Body of Evidence (BOE): Collection of mass values and concomitant sets of hypotheses.

CaRBS: Classification and Ranking Belief Simplex.

Case Deletion: A technique for the management of missing values through the removal of a case (object) when any of its characteristic values are missing.

Ignorance: A general term encompassing uncertainty and incompleteness in data analysis.

Imputation: A technique for the management of missing values through the replacement of missing values by calculated surrogates.

Mass Value: The level of exact belief assigned to a set of hypotheses.

Missing Value: A value not present that should describe a characteristic for a case (object).

Simplex Plot: Equilateral triangle domain representation of triplets of non-negative values which sum to one.

Uncertain Reasoning: The attempt to represent uncertainty and reason about it when using uncertain knowledge and imprecise information.

Knowledge Acquisition from Semantically Heterogeneous Data

INTRODUCTION

Recent advances in sensors, digital storage, computing and communications technologies have led to a proliferation of autonomously operated, geographically distributed data repositories in virtually every area of human endeavor, including e-business and e-commerce, e-science, e-government, security informatics, etc. Effective use of such data in practice (e.g., building useful predictive models of consumer behavior, discovery of factors that contribute to large climatic changes, analysis of demographic factors that contribute to global poverty, analysis of social networks, or even finding out what makes a book a bestseller) requires accessing and analyzing data from multiple heterogeneous sources.

The Semantic Web enterprise (Berners-Lee et al., 2001) is aimed at making the contents of the Web machine interpretable, so that heterogeneous data sources can be used together. Thus, data and resources on the Web are annotated and linked by associating meta data that make explicit the ontological commitments of the data source providers or, in some cases, the shared ontological commitments of a small community of users.

Given the autonomous nature of the data sources on the Web and the diverse purposes for which the data are gathered, in the absence of a universal ontology it is inevitable that there is no unique global interpretation of the data, that serves the needs of all users under all scenarios. Many groups have attempted to develop, with varying degrees of success, tools for flexible integration and querying of data from semantically disparate sources (Levy, 2000; Noy, 2004; Doan, & Halevy, 2005), as well as techniques for discovering semantic correspondences between ontologies to assist in this process (Kalfoglou, & Schorlemmer, 2005; Noy and Stuckenschmidt, 2005). These and related advances in Semantic Web technologies present unprecedented opportunities for exploiting multiple related data sources, each annotated with its own meta data, in discovering useful knowledge in many application domains.

While there has been significant work on applying machine learning to ontology construction, information extraction from text, and discovery of mappings between ontologies (Kushmerick, et al., 2005), there has been relatively little work on machine learning approaches to knowledge acquisition from data sources annotated with meta data that expose the structure (schema) and semantics (in reference to a particular ontology).

However, there is a large body of literature on distributed learning (see (Kargupta, & Chan, 1999) for a survey). Furthermore, recent work (Zhang et al., 2005; Hotho et al., 2003) has shown that in addition to data, the use of meta data in the form of ontologies (class hierarchies, attribute value hierarchies) can improve the quality (accuracy, interpretability) of the learned predictive models.

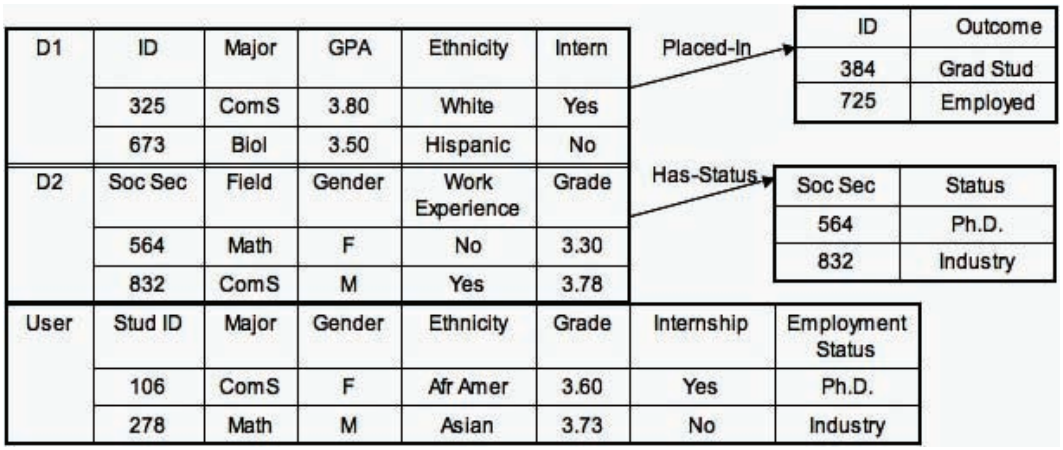
The purpose of this chapter is to precisely define the problem of knowledge acquisition from semantically heterogeneous data and summarize recent advances that have led to a solution to this problem (Caragea et al., 2005).

BACKGROUND

Motivating Example

The problem addressed is best illustrated by an example. Consider two academic departments that independently collect information about their students (Figure 1). Suppose a data set D_1 collected by the first department is organized in two tables, *Student* and *Outcome*, linked by a *Placed-In* relation using

Figure 1. Student data collected by two departments from a statistician's perspective



ID as the common key. Students are described by *ID*, *Major*, *GPA*, *Ethnicity* and *Intern.* Suppose a data set D_2 collected by the second department has a *Student* table and a *Status* table, linked by *Has-Status* relation using *Soc Sec* as the common key. Suppose *Student* in D_2 is described by the attributes *Student ID*, *Field*, *Gender*, *Work-Experience* and *Grade.*

Consider a user, e.g., a university statistician, interested in constructing a predictive model based on data from two departments of interest from his or her own perspective, where the representative attributes are *Student ID*, *Major*, *Gender*, *Ethnicity*, *Grade*, *Internship* and *Employment Status.* For example, the statistician may want to construct a model that can be used to infer whether a typical student (represented as in the entry corresponding to D_U in Figure 1) is likely go on to get a *Ph.D.* This requires the ability to perform queries over the two data sources associated with the departments of interest from the user's perspective (e.g., *fraction of students with internship experience that go onto Ph.D*). However, because the structure (schema) and data semantics of the data sources differ from the statistician's perspective, he must establish the correspondences between the user attributes and the data source attributes.

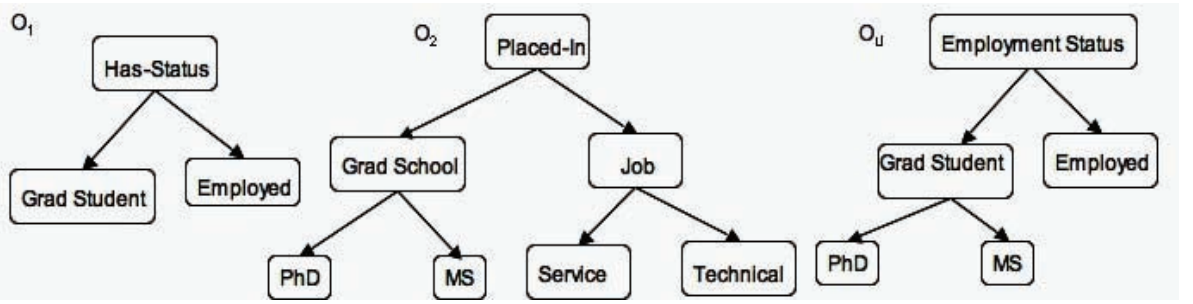
Ontology-Extended Data Sources and User Views

In our framework each data source has associated with it a data source description (i.e., the schema and ontology of the data source). We call the resulting data sources, *ontology extended data sources* (OEDS). An OEDS is a tuple $\mathscr{D}=\{D,S,O\}$, where D is the actual data set in the data source, S the data source schema and O the data source ontology (Caragea et al., 2005). The formal semantics of OEDS are based on ontology-extended relational algebra (Bonatti et al., 2003).

A *data set D* is an instantiation $\mathscr{I}(S)$ of a schema. The *ontology O* of an OEDS $\mathscr{D}$ consists of two parts: *structure ontology*, O_S, that defines the semantics of the data source schema (entities and attributes of entities that appear in data source schema *S*); and *content ontology*, O_I, that defines the semantics of the data instances (values and relationships between values that the attributes can take in instantiations of schema *S*). Of particular interest are ontologies that take the form of *is-a* hierarchies and *has-part* hierarchies. For example, the values of the *Status* attribute in data source D_2 are organized into an *is-a* hierarchy.

Because it is unrealistic to assume the existence of a single global ontology that corresponds to a universally agreed upon set of ontological commitments for all users, our framework allows each user or a community of users to select the ontological commitments that they deem useful in a specific context. A *user's view of data sources* $\mathscr{D}_1,\mathscr{D}_2 \ldots \mathscr{D}_n$ *is specified* by user schema S_U, user ontology O_U, together with a set of semantic *correspondence constraints IC*, and the associated set of *mappings* from the user schema S_U to the data source schemas $S_1,\ldots,S_n$ and from user ontology O_U to the data source ontologies $O_1,\ldots,O_n$ (Caragea et al, 2005).

Figure 2. Attribute value taxonomies (ontologies) O1 and O2 associated with the attributes Has-Status and Placed-In in two data sources of interest. OU is the ontology for Employment Status from the user's perspective



We consider the following types of semantic correspondence constraints: $x \leq y$ (x is semantically subsumed by y), $x \geq y$ (x semantically subsumes y), $x = y$ (x is semantically equivalent to y), $x \neq y$ (x is semantically incompatible with y), $x \approx y$ (x is semantically compatible with y).

Figure 2 shows examples of ontologies that take the form of is-a hierarchies over attribute values. Figure 3 shows some simple examples of user-specified semantic correspondence constraints between the user perspective and the data sources $\mathscr{D}_1$ and $\mathscr{D}_2$ (respectively).

Let $O_1,\ldots,O_n$ be a set of ontologies associated with the data sources $D_1,\ldots,D_n$, respectively, and $P_U=(O_U,IC)$ a user perspective with respect to these ontologies. We say that the ontologies $O_1,\ldots,O_n$, are *integrable* according to the user ontology O_U in the presence of semantic correspondence constraints *IC* if there exist *n* partial injective mappings $\Psi(O_U, O_1),\ldots,\Psi(O_U, O_n)$ from $O_1,\ldots,O_n$, respectively, to O_U.

Related Work

Hull (1997), Davidson et al. (2001), Eckman (2003), Doan & Halevy (2005) survey alternative approaches to data integration, including multi-database systems, mediator based approaches, etc. These efforts addressed, and to varying degrees, solved the following problems in data integration: design of query languages and rules for decomposing queries into sub queries and composing the answers to sub queries into answers to the initial query through schema integration.

However, neither of the existing data integration systems currently support learning from semantically heterogeneous distributed data without first assembling a single data set. While it is possible to retrieve the *data* necessary for learning from a set of heterogeneous data sources, store the retrieved data in a local database, and then apply standard (centralized) learning algorithms, such approach is not feasible when the amounts of data involved are large, and bandwidth and memory are limited, or when the query capabilities of the data sources are limited to providing statistical summaries (e.g., counts of instances that satisfy certain constraints on the values of their attributes) as opposed to data instances. Therefore, solutions to the problem of learning from semantically heterogeneous data sources are greatly needed.

MAIN FOCUS

Problem Definition

Given a data set D, a hypothesis class H, and a performance criterion P, an algorithm L for learning (from centralized data D) outputs a hypothesis $h \in H$ that optimizes P. In pattern classification applications, h is a classifier (e.g., a decision tree, a support vector machine, etc.). The data D typically consists of a set of training examples. Each training example is an ordered tuple of attribute values, where one of the attributes corresponds to a class label and the remaining attributes represent inputs to the classifier. The goal of learning is to produce a hypothesis that optimizes the performance criterion (e.g., minimizing classification error on the training data) and the complexity of the hypothesis.

In the case of semantically heterogeneous data sources, we assume the existence of:

1. A collection of several related OEDSs $\mathscr{D}_1 = \{ D_1,S_1,O_1\}$,$\mathscr{D}_2 = \{ D_2,S_2,O_2\},\ldots,\mathscr{D}_n = \{D_n,S_n,O_n\}$ for which schemas and ontologies are made explicit, and instances in the data sources are labeled according to some criterion of interest to a user (e.g., employment status).
2. A user view, consisting of a user ontology O_U and a set of mappings $\{\Psi_k\}$ that relate the user ontology O_U to the data source ontologies $O_1,\ldots,O_p$. The user view implicitly specifies a user level of abstraction, corresponding to the leaf nodes of the hierarchies in O_U. The mappings $\{\Psi_k\}$ can be specified manually by a user or semi-automatically derived.
3. A hypothesis class H (e.g., Bayesian classifiers) defined over an *instance space* (implicitly specified by concepts, their properties, and the associated ontologies in the domain of interest) and a performance criterion P (e.g., accuracy on a classification task).

The problem of learning classifiers from a collection of related OEDSs can be simply formulated as follows: under the assumptions (1)-(3), the task of a learner L is to output a hypothesis $h \in H$ that optimizes a criterion P, via the mappings $\{\Psi_k\}$.

As in (Caragea et al., 2005), we say that an algorithm L_S for learning from OEDSs $\mathscr{D}_1,\mathscr{D}_{2\ldots}\mathscr{D}_n$, via the mappings $\{\Psi_k\}$ is *exact* relative to its centralized counterpart L_C, if the hypothesis produced by L_S (federated approach) is identical to that obtained by L_C from the data warehouse D constructed by integrating the data sources $\mathscr{D}_1,\mathscr{D}_{2\ldots}\mathscr{D}_n$, according to the user view, via the same mappings $\{\Psi_k\}$ (data warehouse approach).

The *exactness* criterion defined previously assumes that it is possible, in principle, to create an integrated data warehouse in the centralized setting. However, in practice, the data sources $\mathscr{D}_1,\mathscr{D}_{2\ldots}\mathscr{D}_n$ might impose access constraints Z on a user U. For example, data source constraints might prohibit retrieval of raw data from some data sources (e.g., due to query form access limitations, memory or bandwidth limitations, privacy concerns) while allowing retrieval of answers to statistical queries (e.g., count frequency queries).

