeds in three steps.

Phase-1: Transforming Tree-Structured Data into Sequences

To prepare for efficient mining, our first step is to transform each tree in the XML database and each tree variable in the template expression into a sequence while preserving their hierarchical structures. We employ the encoding technique, recently developed by Wang et al. for efficient indexing and querying XML data [Wang et al. 2003], to do such transformation. That is, a tree T is transformed into a sequence *Transform(T)* = $\langle(a_1, p_1), (a_2, p_2), \ldots, (a_n p_n)\rangle$, where a_i represents a node in the tree T, p_i is the path from the root node to node a_i, and $a_1, a_2, \ldots,$ an is the preorder traversal of the tree [Wang et al. 2003].

Phase-2: Discovering Structurally Containing Relationships by Sub-sequence Matching

With the structure-encoded sequences, checking the embedding relationship (i.e., whether an XML document contains a template tree variable) degrades to non-contiguous subsequence matching.

Phase-3: Correlating Concrete Contents with Structures

For each document obtained after Phase-2, the last step is to instantiate every unknown symbol (either node name or node value) in the template with a concrete content extracted from the document, which also observes content constraint(s) as indicated by the template.

To demonstrate the applicability of the XML-enabled association framework, we performed constraint-based XML-enabled association rule mining on the real-life DBLP data (http://dblp.uni-trier.de/xml/), which contains a huge number of bibliography entries in XML. Suppose we are interested in finding out who publishes frequently together with *Michael J. Franklin* in conference proceedings. Figure 2 is the template we use while mining the DBLP data. To restrict the mining space, we pre-process the original big DBLP file of size 187 MB by running an XQuery to extract in total 284663 fragments enclosed by <inproceedings>.....</inproceedings>. After discovering 52 XML segments which structurally contain the two tree variables of the template, i.e., conference papers written by *Michael J. Franklin*, we hash the corresponding co-authors' names into a hash table, and obtain the following rules when the support threshold is set to 0.002%.

Here are some rules, where author is

"*Stanley B. Zdonik*" (*support* = $\frac{10}{284663}$ = 0.004%, *confidences* = $\frac{10}{52}$ = 19.2%)

"*Michael J. Franklin*" (*support* = $\frac{7}{284663}$ = 0.003%, *confidences* = $\frac{7}{52}$ = 13.5%)

"*Samuel Madden*" (*support* = $\frac{6}{284663}$ = 0.003%, *confidences* = $\frac{6}{52}$ = 11.5%)

FUTURE TRENDS

From a structural as well as a semantic point of view, XML-enabled association rule framework is more flexible and powerful than the traditional one in representing both simple and complex structured association relationships. However, mining XML-enabled association relationships poses more challenges for efficient processing than mining traditional association rules. To address the trade-off between the enhanced capabilities on the one side and mining performance on the other side, an appropriate template model will play an necessary and important role in XML-enabled association mining.

CONCLUSION

We integrate the newly emerging XML technology into association rule mining technique. An extended XML-enabled association rule framework is presented, with the aim to discover associations inherent in massive amounts of XML data. From a structural as well as a semantic point of view, such a framework is more flexible and powerful than the traditional one in representing both simple and complex structured association relationships. Experimental results on the real-life DBLP data are presented to demonstrate the applicability of the framework.

KEY TERMS

Association: An association indicates the correlation relationship among items within the same transactions.

Mining Template: A mining template is an expression used to constrain the mining process.

Support and Confidence: Support and confidence are two measures used to describe the statistic significance of association rules.

Tree: A tree implies a tree data structure which has one root node, and any child node has only one parent node.

Tree-Structured Item: A tree-structured item indicates the item which has a tree structure.

XML: XML stands for eXtensible Markup Language.

XML-Enabled Association: XML-enabled association indicates the correlation relationship among tree-structured items which exists within the same XML data.