Partially Specified Data

Consider the data source ontologies O_1 and O_2 and the user ontology O_U shown in Figure 2. The attribute *Has-Status* in data source D_2 is specified in greater detail (lower level of abstraction) than the corresponding attribute *Placed-In* is in D_1. That is, data source D_2 carries information about the precise status of students after they graduate (specific advanced degree program e.g., *Ph.D.*, *M.S.* that the student has been accepted into, or the type of employment that the student has accepted) whereas data source D_1 makes no distinctions between the types of graduate degrees or types of employment. We say that the *Status* of students in data source D_1 are only *partially specified* (Zhang et al., 2005) with respect to the ontology O_U. In such cases, answering statistical queries from semantically heterogeneous data sources requires the user to supply not only the mapping between the user ontology and the ontologies associated with the data sources but also *additional assumptions of a statistical nature* (e.g., that grad program admits in D_1 and D_2 can be modeled by the same underlying distribution). The validity of the answer returned depends on the validity of the assumptions and the soundness of the procedure that computes the answer based on the supplied assumptions.

Sufficient Statistics Based Solution

Our approach to the problem of learning classifiers from OEDSs is a natural extension of a general strategy for

transforming algorithms for learning classifiers from data in the form of a single flat table (as is customary in the case of a vast majority of standard machine learning algorithms) into algorithms for learning classifiers from a collection of *horizontal* or *vertical* fragments of the data, corresponding to partitions of rows or columns of the flat table, wherein each fragment corresponds to an ontology extended data source.

This strategy, inspired by (Kearns, 1998) involves a decomposition of a learning task into two parts: a *statistics gathering* component, which retrieves the statistics needed by the learner from the distributed data sources, and a *hypothesis refinement* component, which uses the statistics to refine a partially constructed hypothesis (starting with an empty hypothesis) (Caragea et al., 2005).

In the case of learning classifiers from semantically disparate OEDSs, the statistics gathering component has to specify the statistics needed for learning as a *query* against the user view and assemble the answer to this query from OEDSs. This entails: decomposition of a posed query into sub-queries that the individual data sources can answer; translation of the sub-queries to the data source ontologies, via user-specific mappings; query answering from (possibly) partially specified data sources; composition of the partial answers into a final answer to the initial query (Figure 4).

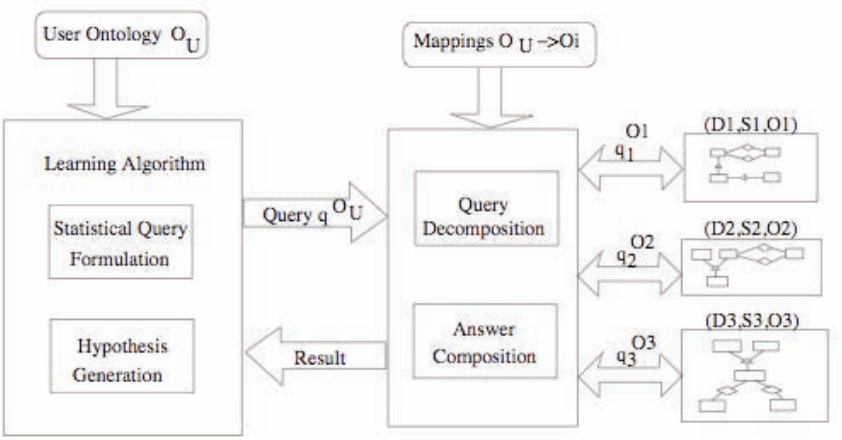
The resulting algorithms for learning from OEDSs are *provably exact* relative to their centralized counterparts, for a family of learning classifiers for which the sufficient statistics take the form of counts of instances satisfying certain constraints on the values of the attributes (e.g., naïve Bayes, decision trees, etc.).

The efficiency of the proposed approach (relative to the centralized setting) depends on the specifics of access constraints and query answering capabilities associated with the individual OEDSs. At present, many data sources on the Web offer query interfaces that can only be used to retrieve small subsets of the data that match a limited set of conditions that can be selected by the user. In order for Web data sources to serve the needs of communities of users interested in building predictive models from the data (e.g., in e-science and other emerging data-rich applications), it would be extremely useful to equip the data sources with statistical query answering capabilities.

FUTURE TRENDS

Some interesting directions for future research include: exploring the effect of using different ontologies and mappings, use of the proposed framework to evaluate mappings, study of the quality of the classifier with respect to the set of mappings used, etc.

Figure 4. Learning classifiers from OEDSs



CONCLUSION

In this chapter, we have precisely formulated the problem of learning classifiers from a collection of several related OEDSs, which make *explicit* (the typically implicit) ontologies associated with the data sources of interest. We have shown how to exploit data sources annotated with relevant meta data in building predictive models (e.g., classifiers) from several related OEDSs, without the need for a centralized data warehouse, while offering strong guarantees of *exactness* of the learned classifiers wrt the centralized traditional relational learning counterparts. User-specific mappings between the user ontology and data source ontologies are used to answer statistical queries that provide the sufficient statistics needed for learning classifiers from OEDSs.

KEY TERMS

Classification Task: A task for which the learner is given experience in the form of labeled examples and it is supposed to learn to classify new unlabeled examples. In a classification task, the output of the learning algorithm is called hypothesis or classifier (e.g., a decision tree, a support vector machine, etc.)

Learning from Semantically Heterogeneous Data Sources: Given a set of related OEDS, a user view (schema, ontology and mappings), a hypothesis class and a performance criterion, the task of the learner is to output a hypothesis that optimizes the performance criterion, via the user mappings. We say that an algorithm for learning from OEDS via a set of mappings is *exact* relative to its centralized counterpart, if the hypothesis it produces is identical to that produced by the centralized learning from the data warehouse constructed by integrating the OEDS, via the same set of mappings.

Learning Task Decomposition: A learning algorithm can be decomposed in two components: (a) an *statistics gathering* component that formulates and sends a statistical query to a data source; and (b) a *hypothesis refinement* component that uses the resulting statistic to modify a partially constructed algorithm output (and further invokes the information extraction component if needed to generate the final algorithm output). In the case of the OESD, the statistics gathering component entails decomposition of a posed query into sub-queries that the individual data sources can answer; translation of the sub-queries to the data source ontologies, via user-specific mappings; query answering from (possibly) partially specified data sources; composition of the partial answers into a final answer to the initial query.

Ontology-Extended Data Sources: An OEDS consists of a data set (representing the instantiation of a schema), a data source schema and a data source ontology. The ontology has two parts, a structure ontology, which defines the semantics of the schema (entities and attributes of entities that appear in data source schema *S*) and a content ontology, which defines the semantics of the data instances (values and relationships between values that the attributes can take in instantiations of the schema).

Sufficient Statistics: A statistic is called a sufficient statistic for a parameter if the statistic captures all the information about the parameter, contained in the data. More generally, a statistic is called a sufficient statistic for learning a hypothesis using a particular learning algorithm applied to a given data set, if there exists an algorithm that takes as input the statistic and outputs the desired hypothesis. A query that returns a statistic is called a statistical query.

User View: A user view of a set of OEDS is specified by a user schema, a user ontology and a set of mapping from the user schema to the data sources schemas, and from the user ontology to the data source ontologies. A data attribute is partially specified wrt a user view, if the the attribute is specified at a higher level of abstraction than the assumed level of abstraction in the user ontology.

Knowledge Discovery in Databases with Diversity of Data Types

INTRODUCTION

Data mining and knowledge discovery aim at finding useful information from typically massive collections of data, and then extracting useful knowledge from the information. To date a large number of approaches have been proposed to find useful information and discover useful knowledge; for example, decision trees, Bayesian belief networks, evidence theory, rough set theory, fuzzy set theory, kNN (k-nearest-neighborhood) classifier, neural networks, and support vector machines. However, these approaches are based on a specific data type. In the real world, an intelligent system often encounters mixed data types, incomplete information (missing values), and imprecise information (fuzzy conditions). In the UCI (University of California – Irvine) Machine Learning Repository, it can be seen that there are many real world data sets with missing values and mixed data types. It is a challenge to enable machine learning or data mining approaches to deal with mixed data types (Ching, 1995; Coppock, 2003) because there are difficulties in finding a measure of similarity between objects with mixed data type attributes. The problem with mixed data types is a long-standing issue faced in data mining. The emerging techniques targeted at this issue can be classified into three classes as follows: (1) Symbolic data mining approaches plus different discretizers (e.g., Dougherty et al., 1995; Wu, 1996; Kurgan et al., 2004; Diday, 2004; Darmont et al., 2006; Wu et al., 2007) for transformation from continuous data to symbolic data; (2) Numerical data mining approaches plus transformation from symbolic data to numerical data (e.g.,, Kasabov, 2003; Darmont et al., 2006; Hadzic et al., 2007); (3) Hybrid of symbolic data mining approaches and numerical data mining approaches (e.g.,, Tung, 2002; Kasabov, 2003; Leng et al., 2005; Wu et al., 2006). Since hybrid approaches have the potential to exploit the advantages from both symbolic data mining and numerical data mining approaches, this chapter, after discassing the merits and shortcomings of current approaches, focuses on applying Self-Organizing Computing Network Model to construct a hybrid system to solve the problems of knowledge discovery from databases with a diversity of data types. Future trends for data mining on mixed type data are then discussed. Finally a conclusion is presented.

BACKGROUND

Each approach for data mining or knowledge discovery has its own merits and shortcomings. For example, EFNN (Evolving Fuzzy Neural Network based on Tokagi-Sgeno fuzzy rules) (Kasabov, 2003; Takagi and Sugeno, 1985), SOFNN (Leng et al., 2005; Kasabov, 2003; Tung, 2002), dynamic fuzzy neural networks, kNN, neural networks, and support vector machines, are good at dealing with continuous valued data. For example, the EFNN (Kasabov, 2003) was applied to deal with benchmark data sets--the gas furnace times series data and the Mackey-Glass time series data (Jang, 1993). High accuracies were reached in the predictive results. The errors were very small i.e. 0.156 for the

Gas-furnace case and 0.039 for the Mackey-Glass case. However, they cannot be directly applied to symbolic data or to a data set with missing values. Symbolic AI techniques (Quinlan, 1986, Quinlan, 1996, Wu et al., 2005) are good at dealing with symbolic data and data sets with missing values. In order to discover knowledge from a database with mixed-type data, traditional symbolic AI approaches always transform continuous valued data to symbolic data. For example, the temperature is a continuous data, but it can be transformed to symbolic data 'cool', 'warm', 'hot', etc. This is a typical transformation of one dimension of continuous data, which is called *discretization*. The transformation for two or more dimensions of continuous data such as pictures or videos can be regarded as object recognition or content extraction. However, information about distance and neighborhood in continuous valued data is ignored if the discretized values are treated as symbolic values in symbolic AI techniques.

On the other hand, symbolic data can be transformed to numerical data using some encoding scheme. This can be done by statistic, rough sets or fuzzy membership functions. For example, 'high', 'mid', and 'low' can be sorted in a sequence and can be represented by fuzzy member functions. However, it is difficult to encode symbols without an explicit sequence, e.g., symbolic values for furniture: 'bed', 'chair', 'bench', 'desk' and 'table'. If the symbols have to be sorted out in a sequence, some additional information is required. For example, they can be sorted by their size or price if the information of price or size are known. Therefore, correct data transformation plays a very important role in data mining or machine learning.

MAIN FOCUS

The Self-Organizing Computing Network Model (Wu et al., 2006) provides a means to combine the transformations and data mining/knowledge discovery approaches to extract useful knowledge from databases with a diversity of data types, and the knowledge is represented in the form of a computing network. The model is designed using a hybrid of symbolic and numerical approaches. Through an analysis of which data type is suitable to which data mining or machine learning approach, data are reclassified into two new classes -- *order dependent attribute* and *order independent attribute*. Then concepts of fuzzy space, statistical learning, neural networks and traditional AI technologies are integrated to the network model to represent knowledge and self-adapt to an instance information system for decision making.

Proper Data Type Transformation

Usually, data can be categorized in two types, i.e. numerical data and symbolic data. From a data mining or machine learning point of view, attribute values can be separated into two classes. If the values of an attribute can be sorted out in a sequence and a distance between two values is significant to data mining or machine learning, the attribute is called an *order dependent attribute*. Numerical attribute can be separated into two kinds of attributes, i.e. a continuous valued attribute and an encoding numerical attribute. A continuous valued attribute is an *order dependent attribute* because a distance between two values can be used to describe neighbors or similarities in data mining or machine learning algorithms. Some encoding numerical attributes are an *order dependent attribute* such as grade numbers 1 to 5 for student courses. Some encoding numerical data such as product identification numbers are not an *order dependent attribute*. There is a distance between two values, but the distance is not significant to data mining or machine learning algorithms. We cannot say product No.1 and product No.2 certainly have similarity or can be regarded as neighbors. If this distance is used in data mining or machine learning algorithms, the results will be degraded. If the values of an attribute cannot be sorted out in a sequence or a distance between two values is not significant to data mining or machine learning, the attribute is called an *order independent attribute*. For example, some symbolic attributes are an *order independent attribute* in which there is neither definition of a distance between two symbolic values nor definition of value sequences or neighborhoods. However, there are some symbolic data with an explicit sequence; for example, 'high', 'mid', and 'low'. These symbolic values are suitable for transfer to numerical data so that value sequence and neighborhood can be used by data mining or machine learning algorithms. Therefore, two attribute channels are designed in the input layer of the Self-Organizing Computing Network Model to lead an attribute with a given data type to a suitable data mining approach. The first channel is called an *order dependent attribute* channel. The data mining or machine learning approaches, which can take

advantages from value sequence or neighborhoods, are designed in this channel. The second channel is called an *order independent attribute* channel. The data mining or machine learning approaches, which do not need the information of value sequence and neighborhood, are designed in this channel.

Structure of Self-Organizing Computing Network

The self-organizing computing network as defined in (Wu et al., 2006) is constructed by means of three classes of computing cells: input cells, hidden cells and output cells, as shown in Figure 1.

In general, computing cells can have different computing mechanisms; for example, neuron models, mathematical functions, computer programs, or processor units. For a self-organizing computing network, input cells are defined as a set of encoders that transform different data values to the internal representation of the network. An input cell corresponds to an attribute in an instance information system (Wu et al., 2005). Therefore, the number of input cells is equal to the number of attributes in the instance information system. Each input cell is connected to hidden cells by means of connection *transfer functions* in matrix T_{IxH} instead of single weights.

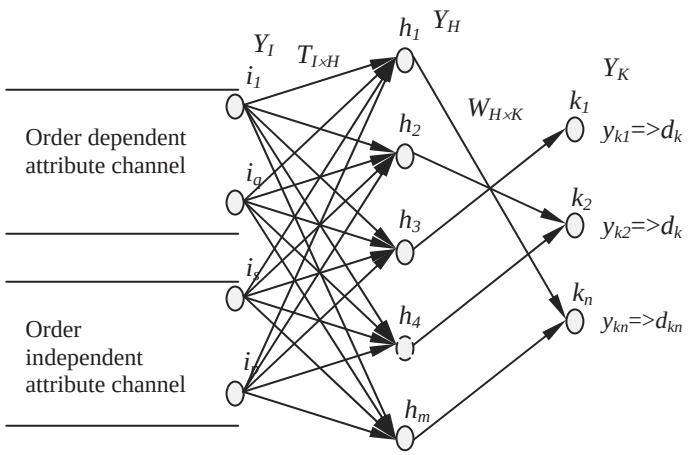
$$T_{I\times H}=\begin{Bmatrix} T^{C}_{i1,h1} & T^{C}_{i1,h2} & \cdots & T^{C}_{i1,h_m} \\ \cdots & \cdots & \cdots & \cdots \\ T^{C}_{iq,h1} & T^{C}_{iq,h2} & \cdots & T^{C}_{iq,h_m} \\ T^{S}_{is,h1} & T^{S}_{is,h1} & \cdots & T^{S}_{is,h_m} \\ \cdots & \cdots & \cdots & \cdots \\ T^{S}_{ip,h1} & T^{S}_{ip,h1} & \cdots & T^{S}_{is,h_m} \end{Bmatrix} \quad (1)$$

Where $T^{c}_{i1,h1}$ represents a transfer function for connection between continuous valued input cell i_1 and hidden cell h_1, $T^{S}_{is,h1}$ represents a transfer function for connection between symbolic input cell i_s and hidden cell h_1. Hidden computing cells are connected to output cells according to the decision values of known instances in the instance information system by a weight matrix W_{HxK}.

$$W_{H\times K}=\begin{Bmatrix} w_{h1,k1} & w_{h1,k2} & w_{h1,k_n} \\ \cdots & \cdots & \cdots \\ w_{h_m,k1} & w_{h_m,k2} & w_{h_m,k_n} \end{Bmatrix} \quad (2)$$

The number of output cells is equal to the number of decisions in the instance information system. The weights are real numbers in the range [0, 1]. A weight in the weight matrix can be regarded as a *decision support degree* for a hidden cell. For example, weight $w_{h,k}$=1 means that hidden cell *h* supports the decision

Figure 1. Architecture of a Self-Organizing Computing Network. $x_1,\ldots x_q$ represent q inputs for order dependent attribute channel. $x_s,\ldots x_p$ represent p-s+1 inputs for order independent attribute channel. $Y_I=\{y_{i1},y_{i2},\ldots y_q,y_s,\ldots y_p\}$ represents a set of outputs of first layer. $I=\{i_1,\ldots i_p\}$. $H=\{h_1,\ldots h_m\}$. $K=\{k_1,\ldots k_m\}$. $Y_H=\{y_{h1},\ldots y_{hm}\}$ represents a set of outputs of hidden layer. $Y_K=\{y_{k1},\ldots y_{kn}\}$ represents a set of outputs of output layer. T_{IxH} represents transfer function matrix. $W_{H\times K}$ represents weight matrix. $V_d=\{d_{k1},\ldots d_{kn}\}$ represents a set of decisions.



corresponding to output cell k. Weight $w_{h,k}$=0 means that hidden cell h does not support the decision corresponding to output cell k.

Internal Information Representation

Through two channels in the Self-Organizing Computing Network Model, input data can be transformed to an internal information representation, which is represented by an interval of integer numbers such as [1, 50], or [1,100] because an integer number can be regarded as not only discrete continuous data but also code of symbolic data. Mixed-type input data are transferred to internal representation by the input cells.

$$y_i = (x_i - x_{i(\min)})s_i,\ s_i = s_w / (x_{i(\max)} - x_{i(\min)}),\ \text{for } i \in I_c\ , \tag{3}$$

For order independent symbolic data, we have

$$y_i = Numerical\ Code(x_i)\ ,\ \text{for } i \in I_s \tag{4}$$

where $I_c = \{i_1, \ldots i_q\}$, $I_s = \{i_s, \ldots i_p\}$, and s_w is the encoding range. In order to encode symbolic data, s_w is set to an integer for example 50 or 100.

A cell in the hidden layer corresponds to a fuzzy rule. The connections from the hidden cell to input cells are regarded as fuzzy conditions. Each input cell in the *order dependent attribute* channel is connected to the hidden layer by a *self-adaptive sense-function* as follows:

$$T_{i,h}^{C}(y_i) = \begin{cases} e^{-\frac{(y_i - y_{L(i,h)})^2}{\delta_{i,h}^2}} & y_i < y_{L(i,h)} \\ 1 & y_{L(i,h)} \le y_i \le y_{U(i,h)} \\ e^{-\frac{(y_i - y_{U(i,h)})^2}{\delta_{i,h}^2}} & y_i > y_{U(i,h)} \end{cases} \tag{5}$$

where y_i is a value from input cell i, $y_{L(i,h)}$ is the lower fuzzy edge, $y_{U(i,h)}$ is the upper fuzzy edge, and $\delta_{i,h}$ is a fuzzy degree for both edges. Constants $y_{L(i,h),}$ $y_{U(i,h),}$ and $\delta_{i,h.}$ can be adjusted by the learning algorithm.

Each input cell in the *order independent attribute* channel is connected to the hidden layer by a *statistical learning function* (Wu et al., 2005) as follows. Suppose that one hidden cell supports only one decision $d_h \in V_d$.

$$T_{i,h}^{S}(y_i) = Sup(y_i \mid d_h) = \frac{N_{xi,yi,h} + \beta\ |U|}{N_{xi,dh} + \beta\ |U|\,|V_{xi}|_{\mathrm{f}}} \tag{6}$$

where U is the set of all instances in an instance information system, $|U|$ is the total number of instances, $N_{xi,yi,h}$ is the number of attribute values y_i that supports decision d_h, $N_{xi,dh}$ is the number of instances with decision d_h in U, V_{xi} is the domain of attribute x_i, $|V_{xi}|$ is the number of symbolic values in V_{xi}, and β is a small number with typical value 0.02. Through the transformation of the two types of connection functions, the input data is transferred to a *conditional matched-degree*. A hidden cell can integrate *conditional matched-degrees* from all the input cells, and then output an overall *matched-degree*. It is expressed as follows:

$$\begin{aligned} y_h(Y_I) &= y_h(Y_{I_c})\, y_h(Y_{I_s}) \\ &= [\prod_{i \in I_c} T_{i,h}^{C}(y_i)]^{\frac{1}{q}} [\prod_{i \in I_s} T_{i,h}^{S}(y_i)]^{\frac{1}{p-q}} \qquad \text{for } h \in H \end{aligned} \tag{7}$$

Connection weights between hidden layer and output layer can be regarded as *support degree* for a hidden cell to support a decision corresponding to an output cell. Connection weights can be trained by training sets. An output value of an output cell in output layer is defined as *belief* for a specific decision.

Self-Organizing

Corresponding to the multiple inputs, each hidden cell has a specific *fuzzy sub-superspace* determined by the *self-adaptive sense-function*s and *statistical learning function* in Equation . The parameters lower fuzzy edge $y_{L(i,h)}$ and high fuzzy edge $y_{U(i,h)}$ for the *fuzzy sub-superspace* are self-organized by adjusting sense-range so that $y_{L(i,h)} = L_{i,\,hj\ (\min)}$ and $y_{U(i,h)} = U_{i,\,hj\ (\min)}$, and the hidden cell can adapt to the decision $d \in V_d$. The algorithm for this adjusting is as follows:

$$L_{i,hj\,(\min)} = \min\{L_{i,hj} : y_{hj}(u) < \theta \ \ for\ u \notin TR_d\ ), \text{for all } i \in \{1, 2, \ldots, p\}$$

$$U_{i,hj(\max)} = \max\{U_{i,hj} : y_{hj}(u) < \theta \ \ for\ u \notin TR_d\ ), \text{for all } i \in \{1, 2, \ldots, p\}$$

where u is an instance with attributes $(x_1, \ldots x_p)$, a decision value d, TR_d is a set of training instances, and θ

is a threshold value. The weights between the hidden layer and output layer are also trained using instances in training sets. After training, each hidden cell has a specific *response sub-superspace*. In order to make sure that the algorithm converges to an optimal *response sub-superspace*, the order for attributes to adjust the sense function parameters can be determined by important degree (Wu et al., 2005). A tolerance can be used to stop the adjusting (Wu et al., 2006).

Decision Making

A Self-Organizing Computing Network can be created using a training set from an instance information system. After a specific Self-Organizing Computing Network is obtained, the network can be applied to make decisions. If a set of mixed-type values presents to the network, the network take in the data from two channels, i.e. the order dependent attribute channel and order independent attribute channel. The data are transferred to internal representation by the first layer cells, and then transferred to condition-matched degree by the sense-functions. The hidden cells integrate the condition-matched degrees. The output cells will give the belief distribution over the decision space.

$$y_{d(\max)} = \max_{h \in H}(w_{h,d}\, y_h) \text{ for } d \in \boldsymbol{V}_d \qquad (8)$$

The maximal belief can be used to make a final decision.

$$d_M = \arg\max_{d \in V_d}(y_{d(\max)}) \qquad (9)$$

This approach has been applied to data sets from the UCI Machine Learning Repository. The decision accuracies obtained by the proposed approach were better than other approaches (Wu et al., 2006).

FUTURE TRENDS

As mentioned in the background section, a single data mining approach is very unlikely to solve a mixed type data problem. Hybrid approaches, multiple classifier approaches, and biologically inspired approaches are the trends to improve the solutions of this problem. The Self-Organizing Computing Network Model is a general model. Based on the model, the connection transfer function, computing mechanism of the cells and training algorithms can be changed and it is possible to find better components for the network model. In current researches, the defined sense-function in equation is applied to the computing network model. Using this function and the proposed sense function adjusting algorithm, the fuzzy sub-superspace is expanded by grids. It is possible to apply other functions to enable the fuzzy sub-superspace to be expanded elliptically. For order independent inputs, the modified Naïve Bayes approach (Wu et al., 2005) has been integrated in the Computing Network Model. This also can be tried with decision tree and rough set approaches, etc. The computing mechanism of hidden cells is a multiplier in the proposed network. However, other computing mechanisms can replace the multiplier. These are topics for further study.

CONCLUSION

The Self-Organizing Computing Network provides a means to create a hybrid of symbolic AI techniques and computational intelligence approaches. In this approach, the input layer is designed as a set of data converters. Each hidden cell responds to a fuzzy sub-superspace within the input superspace. The fuzzy sub-superspace of a hidden cell adapts to the training set according to the self-organizing algorithms. Based on the definitions for the computing cell and its connections, each output value can be explained using symbolic AI concepts such as belief, support degree, match degree, or probability. Using this network, instance information systems with mixed data types can be handled directly. Note that preparation of input data is included in the self-organizing algorithm. Therefore, this approach has neither directly given results for data reduction and aggregation, nor for structural and semantic heterogeneity. It may be possible to extend the cells in the hidden layer to retrieve these. This is a topic for further study.

KEY TERMS

Condition Match Degree: A value in [0,1] represents how much a given set of condition attribute values match the Response Sub-Superspace.

Fuzzy Sub-Superspace: A sub space in a multiple dimension input space is determined by a set of sense-functions.

Order Dependent Attribute: Values of an attribute can be sorted out in a sequence and a distance between two values is significant to data mining or machine learning.

Order Independent Attribute: There are no sequence definition and distance definition for values of an attribute.

Response Sub-Superspace: A fuzzy sub-superspace is determined by a training set.

Self-Organizing Computing Network Model: A network is defined by flexible computing cells and connection functions for hybrid of different data mining or machine learning approaches.

Sense-Function: A fuzzy member function is defined to connect cells between the first layer cells and hidden layer cells in the Self-Organizing Computing Network.

Support Degree: As each hidden cell represents a fuzzy rule in a Self-Organizing Computing Network, the output of a hidden cell is a condition match-degree. The product of this condition match-degree and the connection weight is regarded as a Support Degree for the hidden cell to corresponding output cell.

Learning Bayesian Networks

INTRODUCTION

Born at the intersection of artificial intelligence, statistics, and probability, Bayesian networks (Pearl, 1988) are a representation formalism at the cutting edge of knowledge discovery and data mining (Heckerman, 1997). Bayesian networks belong to a more general class of models called *probabilistic graphical models* (Whittaker, 1990; Lauritzen, 1996) that arise from the combination of graph theory and probability theory, and their success rests on their ability to handle complex probabilistic models by decomposing them into smaller, amenable components. A probabilistic graphical model is defined by a graph, where nodes represent stochastic variables and arcs represent dependencies among such variables. These arcs are annotated by probability distribution shaping the interaction between the linked variables. A probabilistic graphical model is called a Bayesian network, when the graph connecting its variables is a directed acyclic graph (DAG). This graph represents conditional independence assumptions that are used to factorize the joint probability distribution of the network variables, thus making the process of learning from a large database amenable to computations. A Bayesian network induced from data can be used to investigate distant relationships between variables, as well as making prediction and explanation, by computing the conditional probability distribution of one variable, given the values of some others.

BACKGROUND

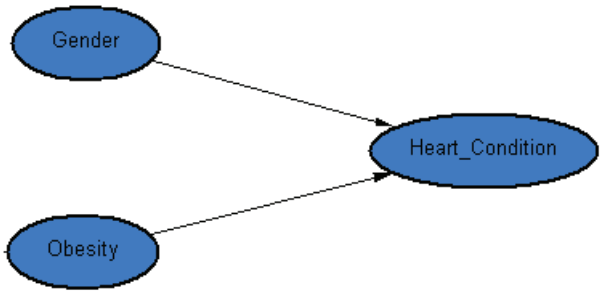
The origins of Bayesian networks can be traced back as far as the early decades of the 20th century, when Sewell Wright developed path analysis to aid the study of genetic inheritance (Wright, 1923, 1934). In their current form, Bayesian networks were introduced in the early 1980s as a knowledge representation formalism to encode and use the information acquired from human experts in automated reasoning systems in order to perform diagnostic, predictive, and explanatory tasks (Charniak, 1991; Pearl, 1986, 1988). Their intuitive graphical nature and their principled probabilistic foundations were very attractive features to acquire and represent information burdened by uncertainty. The development of amenable algorithms to propagate probabilistic information through the graph (Lauritzen, 1988; Pearl, 1988) put Bayesian networks at the forefront of artificial intelligence research. Around the same time, the machine-learning community came to the realization that the sound probabilistic nature of Bayesian networks provided straightforward ways to learn them from data. As Bayesian networks encode assumptions of conditional independence, the first machine-learning approaches to Bayesian networks consisted of searching for conditional independence structures in the data and encoding them as a Bayesian network (Glymour, 1987; Pearl, 1988). Shortly thereafter, Cooper and Herskovitz (1992) introduced a Bayesian method that was further refined by Heckerman, et al. (1995) to learn Bayesian networks from data.

These results spurred the interest of the data-mining and knowledge-discovery community in the unique features of Bayesian networks (Heckerman, 1997); that is, a highly symbolic formalism, originally developed to be used and understood by humans, well-grounded on the sound foundations of statistics and probability theory, able to capture complex interaction mechanisms and to perform prediction and classification.

MAIN THRUST

A Bayesian network is a graph, where nodes represent stochastic variables and (arrowhead) arcs represent

Figure 1.



dependencies among these variables. In the simplest case, variables are discrete, and each variable can take a finite set of values.

Representation

Suppose we want to represent the variable *gender*. The variable gender may take two possible values: male and female. The assignment of a value to a variable is called the *state of the variable*. So, the variable gender has two states: Gender = Male and Gender = Female. The graphical structure of a Bayesian network looks like this:

The network represents the notion that obesity and gender affect the heart condition of a patient. The variable obesity can take three values: yes, borderline and no. The variable heart condition has two states: true and false. In this representation, the node heart condition is said to be a *child* of the nodes gender and obesity, which, in turn, are the *parents* of heart condition.

The variables used in a Bayesian networks are stochastic, meaning that the assignment of a value to a variable is represented by a probability distribution. For instance, if we do not know for sure the gender of a patient, we may want to encode the information so that we have better chances of having a female patient rather than a male one. This guess, for instance, could be based on statistical considerations of a particular population, but this may not be our unique source of information. So, for the sake of this example, let's say that there is an 80% chance of being female and a 20% chance of being male. Similarly, we can encode that the incidence of obesity is 10%, and 20% are borderline cases. The following set of distributions tries to encode the fact that obesity increases the cardiac risk of a patient, but this effect is more significant in men than women:

The dependency is modeled by a set of probability distributions, one for each combination of states of the variables gender and obesity, called the parent variables of heart condition.

Figure 2.

Heart_Condition

Obesity	Gender	True	False
Yes	Male	0.800	0.200
Yes	Female	0.700	0.300
Borderline	Male	0.750	0.250
Borderline	Female	0.600	0.400
No	Male	0.200	0.800
No	Female	0.100	0.900

Learning

Learning a Bayesian network from data consists of the induction of its two different components: (1) the graphical structure of conditional dependencies (model selection) and (2) the conditional distributions quantifying the dependency structure (parameter estimation).

There are two main approaches to learning Bayesian networks from data. The first approach, known as constraint-based approach, is based on conditional independence tests. As the network encodes assumptions of conditional independence, along this approach we need to identify conditional independence constraints in the data by testing and then encoding them into a Bayesian network (Glymour, 1987; Pearl, 1988; Whittaker, 1990).

The second approach is Bayesian (Cooper & Herskovitz, 1992; Heckerman et al., 1995) and regards model selection as an hypothesis testing problem. In this approach, we suppose to have a set M= $\{M_0, M_1, ..., M_g\}$ of Bayesian networks for the random variables $Y_1, ..., Y_v$,, and each Bayesian network represents an hypothesis on the dependency structure relating these variables. Then, we choose one Bayesian network after observing a sample of data D = $\{y_{1k}, ..., y_{vk}\}$, for $k = 1, \ldots, n$. If $p(M_h)$ is the prior probability of model M_h, a Bayesian solution to the model selection problem consists of choosing the network with maximum posterior probability:

$p(M_h|D) \propto p(M_h)p(D|M_h)$.

The quantity $p(M_h|D)$ is the marginal likelihood, and its computation requires the specification of a parameterization of each model M_h and the elicitation of a prior distribution for model parameters. When all variables are discrete or all variables are continuous, follow Gaussian distributions, and the dependencies are linear and the marginal likelihood factorizes into the product of marginal likelihoods of each node and its parents. An important property of this likelihood modularity is that in the comparison of models that differ only for the parent structure of a variable Y_i, only the local marginal likelihood matters. Thus, the comparison of two local network structures that specify different parents for Y_i can be done simply by evaluating the product of the local Bayes factor $BF_{h,k} = p(D|M_{hi}) / p(D|M_{ki})$, and the ratio $p(M_{hi})/ p(M_{ki})$, to compute the posterior odds of one model vs. the other as $p(M_{hi}|D) / p(M_{ki}|D)$.

In this way, we can learn a model locally by maximizing the marginal likelihood node by node. Still, the space of the possible sets of parents for each variable grows exponentially with the number of parents involved, but successful heuristic search procedures (both deterministic and stochastic) exist to render the task more amenable (Cooper & Herskovitz, 1992; Singh & Larranaga, 1996; Valtorta, 1995).

Once the structure has been learned from a dataset, we still need to estimate the conditional probability distributions associated to each dependency in order to turn the graphical model into a Bayesian network. This process, called *parameter estimation*, takes a graphical structure and estimates the conditional probability distributions of each parent-child combination. When all the parent variables are discrete, we need to compute the conditional probability distribution of the child variable, given each combination of states of its parent variables. These conditional distributions can be estimated either as relative frequencies of cases or, in a Bayesian fashion, by using these relative frequencies to update some, possibly uniform, prior distribution. A more detailed description of these estimation procedures for both discrete and continuous cases is available in Ramoni and Sebastiani (2003).

Prediction and Classification

Once a Bayesian network has been defined, either by hand or by an automated discovery process from data, it can be used to reason about new problems for prediction, diagnosis, and classification. Bayes' theorem is at the heart of the propagation process.

One of the most useful properties of a Bayesian network is the ability to propagate evidence irrespective of the position of a node in the network, contrary to standard classification methods. In a typical classification system, for instance, the variable to predict (i.e., the class) must be chosen in advance before learning the classifier. Information about single individuals then will be entered, and the classifier will predict the class (and only the class) of these individuals. In a Bayesian network, on the other hand, the information about a single individual will be propagated in any direction in the network so that the variable(s) to predict must not be chosen in advance.

Although the problem of propagating probabilistic information in Bayesian networks is known to be, in the general case, NP-complete (Cooper, 1990), several scalable algorithms exist to perform this task in networks with hundreds of nodes (Castillo, et al., 1996; Cowell et al., 1999; Pearl, 1988). Some of these propagation algorithms have been extended, with some restriction or approximations, to networks containing continuous variables (Cowell et al., 1999).

FUTURE TRENDS

The technical challenges of current research in Bayesian networks are focused mostly on overcoming their current limitations. Established methods to learn Bayesian networks from data work under the assumption that each variable is either discrete or normally distributed around a mean that linearly depends on its parent variables. The latter networks are termed *linear Gaussian* networks, which still enjoy the decomposability properties of the marginal likelihood. Imposing the assumption that continuous variables follow linear Gaussian distributions and that discrete variables only can be parent nodes in the network but cannot be children of any continuous node, leads to a closed-form solution for the computation of the marginal likelihood (Lauritzen, 1992). The second technical challenge is

the identification of sound methods to handle incomplete information, either in the form of missing data (Sebastiani & Ramoni, 2001) or completely unobserved variables (Binder et al., 1997). A third important area of development is the extension of Bayesian networks to represent dynamic processes (Ghahramani, 1998) and to decode control mechanisms.

The most fundamental challenge of Bayesian networks today, however, is the full deployment of their potential in groundbreaking applications and their establishment as a routine analytical technique in science and engineering. Bayesian networks are becoming increasingly popular in various fields of genomic and computational biology—from gene expression analysis (Friedman, 2004) to proteimics (Jansen et al., 2003) and genetic analysis (Lauritzen & Sheehan, 2004)—but they are still far from being a received approach in these areas. Still, these areas of application hold the promise of turning Bayesian networks into a common tool of statistical data analysis.

CONCLUSION

Bayesian networks are a representation formalism born at the intersection of statistics and artificial intelligence. Thanks to their solid statistical foundations, they have been turned successfully into a powerful data-mining and knowledge-discovery tool that is able to uncover complex models of interactions from large databases. Their high symbolic nature makes them easily understandable to human operators. Contrary to standard classification methods, Bayesian networks do not require the preliminary identification of an outcome variable of interest, but they are able to draw probabilistic inferences on any variable in the database. Notwithstanding these attractive properties and the continuous interest of the data-mining and knowledge-discovery community, Bayesian networks still are not playing a routine role in the practice of science and engineering.

KEY TERMS

Bayes Factor: Ratio between the probability of the observed data under one hypothesis divided by its probability under an alternative hypothesis.

Conditional Independence: Let X, Y, and Z be three sets of random variables; then X and Y are said to be conditionally independent given Z, if and only if $p(x|z,y)=p(x|z)$ for all possible values x, y, and z of X, Y, and Z.

Directed Acyclic Graph (DAG): A graph with directed arcs containing no cycles; in this type of graph, for any node, there is no directed path returning to it.

Probabilistic Graphical Model: A graph with nodes representing stochastic variables annotated by probability distributions and representing assumptions of conditional independence among its variables.

Statistical Independence: Let X and Y be two disjoint sets of random variables; then X is said to be independent of Y, if and only if $p(x)=p(x|y)$ for all possible values x and y of X and Y.

Learning Exceptions to Refine a Domain Expertise

Rallou Thomopoulos
INRA/LIRMM, France

INTRODUCTION

This chapter deals with the problem of the cooperation of heterogeneous knowledge for the construction of a domain expertise, and more specifically for the discovery of new unexpected knowledge. Two kinds of knowledge are taken into account:

- Expert statements. They constitute generic knowledge which rises from the experience of domain experts and describes commonly admitted mechanisms that govern the domain. This knowledge is represented as conceptual graph rules, which has the advantage to combine a logic-based formalism and an equivalent graphical representation, essential for non-specialist users (Bos, 1997).
- Experimental data, given by international literature of the domain. They are represented in the relational model. These numerous data describe in detail, in a quantitative way, experiments that were carried out to deepen the knowledge of the domain, and the obtained results. These results may confirm the knowledge provided by the expert statements – or not.

The cooperation of both kinds of knowledge aims, firstly, at testing the validity of the expert statements within the experimental data, secondly, at discovering refinements of the expert statements to consolidate the domain expertise.

Two major differences between the two formalisms are the following. Firstly, the conceptual graphs represent knowledge at a more generic level than the relational data. Secondly, the conceptual graph model includes an ontological part (hierarchized vocabulary that constitutes the support of the model), contrary to the relational model.

We introduce a process that allows one to test the validity of expert statements within the experimental data, that is, to achieve the querying of a relational database by a system expressed in the conceptual graph formalism. This process is based on the use of annotated conceptual graph patterns. When an expert statement appears not to be valid, a second-step objective is to refine it. This refinement consists of an automatic *exception rule learning* which provides unexpected knowledge in regard of previously established knowledge.

The examples given in this chapter have been designed using the CoGui tool (http://www.lirmm.fr/cogui/) and concern a concrete application in the domain of food quality.

BACKGROUND

Related Work

Handling exceptions is quite an old feature of artificial intelligence (Goodenough, 1975) that has been approached in various directions. In this project, we are concerned with the more specific theme of exception rules. Hussain (2000) explains very well the interest of exceptions as contradictions of common belief. Approaches for finding "interesting" rules are usually classified in two categories (Silberschatz, 1996): objective finding (as in Hussain, 2000), which relies on frequency based criteria and consists of identifying deviations among rules learnt from data, and subjective finding, which relies on belief based criteria and consists of identifying deviations to rules given by the user. Finding "unexpected" rules is part of the second category and can itself be subdivided in syntax based (Liu, 1997; Li, 2007 for a very recent work on sequence mining) and logic based (Padmanabhan, 1998; Padmanabhan, 2006) approaches.

Our approach is related to the latter, and more specifically to first-order rule learning techniques (Mitchell, 1997). However in the above approaches, rule learning is purely data driven and user knowledge is used as a filter, either in post-analysis (Liu, 1997; Sahar, 1999)

or in earlier stages (Padmanabhan, 1998, Wang, 2003), whereas we propose to find exception rules by trying variations – refinements – of the forms of the rules given by the experts, using an ontology that has been conceived with this specific purpose. Data are only used for rule verification. This reversed approach is relevant in domains characterized by a relatively high confidence in human expertise, and guarantees the learnt exceptions to be understandable and usable. This advantage is enforced by the graphical representation of the rules, expressed in the conceptual graph model.

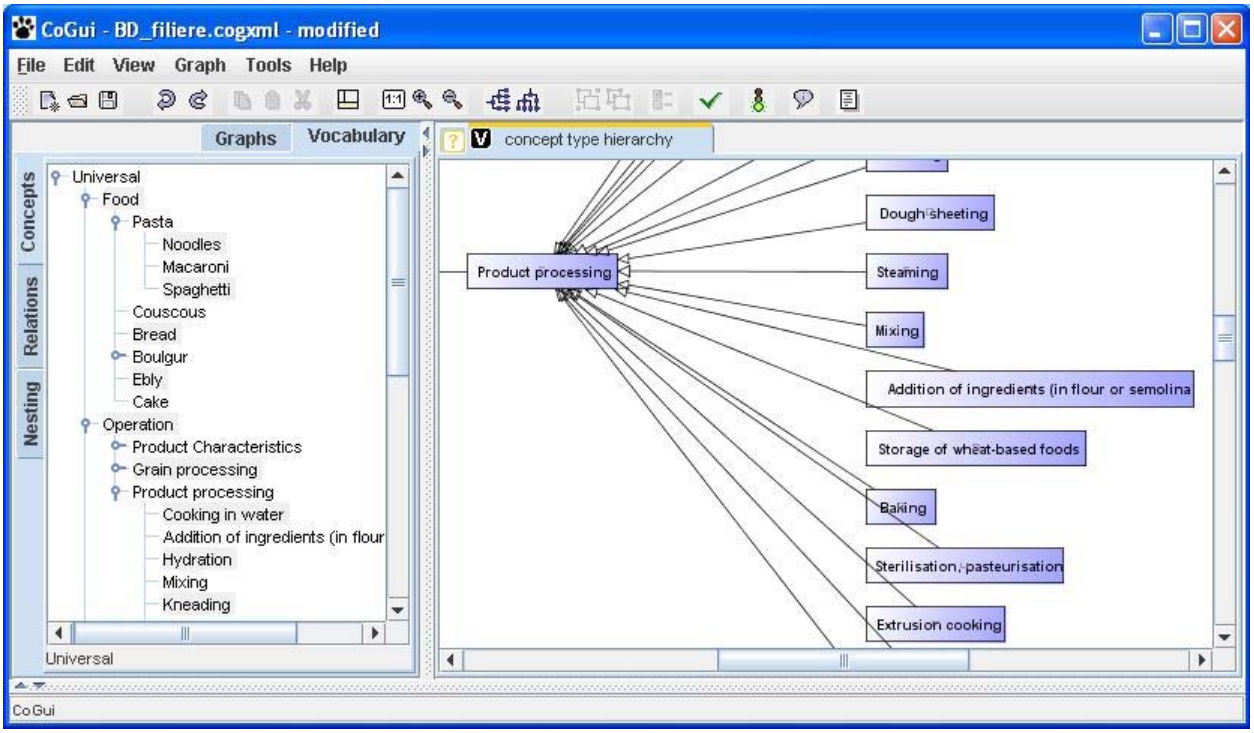
Conceptual Graph Model

The Conceptual Graph model (or CG) (Sowa, 1984), is a knowledge representation formalism based on labelled graphs. We use the formalization presented in (Mugnier, 2000). We will briefly present the support (terminological knowledge), the conceptual graphs (assertional knowledge), the specialization relation, and the rules.

The support provides the ground vocabulary used to build the knowledge base: types of concepts, instances of these types, and types of relations linking the concepts. The set of concept types is partially ordered by the "kind of" relation. Figure 1 presents a part of the set of concept types used in the application. An example of relation type is "undergoes" which is a binary relation allowing one to link a Food with an Operation (which are both concept types). The set of individual markers contains the instances of the concepts. For example, "months" can be an instance of Duration unit. The generic marker (denoted *) is a particular marker referring to an unspecified instance of a concept.

The conceptual graphs, built upon the support are composed of two kinds of vertices: (i) concept vertices (denoted in rectangles) which represent the entities, attributes, states, events; (ii) relation vertices (denoted in ovals) which express the nature of the relationship between concepts. The label of a concept vertex is a pair composed of a concept type and a marker (individual

Figure 1. A part of the set of concept types



or generic) of this type. The label of a relation vertex is its relation type.

Conceptual graph rules (Salvat, 1996) form an extension of the CG formalism, in which rules of the form "if A then B" are added to a knowledge base, where A and B are two simple conceptual graphs. The addition of rules considerably increases the expressivity of the language. Figure 3 shows a simple example of rule representing the information "If a food product undergoes cooking in water, then its vitamin content decreases".

The set of CGs is partially pre-ordered by the specialization relation (denoted ≤), which can be computed by the projection operation (a graph morphism allowing a restriction of the vertex labels): G2 ≤ G1 if and only if there is a projection of G1 into G2. The projection is a ground operation in the CG model since it allows the search for answers, which can be viewed as specializations of a query.

MAIN FOCUS

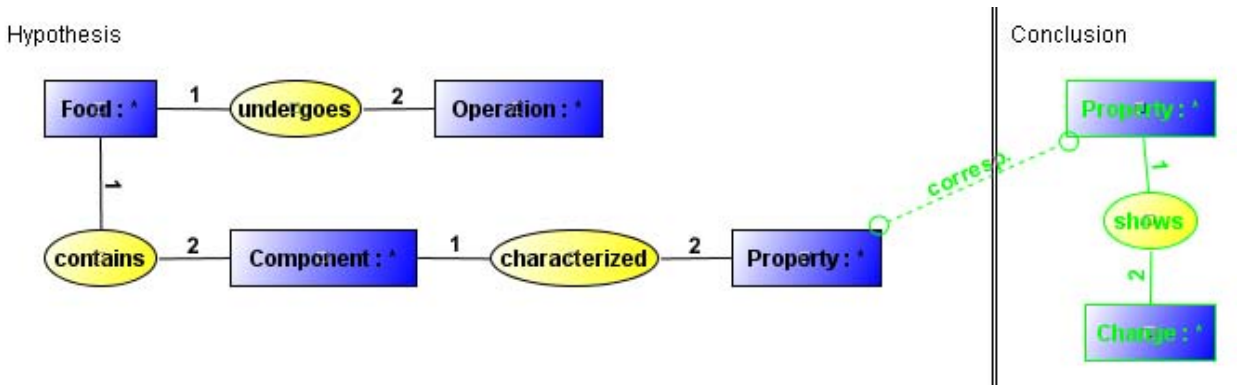
A preliminary step, presented in (Thomopoulos, 2007), was to automate the generation of an ontology, constituted of the set of concept types, by using the existing relational schema and data. This is processed in two main steps: the identification of high-level concept types, and the organization of these concept types into a hierarchy. Hence there are correspondancies between the vocabularies of both formalisms, which is assumed in the following.

Searching for Exceptions to Expert Rules within Experimental Data

The objective is to test whether the expert knowledge expressed as conceptual graph rules is valid within the experimental data of the relational database. This must be achieved without having to define manually, for each rule, the queries to be executed in the database to obtain this information. A confidence rate is computed for the tested rule and the data that constitute exceptions to the rule are identified and can be visualized by the user.

1. *Confidence* - Evaluating the validity of an expert rule within the data consists of calculating the proportion of data which satisfy both the hypothesis and the conclusion of the rule, among the data which satisfy the hypothesis of the rule. Let n_H be the number of data that satisfy the hypothesis and $n_{H\wedge C}$ the number of data that satisfy both the hypothesis and the conclusion. The confidence is $\tau = (n_{H\wedge C}) / n_H \times 100$, where n_H and $n_{H\wedge C}$ are the results of SQL queries counting the data. The problem to solve is the automation of the construction of these queries.
2. *Rule Patterns, Rule Instances and Associated Properties* - Although the expert rules can take various forms, they can be grouped into sets of

Figure 2. Example of rule pattern representing the information "If a food product, that contains a component characterized by a property, undergoes an operation, then this property changes"



rules which follow the same general form. The "general form" can itself be represented by a rule, called rule pattern. Its structure is identical to that of the expert rules that compose the set (called rule instances), but its concept vertices are more general. In other words, each instance rule has a hypothesis and a conclusion which are specializations of those of the rule pattern. For example, the rule instance of Figure 3 conforms to the rule pattern of Figure 2. Patterns help to constrain the search, and are a language bias.

The concept types that appear in a rule pattern provide a list of table names of the database. The hypothesis (respectively, the conclusion) of a rule pattern can be interpreted, within the database, as the formula of a query that selects the data satisfying the hypothesis (respectively, the conclusion). This formula simply specifies a query schema. It does not specify any particular selection criteria.

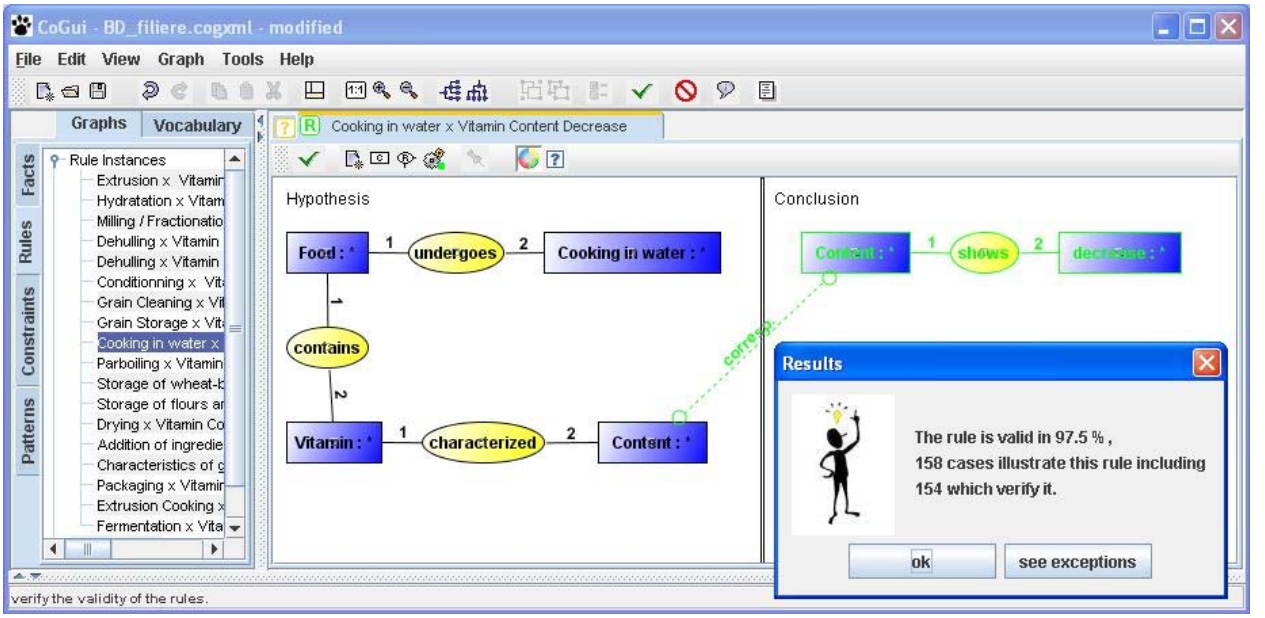
To allow the computation of the confidence and the link with the database, each rule pattern P is annotated with:

- a hypothesis query, that counts the tuples of the database satisfying the hypothesis of P;
- a hypothesis and conclusion query, that counts the tuples of the database satisfying both the hypothesis and the conclusion of P;
- for each of its concepts, the attribute of the database that contains the specializations of this concept expected in the rule instances conforming to P.

3. *Validation of a Rule Instance* - To test the validity of an expert rule, i.e. of a rule instance, two new queries are automatically built: a query that counts the data satisfying the hypothesis of the rule instance and a query that counts the data satisfying both the hypothesis and the conclusion.

These queries are composed of two parts: (i) the first part describes the schema of the query to be executed: this part corresponds to the query associated with the rule pattern, it is thus provided by the annotations of the rule pattern; (ii) the second part allows one to select exclusively the tuples which take the attribute values corresponding to the specializations that appear in the

Figure 3. Evaluation of the validity of an expert rule



rule instance. This part thus specifies selection criteria, which are automatically built by using, as selection attributes, the annotations of the rule pattern (database attributes) and as selection values, the labels of concepts in the rule instance to be evaluated.

The results of the queries are respectively n_H and $n_{H\wedge C}$, which allows the computation of the rule confidence. The rules whose confidence is strictly lower than 100% have exceptions within the database. For example the confidence τ of the rule of Figure 3 is equal to 97.5%. Confidence spread out from 73 to 100% in the application.

Unexpected Rule Mining

The aim of this part is to learn new unexpected rules corresponding to the exceptions identified in the previous stage. Three steps are proposed to achieve this objective, respectively negation, specialization and completion.

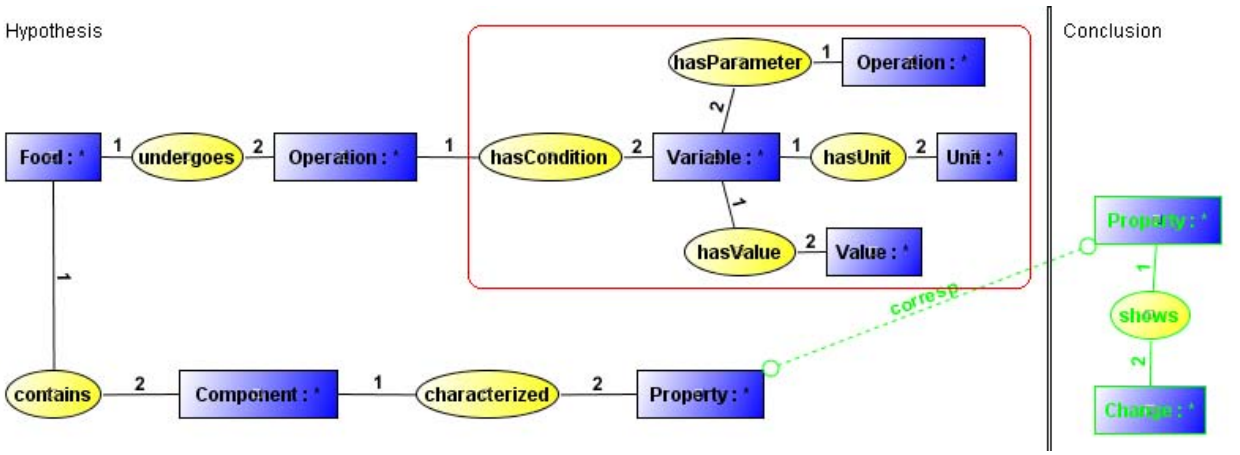
1. *Rule conclusion negation* – The exceptions to an expert rule do not satisfy the conclusion of this rule – this is the definition of such an exception. The first step of rule exception learning consists of negating the conclusion of the considered rule. The concepts to be negated are automatically identified through annotations of rule patterns. The images (through the projection operation) of rule pattern concepts that have the "negation" annotation are those to be negated in the rule instances. For instance, in the rule pattern of Figure 2, the concept of type Change has the "negation" annotation. After the negation step, the rule instance of Figure 3 is changed into: "if a food product undergoes cooking in water, then its vitamin content does **not** decrease" (it may increase or stagnate in the exceptions to the rule). The change in the rule conclusion is shown in Figure 5.
2. *Specialization* - Exceptions to generally admitted rules may be due to specific behaviors of particular sub-concepts. For instance, nutritional components are classified into heterogeneous families, whose specificities may explain the existence of exceptions. As in the previous step, the concepts to be specialized are identified through annotations of the rule patterns. The algorithmic principle of the specialization step is the following:
   - Let C be a concept, belonging to a rule R built in previous step, to be specialized (C is the image of a rule pattern concept having the "specialization" annotation).
   - Take the set (denoted S) of all the super-types more specific than the type of C in exceptions of R. In other words, we try to find a generalization of the concept types appearing in exceptions, that remains more specific than the concept type appearing in R.
   - Within these super-types, take the set of most general ones (this set is denoted E and is reduced to one element at the beginning, the type of C). For each type t of E, test if t or a sub-type of t appears in non-exceptions without appearing in exceptions. If it is the case, remove t from E and replace it by its most general sub-types in S, not comparable with types already present in E.
   - Go to next type t, until E remains stable. Create the exception rules by replacing the type of C by a type t of E, in the rule R.

   After the specialization step, the rule of Figure 3 has its "Vitamin" vertex specialized into "Liposoluble vitamin", as shown in Figure 5.
3. *Completion* - Exceptions to generally admitted rules may be due to the influence of other concepts, that are not taken into account in the rule. For instance, specific parameters of experimental conditions may explain the existence of exceptions. Predefined completion patterns (also annotated) are determined. Concepts of the rules to be precised by additional information are identified through annotations of the rule patterns. For example, the rule pattern of Figure 2 leads to a new rule pattern shown in Figure 4 (the completion pattern is encircled).

The algorithmic principle of the completion step is the following:

- For each rule built in previous step, fusion the concepts that are images of rule pattern concepts annotated by "completion" with corresponding concepts of completion patterns. The SQL query associated with the new rule will automatically be built by conjunction of the selection criteria

Figure 4. New rule pattern

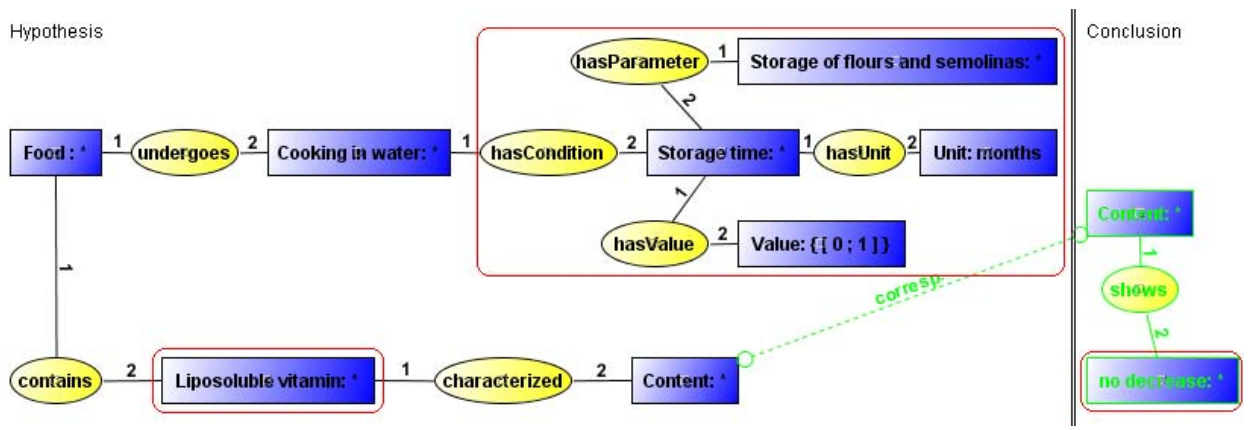


of the SQL queries associated with the merged graphs.

- Within the merged graph, a choice of more specialized concepts must be done (identified by annotations) to determine the most discriminating conditions that may explain the existence of exceptions. The following process is proposed. Let L be the list of experimental data that satisfy the hypothesis of the rule R which is being refined.

Within L, let L_e be the list of exceptions to R and L_v the list of data validating R. The concepts to be specialized will have their corresponding values in L examined. For each possible specialization of these concepts that appears in the values of L_e, an error is calculated, defined as the number of data in L_v that also take these values. Only the specializations that have the smaller error are retained.

Figure 5. The rule of Figure 3 after the negation, specialization and completion steps



After the three steps (negation, specialization and completion), the rule of Figure 3 produces the rule of Figure 5. It represents the information: "If a food product undergoes cooking in water, with a storage time of flours and semolina lower than one month, then its liposoluble vitamin content does not decrease".

FUTURE TRENDS

The long-term objective is to use the presented rules for decision-making: given a user's query that expresses a required goal, the issue is to determine which conditions allow one to achieve this goal, by identifying rules whose conclusions would satisfy the required goal, and whose hypotheses would provide sufficient conditions to obtain it.

This objective requires a deep knowledge of the domain rules. The approach presented in this chapter for exception rule learning contributes to this aim.

CONCLUSION

Given two heterogeneous kinds of information available on a domain (generic expert rules, and detailed experimental results) represented in two distinct formalisms (respectively the conceptual graph model and the relational model), in this article we proposed two stages for the construction of a deep expertise on the domain: (i) the evaluation of the validity of expert knowledge within the experimental data. This stage is based on the notion of rule pattern in the conceptual graph formalism, associated with a corresponding SQL query schema in the relational formalism. The evaluation of a rule instance that conforms to a given rule pattern is then processed by completing the query schema associated with the pattern by selection criteria specific to the considered rule instance; (ii) learning of unexpected and more precise rules that correspond to exceptions to rules, detected in the previous stage. These stages are automatic, which is allowed by annotations of the rule patterns.

The proposed methodology thus relies on the cooperation of the two kinds of information and the two heterogeneous formalisms.

KEY TERMS

CG Rule Instance: A conceptual graph rule that is obtained by specialization of a CG rule pattern.

CG Rule Pattern: A conceptual graph rule that contains generic vertices and translates the general form common to several pieces of information.

Conceptual Graphs: A knowledge representation and reasoning model from artificial intelligence, of the family of semantic networks.

Data and Expert Knowledge Cooperation: Mixed information handling approach, both data driven and symbolic-rooted through expert statements.

Knowledge Refinement: Definition of more specific knowledge than the initially available one.

Rule Validation: Checking the absence of exceptions to a given rule within raw data.

Unexpected Knowledge: Knowledge that constitutes an exception to commonly admitted information on a domain.

Learning from Data Streams

João Gama
University of Porto, Portugal

Pedro Pereira Rodrigues
University of Porto, Portugal

INTRODUCTION

In the last two decades, machine learning research and practice has focused on batch learning usually with small datasets. In batch learning, the whole training data is available to the algorithm that outputs a decision model after processing the data eventually (or most of the times) multiple times. The rationale behind this practice is that examples are generated at random accordingly to some stationary probability distribution. Also, most learners use a greedy, hill-climbing search in the space of models.

What distinguishes current data sets from earlier ones are the continuous flow of data and the automatic data feeds. We do not just have people who are entering information into a computer. Instead, we have computers entering data into each other. Nowadays there are applications in which the data is modelled best not as persistent tables but rather as transient data streams. In some applications it is not feasible to load the arriving data into a traditional DataBase Management Systems (DBMS), and traditional DBMS are not designed to directly support the continuous queries required in these application (Babcock et al., 2002). These sources of data are called *Data Streams*. There is a fundamental difference between learning from small datasets and large datasets. As pointed-out by some researchers (Brain & Webb, 2002), current learning algorithms emphasize variance reduction. However, learning from large datasets may be more effective when using algorithms that place greater emphasis on bias management.

Algorithms that process data streams deliver approximate solutions, providing a fast answer using few memory resources. They relax the requirement of an exact answer to an approximate answer within a small error range with high probability. In general, as the range of the error decreases the space of computational resources goes up. In some applications, mostly database oriented, an approximate answer should be within an admissible error margin. Some results on tail inequalities provided by statistics are useful to accomplish this goal.

LEARNING ISSUES: ONLINE, ANYTIME AND REAL-TIME LEARNING

The challenge problem for data mining is the ability to permanently maintain an accurate decision model. This issue requires learning algorithms that can modify the current model whenever new data is available at the rate of data arrival. Moreover, they should forget older information when data is out-dated. In this context, the assumption that examples are generated at random according to a stationary probability distribution does not hold, at least in complex systems and for large time periods. In the presence of a non-stationary distribution, the learning system must incorporate some form of forgetting past and outdated information. Learning from data streams require incremental learning algorithms that take into account concept drift. Solutions to these problems require new sampling and randomization techniques, and new approximate, incremental and decremental algorithms. In (Hulten & Domingos, 2001), the authors identify desirable properties of learning systems that are able to mine continuous, high-volume, open-ended data streams as they arrive: *i*) incrementality, *ii*) online learning, *iii*) constant time to process each example using fixed memory, *iv*) single scan over the training data, and *v*) tacking drift into account.

Examples of learning algorithms designed to process open-ended streams include predictive learning: Deci-

sion Trees (Domingos & Hulten, 2000; Hulten et al., 2001; Gama et al., 2005, 2006), Decision Rules (Ferrer et al., 2005); descriptive learning: variants of k-Means Clustering (Zhang et al., 1996; Sheikholeslami et al., 1998), Clustering (Guha et al., 1998; Aggarwal et al., 2003), Hierarchical Time-Series Clustering (Rodrigues et al., 2006); Association Learning: Frequent Itemsets Mining (Jiang & Gruemwald, 2006), Frequent Pattern Mining (Jin & Agrawal 2007); Novelty Detection (Markou & Singh, 2003; Spinosa et al. 2007); Feature Selection (Sousa et al., 2006), etc.

All these algorithms share some common properties. They process examples at the rate they arrive using a single scan of data and fixed memory. They maintain a decision model at any time, and are able to adapt the model to the most recent data.

Incremental and Decremental Issues

The ability to update the decision model whenever new information is available is an important property, but it is not enough. Another required operator is the ability to *forget* past information (Kifer et al., 2004). Some data stream models allow delete and update operators. For example, *sliding windows* models require the forgetting of old information. In these situations the incremental property is not enough. Learning algorithms need forgetting operators that reverse learning: decremental unlearning (Cauwenberghs & Poggio, 2000).

Cost-Performance Management

Learning from data streams require to update the decision model whenever new information is available. This ability can improve the *flexibility* and *plasticity* of the algorithm in fitting data, but at some *cost* usually measured in terms of resources (time and memory) needed to update the model. It is not easy to define where is the trade-off between the benefits in flexibility and the cost for model adaptation. Learning algorithms exhibit different profiles. Algorithms with strong variance management are quite efficient for small training sets. Very simple models, using few free-parameters, can be quite efficient in variance management, and effective in incremental and decremental operations (for example naive Bayes (Domingos & Pazzani, 1997)) being a natural choice in the sliding windows framework. The main problem with simple approaches is the boundary in generalization performance they can achieve; they are limited by high bias. Complex tasks requiring more complex models increase the search space and the cost for structural updating. These models require efficient control strategies for the trade-off between the gain in performance and the cost of updating.

Monitoring Learning

Whenever data flows over time, it is highly improvable the assumption that the examples are generated at random according to a stationary probability distribution (Basseville & Nikiforov, 1993). At least in complex systems and for large time periods, we should expect changes (smooth or abrupt) in the distribution of the examples. A natural approach for these *incremental tasks* is *adaptive learning algorithms*, incremental learning algorithms that take into account concept drift.

Change Detection

Concept drift (Klinkenberg, 2004, Aggarwal, 2007) means that the concept about which data is being collected may shift from time to time, each time after some minimum permanence. Changes occur over time. The evidence for changes in a concept is reflected in some way in the training examples. Old observations, that reflect the behaviour of nature in the past, become irrelevant to the current state of the phenomena under observation and the learning agent must forget that information. The nature of change is diverse. Changes may occur in the context of learning, due to changes in hidden variables, or in the characteristic properties of the observed variables.

Most learning algorithms use blind methods that adapt the decision model at regular intervals without considering whether changes have really occurred. Much more interesting are explicit change detection mechanisms. The advantage is that they can provide meaningful description (indicating change-points or small time-windows where the change occurs) and quantification of the changes. They may follow two different approaches:

- Monitoring the evolution of performance indicators adapting techniques used in Statistical Process Control (Gama et al., 2004).
- Monitoring distributions on two different time windows (Kiffer et al., 2004). The method monitors the evolution of a distance function between

two distributions: data in a *reference window* and in a current window of the most recent data points.

The main research issue is to develop methods with fast and accurate detection rates with few false alarms. A related problem is: how to incorporate change detection mechanisms inside learning algorithms. Also, the level of *granularity* of decision models is a relevant property (Gaber et al., 2004), because it can allow partial, fast and efficient updating in the decision model instead of rebuilding a complete new model whenever a change is detected. Finally, the ability to recognize seasonal and re-occurring patterns is an open issue.

FUTURE TRENDS IN LEARNING FROM DATA STREAMS

Streaming data offers a symbiosis between Streaming Data Management Systems and Machine Learning. The techniques developed to estimate synopsis and sketches require counts over very high dimensions both in the number of examples and in the domain of the variables. On one hand, the techniques developed in data streams management systems can provide tools for designing Machine Learning algorithms in these domains. On the other hand, Machine Learning provides compact descriptions of the data than can be useful for answering queries in DSMS. What are the current trends and directions for future research in learning from data streams?

Issues on incremental learning and forgetting are basic issues in stream mining. In most applications, we are interested in maintaining a decision model consistent with the current status of the nature. This has led us to the sliding window models where data is continuously inserted and deleted from a window. So, learning algorithms must have operators for incremental learning and forgetting. Closed related are change detection issues. Concept drift in the predictive classification setting is a well studied topic (Klinkenberg, 2004). In other scenarios, like clustering, very few works address the problem. The main research issue is how to incorporate change detection mechanisms in the learning algorithm for different paradigms. Another relevant aspect of any learning algorithm is the hypothesis evaluation criteria and metrics. Most of evaluation methods and metrics were designed for the static case and provide a single measurement about the quality of the hypothesis. In the streaming context, we are much more interested in how the evaluation metric evolves over time. Results from the *sequential statistics* (Wald, 1947) may be much more appropriate.

CONCLUSION

Learning from data streams is an increasing research area with challenging applications and contributions from fields like data bases, learning theory, machine learning, and data mining. Sensor networks, scientific data, monitoring processes, web analysis, traffic logs, are examples of real-world applications were stream algorithms have been successful applied. Continuously learning, forgetting, self-adaptation, and self-reaction are main characteristics of any intelligent system. They are characteristic properties of stream learning algorithms.

KEY TERMS

Adaptive Learning: Learning algorithms that self-modify their model by incorporating new information and/or forgetting outdated information.

Association rules: Rules that describe events that are frequently observed together.

Concept Drift: Any change in the distribution of the examples that describe a concept.

Data Mining: The process of extraction of useful information in large Data Bases.

Data Stream: Continuous flow of data eventually at high speed

Decremental Learning: Learning that modifies that current decision model by forgetting the oldest examples.

Feature selection: Process focussing on selecting the attributes of a dataset, which are relevant for the learning task.

Incremental Learning: Learning that modifies that current decision model using only the most recent examples

Machine Learning: Programming computers to optimize a performance criterion using example data or past experience.

Novelty Detection: The process of identification new and unknown patterns that a machine learning system is not aware of during training.

Online Learning: Learning by a sequence of predictions followed by rewards from the environment.

Learning Kernels for Semi-Supervised Clustering

Bojun Yan
George Mason University, USA

Carlotta Domeniconi
George Mason University, USA

INTRODUCTION

As a recent emerging technique, semi-supervised clustering has attracted significant research interest. Compared to traditional clustering algorithms, which only use unlabeled data, semi-supervised clustering employs both unlabeled and supervised data to obtain a partitioning that conforms more closely to the user's preferences. Several recent papers have discussed this problem (Cohn, Caruana, & McCallum, 2003; Bar-Hillel, Hertz, Shental, & Weinshall, 2003; Xing, Ng, Jordan, & Russell, 2003; Basu, Bilenko, & Mooney, 2004; Kulis, Dhillon, & Mooney, 2005).

In semi-supervised clustering, limited supervision is provided as input. The supervision can have the form of labeled data or pairwise constraints. In many applications it is natural to assume that pairwise constraints are available (Bar-Hillel, Hertz, Shental, & Weinshall, 2003; Wagstaff, Cardie, Rogers, & Schroedl, 2001). For example, in protein interaction and gene expression data (Segal, Wang, & Koller, 2003), pairwise constraints can be derived from the background domain knowledge. Similarly, in information and image retrieval, it is easy for the user to provide feedback concerning a qualitative measure of similarity or dissimilarity between pairs of objects. Thus, in these cases, although class labels may be unknown, a user can still specify whether pairs of points belong to the same cluster (Must-Link) or to different ones (Cannot-Link). Furthermore, a set of classified points implies an equivalent set of pairwise constraints, but not vice versa. Recently, a kernel method for semi-supervised clustering has been introduced (Kulis, Dhillon, & Mooney, 2005). This technique extends semi-supervised clustering to a kernel space, thus enabling the discovery of clusters with non-linear boundaries in input space. While a powerful technique, the applicability of a kernel-based semi-supervised clustering approach is limited in practice, due to the critical settings of kernel's parameters. In fact, the chosen parameter values can largely affect the quality of the results. While solutions have been proposed in supervised learning to estimate the optimal kernel's parameters, the problem presents open challenges when no labeled data are provided, and all we have available is a set of pairwise constraints.

BACKGROUND

In the context of supervised learning, the work in (Chapelle & Vapnik) considers the problem of automatically tuning multiple parameters for a support vector machine. This is achieved by minimizing the estimated generalization error achieved by means of a gradient descent approach over the set of parameters. In (Wang, Xu, Lu, & Zhang, 2002), a Fisher discriminant rule is used to estimate the optimal spread parameter of a Gaussian kernel. The authors in (Huang, Yuen, Chen & Lai, 2004) propose a new criterion to address the selection of kernel's parameters within a kernel Fisher discriminant analysis framework for face recognition. A new formulation is derived to optimize the parameters of a Gaussian kernel based on a gradient descent algorithm. This research makes use of labeled data to address classification problems. In contrast, the approach we discuss in this chapter optimizes kernel's parameters based on unlabeled data and pairwise constraints, and aims at solving clustering problems. In the context of semi-supervised clustering, (Cohn, Caruana, & McCallum, 2003) uses gradient descent combined with a weighted Jensen-Shannon divergence for EM clustering. (Bar-Hillel, Hertz, Shental, & Weinshall, 2003) proposes a Redundant Component Analysis (RCA) algorithm that uses only must-link constraints to learn a Mahalanobis distance. (Xing, Ng, Jordan, & Russell, 2003) utilizes both must-link and cannot-link constraints

to formulate a convex optimization problem which is local-minima-free. (Segal, Wang, & Koller, 2003) proposes a unified Markov network with constraints. (Basu, Bilenko, & Mooney, 2004) introduces a more general HMRF framework, that works with different clustering distortion measures, including Bregman divergences and directional similarity measures. All these techniques use the given constraints and an underlying (linear) distance metric for clustering points in input space. (Kulis, Dhillon, & Mooney, 2005) extends the semi-supervised clustering framework to a non-linear kernel space. However, the setting of the kernel's parameter is left to manual tuning, and the chosen value can largely affect the results. The selection of kernel's parameters is a critical and open problem, which has been the driving force behind our research work.

MAIN FOCUS

In kernel-based learning algorithms, a kernel function $K(x_i, x_j)$ allows the calculation of dot products in feature space without knowing explicitly the mapping function. It is important that the kernel function in use conforms to the learning target. For classification, the distribution of data in feature space should be correlated to the label distribution. Similarly, in semi-supervised clustering, one wishes to learn a kernel that maps pairs of points subject to a must-link constraint close to each other in feature space, and maps points subject to a cannot-link constraint far apart in feature space. The authors in (Cristianini, Shawe-Taylor, & Elisseeff) introduce the concept of kernel alignment to measure the correlation between the groups of data in feature space and the labeling to be learned. In (Wang, Xu, Lu & Zhang), a Fisher discriminant rule is used to estimate the optimal spread parameter of a Gaussian kernel. The selection of kernel's parameters is indeed a critical problem. For example, empirical results in the literature have shown that the value of the spread parameter σ of a Gaussian kernel can strongly affect the generalization performance of an SVM. Values of σ which are too small or too large lead to poor generalization capabilities. When $\sigma \to 0$, the kernel matrix becomes the identity matrix. In this case, the resulting optimization problem gives Lagrangians which are all 1s, and therefore every point becomes a support vector. On the other hand, when $\sigma \to \infty$, the kernel matrix has entries all equal to 1, and thus each point in feature space is maximally similar to each other. In both cases, the machine will generalize very poorly. The problem of setting kernel's parameters, and of finding in general a proper mapping in feature space, is even more difficult when no labeled data are provided, and all we have available is a set of pairwise constraints. In our research we utilize the given constraints to derive an optimization criterion to automatically estimate the optimal kernel's parameters. Our approach integrates the constraints into the clustering objective function, and optimizes the kernel's parameters iteratively while discovering the clustering structure. Specifically, we steer the search for optimal parameter values by measuring the amount of must-link and cannot-link constraint violations in feature space. Following the method proposed in (Basu, Bilenko, & Mooney, 2004; Bilenko, Basu, & Mooney), we scale the penalty terms by the distances of points, that violate the constraints, in feature space. That is, for violation of a must-link constraint (x_i, x_j), the larger the distance between the two points x_i and x_j in feature space, the larger the penalty; for violation of a cannot-link constraint (x_i, x_j), the smaller the distance between the two points x_i and x_j in feature space, the larger the penalty. Considering the Gaussian kernel function

$$K(x_i, x_j) = \exp\left(-\left\|x_i - x_j\right\|/(2\sigma^2)\right)$$

and adding the constraint

$$\sum_{x_i \in X} \left\|\phi(x_i) - \phi(x_r)\right\|^2 \geq Const$$

(where x_r is a point randomly selected from data set X) to avoid the trivial minimization of the objective function $J_{kernel-obj}$, we obtain the following function:

$$J_{kernel-obj} = \sum_{c=1}^{k} \sum_{x_i, x_j \in \pi_c} \frac{1 - K(x_i, x_j)}{|\pi_c|} + \sum_{(x_i, x_j) \in ML, l_i \neq l_j} 2w_{ij}(1 - K(x_i, x_j)) + \sum_{(x_i, x_j) \in CL, l_i = l_j} 2\overline{w}_{ij}(K(x_i, x_j) - K(x', x'')) - \left(\sum_{x_i \in X} 2(1 - K(x_i, x_r)) - Const\right)$$

where LM is the set of must-link constraints, LC is the set of cannot-link constraints, π_c represents the C^{th} cluster, x' and x'' are the farthest points in feature space, w_{ij} and $\overline{w}_{ij}$ are the penalty costs for violating a must-link and a cannot-link constraints respectively, and l_i represents the cluster label of x_i. The resulting minimization problem is non-convex.

EM-Based Strategy

To minimize the objective function $J_{kernel-obj}$, we use an EM-based strategy. The clusters are initialized through the mechanism proposed in (Kulis, Dhillon, & Mooney, 2005): we take the transitive closure of the constraints to form neighborhoods, and then perform a farthest-first traversal on these neighborhoods to get the K initial clusters.

E-step: The algorithm assigns data points to clusters so that the objective function $J_{kernel-obj}$ is minimized. Since the objective function integrates the given must-link and cannot-link constraints, the optimal assignment of each point is the one that minimizes the distance between the point and its cluster representative in feature space (first term of $J_{kernel-obj}$), while incurring a minimal penalty for constraint violations caused by this assignment (second and third terms of $J_{kernel-obj}$). The fourth term of $J_{kernel-obj}$ is constant during the assignment of data points in each iteration. When updating the cluster assignment of a given point, the assignment for the other points is kept fixed (Besag, 1986; Zhang, Brady, & Smith, 2001). During each iteration, data points are re-ordered randomly. The process is repeated until no change in point assignment occurs.

M-step: The algorithm re-computes the cluster representatives. Constraints are not used in this step. Therefore, only the first term of $J_{kernel-obj}$ is minimized. We note that all the steps so far are executed with respect to the current feature space. We now optimize the feature space by optimizing the kernel parameter σ. To this extent, the gradient descent rule is applied to update the parameter σ of the Gaussian kernel:

$$\sigma^{(new)} = \sigma^{(old)} - \rho \frac{\partial J_{Kernel-obj}}{\partial \sigma},$$

where ρ is a scalar step length parameter optimized via a line-search method.

Given the non-convex formulation, EM-based optimization can only reach a local optimal solution. Thus, the optimum parameter obtained by solving the adaptive kernel formulation may not be global. Nevertheless, obtaining global optimal parameter for clustering is very hard in general.

FUTURE TRENDS

Semi-supervised clustering is becoming an increasingly important research area in the fields of machine learning and data mining. Targeting at utilizing the limited pairwise constraints to improve clustering results, researchers are exploring different ways to maximize the utility of the given side information. One promising direction is the active learning of constraints which are most informative. Learning kernel functions (e.g., polynomial), as well as combinations of different types of kernels is also an interesting route to explore. Finally, we need to develop general methods to integrate constraints into the current existing clustering algorithms.

CONCLUSION

The proposed adaptive semi-supervised Kernel-KMeans algorithm can integrate the given constraints with the kernel function, and is able to automatically embed, during the clustering process, the optimal non-linear similarity within the feature space. As a result, the proposed algorithm is capable of discovering clusters with non-linear boundaries in input space with high accuracy. This technique enables the practical utilization of powerful kernel-based semi-supervised clustering approaches by providing a mechanism to automatically set the involved critical parameters.

KEY TERMS

Adaptive Kernel Method: A new optimization criterion that can automatically determine the optimal parameter of an RBF kernel, directly from the data and the given constraints.

Cannot-Link Constraints: Two points that must be assigned to different clusters.

Clustering: The process of grouping objects into subsets, such that those within each cluster are more closely related to one another than objects assigned to different clusters, according to a given similarity measure.

EM: Expectation Maximization. The algorithm iteratively calculates the expectation of the likelihood function (E-Step) and maximizes the likelihood function (M-Step) to find the maximum likelihood estimates of parameters.

Kernel Kmeans: The clustering algorithm that first maps the data to a feature space, and then use the kernel trick to compute Euclidean distances in feature space to assign data points to the cluster with the nearest centroid.

Kernel Methods: Pattern analysis techniques that work by embedding the data into a high dimensional vector space, and by detecting linear relations in that space. A kernel function takes care of the embedding.

KMeans: The clustering algorithm that uses Euclidean distance as the metric to assign the data points to the cluster with nearest centroid.

Must-Link Constraints: Two points that must be assigned to the same cluster.

Semi-Supervised Clustering: An extension of unsupervised clustering algorithms that can utilize the limited supervision given as labeled data or pairwise constraints to improve the clustering results.

Learning Temporal Information from Text

Feng Pan
University of Southern California, USA

INTRODUCTION

As an essential dimension of our information space, *time* plays a very important role in every aspect of our lives. Temporal information is necessarily required in many applications, such as temporal constraint modeling in intelligent agents (Hritcu and Buraga, 2005), semantic web services (Pan and Hobbs, 2004), temporal content modeling and annotation for semantic video retrieval (QasemiZadeh et al., 2006), geographic information science (Agarwal, 2005), data integration of historical stock price databases (Zhu et al., 2004), ubiquitous and pervasive systems for modeling the time dimension of the context (Chen et al., 2004), and so on.

Extracting temporal information from text is especially useful for increasing the temporal awareness for different natural language applications, such as question answering, information retrieval, and summarization. For example, in summarizing a story in terms of a timeline, a system may have to extract and chronologically order events in which a particular person participated. In answering a question as to a person's current occupation, a system may have to selectively determine which of several occupations reported for that person is the most recently reported one (Mani et al., 2004).

This chapter presents recent advances in applying machine learning and data mining approaches to automatically extract explicit and implicit temporal information from natural language text. The extracted temporal information includes, for example, events, temporal expressions, temporal relations, (vague) event durations, event anchoring, and event orderings.

BACKGROUND

Representing and reasoning about temporal information has been a very active area in artificial intelligence and natural language processing. In general there are two approaches to temporal ontology for natural language. The first one is the descriptive approach (Moens and Steedman, 1988; Smith, 1991), which most concerns the descriptive properties of tense and aspect in natural language. The logical and computational approach (Allen and Ferguson, 1997; Hobbs and Pan, 2004) is the other approach that tries to formalize this quite complex ontology, for example, in first-order logic.

More recently, there has been much work on automatically extracting temporal information from text, especially on recognizing events, temporal expressions and relations (Boguraev and Ando, 2005; Mani et al., 2006; Ahn et al., 2007; Chambers et al., 2007). Pan et al. (2006, 2007) shows that implicit and vague temporal information (e.g., vague event durations) is also useful for temporal reasoning and can be learned by standard supervised machine learning techniques (e.g., Support Vector Machines (SVM), Naïve Bayes, and Decision Trees). The TimeBank corpus annotated in TimeML (Pustejovsky et al., 2003) has become a major resource for providing the annotated data for learning temporal information from text. TimeML is a rich specification language for event and temporal expressions in natural language text; unlike most previous attempts, it separates the representation of event and temporal expressions from the anchoring or ordering dependencies that may exist in a given text.

MAIN FOCUS

Machine learning approaches have become more and more popular in extracting temporal information from text. This section focuses on the most recent efforts on extracting both explicit and implicit temporal information from natural language text.

Learning Explicit Temporal Information

The TimeBank corpus currently contains only 186 documents (64,077 words of text), which is a very small size corpus for machine learning tasks. In order to address this challenge of data sparseness, especially for lacking temporal relation annotations, Mani et al. (2006) proposed to use temporal reasoning as an oversampling method. It takes known temporal relations in a document and derives new implied relations from them. There are a total of 745 derivation rules created based on Allen's interval algebra (Allen, 1984). For example, if it is known from a document that event A is before event B and event B includes event C (i.e., event C occurs during event B), then we can derive a new relation that event A is before event C. This oversampling method dramatically expands the amount of training data for learning temporal relations from text. As a result, they have achieved a predictive accuracy on recognizing temporal relations as high as 93% by using a classic Maximum Entropy classifier.

Boguraev and Ando (2005) proposed another approach to the data sparseness problem of the current TimeBank corpus. They developed a hybrid system that combines a finite-state system with a machine learning component capable of effectively using large amounts of unannotated data for classifying events and temporal relations. Specifically, temporal expressions are recognized by the finite-state system; events and temporal relations, especially relations between events and temporal expressions, are learned by the machine learning component with features extracted from the local context and the finite-state system outputs.

Modeling and Learning Implicit Temporal Information

Compared with much work of learning *explicit* temporal information, there has been little work on how to model and extract *implicit* temporal information from natural language text. For example, consider the sentence from a news article:

George W. Bush met with Vladimir Putin in Moscow.

How long did the meeting last? Our first inclination is to say we have no idea. But in fact we do have some idea. We know the meeting lasted more than ten seconds and less than one year. As we guess narrower and narrower bounds, our chances of being correct go down. As part of our commonsense knowledge, we can estimate roughly how long events of different types last and roughly how long situations of various sorts persist. For example, we know government policies typically last somewhere between one and ten years, while weather conditions fairly reliably persist between three hours and one day. There is much temporal information in text that has hitherto been largely unexploited, implicitly encoded in the descriptions of events and relying on our knowledge of the range of usual durations of types of events.

Pan et al. (2006, 2007) presented their work on how to model and automatically extract this kind of implicit and vague temporal information from text. Missing durations is one of the most common sources of incomplete information for temporal reasoning in natural language applications, because very often explicit duration information (e.g., "a five-day meeting", "I have lived here for three years") is missing in natural language texts. Thus, this work can be very important in applications in which the time course of events is to be extracted from text. For example, whether two events overlap or are in sequence often depends very much on their durations. If a war started yesterday, we can be pretty sure it is still going on today. If a hurricane started last year, we can be sure it is over by now.

They have added their new annotations of the implicit and vague temporal information to the TimeBank corpus, and proposed to use normal distributions to model the judgments (i.e., annotations) that are intervals on a scale. The inter-annotator agreement between annotations is defined as the overlapping area between normal distributions. In their corpus every event to be annotated was already annotated in the TimeBank corpus, and annotators were instructed to provide lower and upper bounds on the estimated duration of the event excluding anomalous cases, and taking the entire context of the article into account. A logarithmic scale is used for the annotated data because of the intuition that the difference between 1 second and 20 seconds is significant, while the difference between 1 year 1 second and 1 year 20 seconds is negligible. A preliminary exercise in annotation revealed about a dozen classes of systematic discrepancies among annotators' judgments. So they developed annotation guidelines to make annotators aware of these cases and to guide them in making the judgments.

Then, they applied supervised machine learning techniques (e.g., Support Vector Machines (SVM) with a linear kernel, Naïve Bayes, and Decision Trees C4.5) to the annotated data, and showed that the learning algorithm with the best performance (i.e., SVM) considerably outperformed a baseline and approached human performance. The features they have explored include the local context (i.e., the event word and *n* tokens to its right and left), syntactic relations (i.e., the subject and the object of the event), and WordNet hypernyms (Miller, 1990) of the event word and its subject and object. The features used are very easy to extract and typical in many natural language learning applications.

The new annotations of the implicit temporal information have also been integrated into the TimeBank corpus to enrich the expressiveness of TimeML and also to provide applications that exploit the corpus with the additional implicit information for their temporal reasoning tasks.

FUTURE TRENDS

Given the small size of the current available corpus of temporal information (e.g., TimeBank), more unsupervised and semi-supervised machine learning techniques will be explored for learning temporal information from larger corpora, e.g., the Web. Explicit and implicit temporal information will be extracted and combined together to improve the performance of the current temporal reasoning systems. The method of using normal distributions to model implicit and vague temporal information can be extended from time to other kinds of vague but substantive information.

CONCLUSION

In this chapter we focused on recent work on applying machine learning techniques to automatically extract explicit temporal information from text, including recognizing events, temporal expressions, and temporal relations. Different approaches to the data sparseness problem of the TimeBank corpus were described. We have also presented the work of modeling and learning implicit and vague temporal information from text, which had very little study before.

KEY TERMS

Corpus: A large set of texts that are usually used to do statistical analysis, checking occurrences or validating linguistic rules.

Data Sparseness: Not having enough data for learning the desired patterns or functions.

Finite-State System: A system of behavior modeling that consists of a finite number of states and transitions between those states.

Natural Language: A language that is spoken, written, or signed (visually or tactilely) by humans for general-purpose communications, and natural language processing (NLP) is a field that studies the problems of automatically processing, understanding, and generating the natural language.

Ontology: A data model that represents categories or concepts and relationships between them for a specific domain.

Oversampling: The process of increasing the number of instances in a minority class.

Semi-Supervised Machine Learning: Learning from both labeled and unlabeled training data, usually with a small amount of labeled data and a large amount of unlabeled data.

Supervised Machine Learning: Learning from labeled training data that contains examples with a set of features and desired outputs.

Unsupervised Machine Learning: Learning from unlabeled data that doesn't contain desired outputs.

Learning with Partial Supervision

Abdelhamid Bouchachia
University of Klagenfurt, Austria

INTRODUCTION

Recently the field of machine learning, pattern recognition, and data mining has witnessed a new research stream that is *learning with partial supervision* -LPS- (known also as *semi-supervised learning)*. This learning scheme is motivated by the fact that the process of acquiring the labeling information of data could be quite costly and sometimes prone to mislabeling. The general spectrum of learning from data is envisioned in Figure 1. As shown, in many situations, the data is neither perfectly nor completely labeled.

LPS aims at using available labeled samples in order to guide the process of building classification and clustering machineries and help boost their accuracy. Basically, LPS is a combination of two learning paradigms: supervised and unsupervised where the former deals exclusively with labeled data and the latter is concerned with unlabeled data. Hence, the following questions:

- Can we improve supervised learning with unlabeled data?
- Can we guide unsupervised learning by incorporating few labeled samples?

Typical LPS applications are medical diagnosis (Bouchachia & Pedrycz, 2006a), facial expression recognition (Cohen et al., 2004), text classification (Nigam et al., 2000), protein classification (Weston et al., 2003), and several natural language processing applications such as word sense disambiguation (Niu et al., 2005), and text chunking (Ando & Zhangz, 2005).

Because LPS is still a young but active research field, it lacks a survey outlining the existing approaches and research trends. In this chapter, we will take a step towards an overview. We will discuss (i) the background of LPS, (iii) the main focus of our LPS research and explain the underlying assumptions behind LPS, and (iv) future directions and challenges of LPS research.

BACKGROUND

LPS is about devising algorithms that combine labeled and unlabeled data in a symbiotic way in order to boost classification accuracy. The scenario is portrayed in Fig.2 showing that the combination can mainly be done in two ways: active/passive pre-labeling, or via 'pure' LPS (Fig. 4). We try to draw a clear picture about these schemes by means of an up-to-date taxonomy of methods.

Active and Passive Pre-Labeling

Pre-labeling aims at assigning a label to unlabeled samples (called queries). These samples are used together with the originally labeled samples to train a fully supervised classifier (Fig. 3). "Passive" pre-label-

Figure 1. Learning from data spectrum

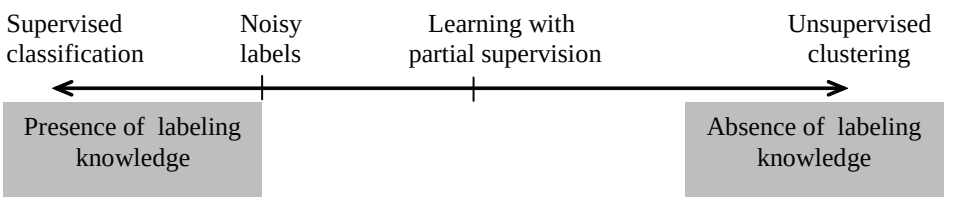

Figure 2. Combining labeled and unlabeled data

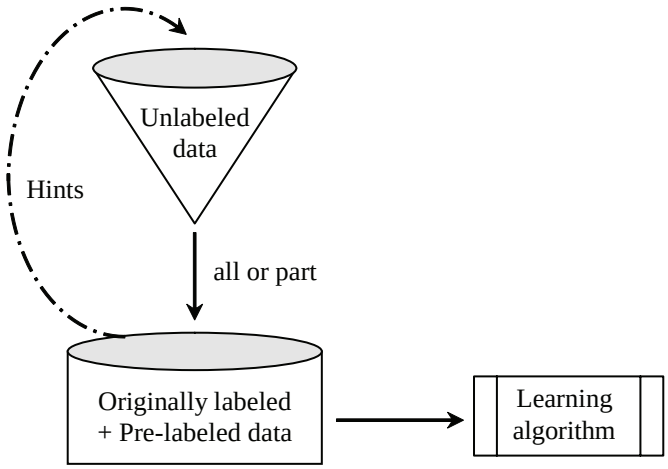

Figure 3. Pre-labeling approaches

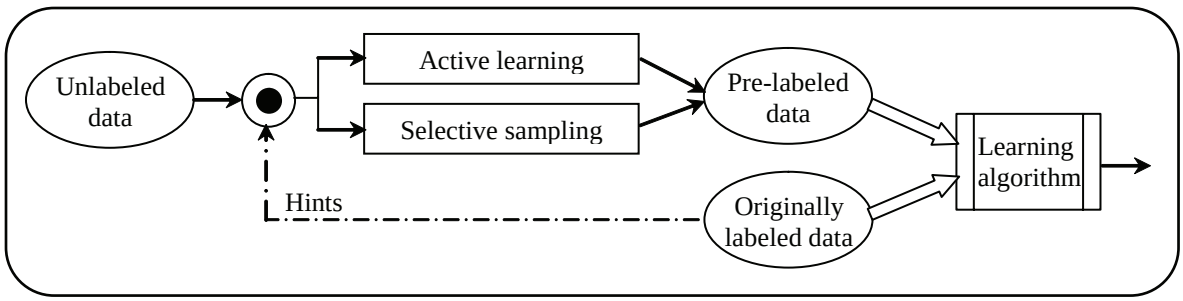

Figure 4. Combining labeled and unlabeled data

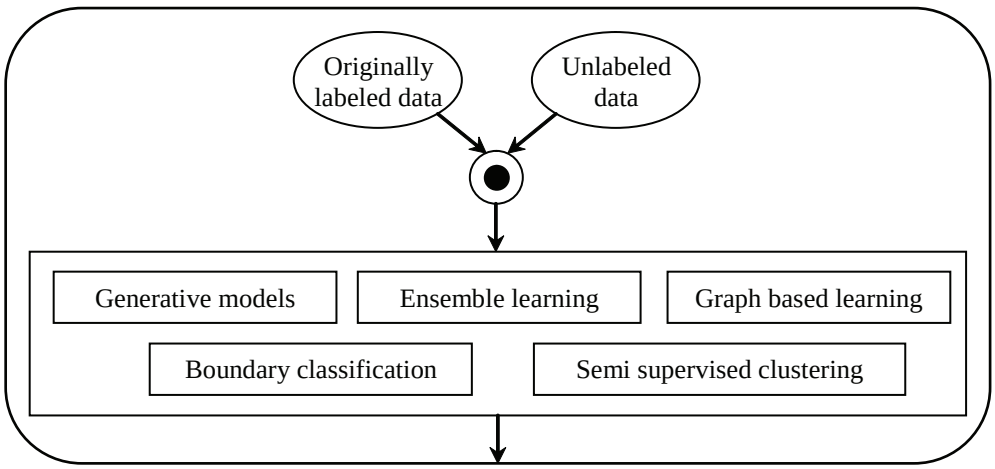


ing means that pre-labeling is done automatically and is referred to as selective sampling or self-training. It has been extensively discussed and consists of first training a classifier before using it to label the unlabeled data (for more details see, Bouchachia, 2007). Various algorithms are used to perform selective sampling, such as multilayer perceptron (Verikas et al., 2001), slef-organizing maps (Dara et al., 2002), and clustering techniques (Bouchachia, 2005a). On the other hand, in active learning, queries are sequentially submitted to an oracle for labeling. Different models have been applied; such as neural networks inversion (Baum, 1991), decision trees (Wiratunga et al., 2003), and query by committee (Freund & Shapire, 1997).

Pure LPS

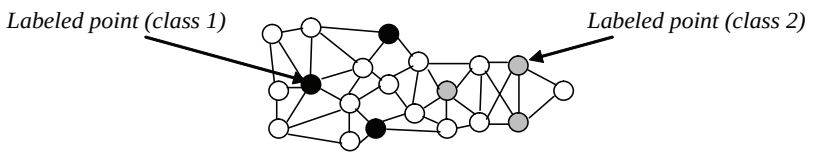
This paradigm corresponds to LPS where the labeled and unlabeled data are reated at the same time. There are several LPS approaches including generative, ensemble learning, graph-based, boundary classification, and semi-supervised clustering models (Fig.4). We briefly outline the concepts behind these approaches without claiming any exhaustiveness due to space limitation.

Much LPS research has focused on *generative approaches* (Nigam et al., 2000)) which seek to optimize a probabilistic model defined by some characteristics such as the cluster center and standard deviation. Usually such models rely on an iterative process to estimate their characteristics. A frequently used method is *Expectation-Maximization* (EM) (Lu *et al.*, 2007).

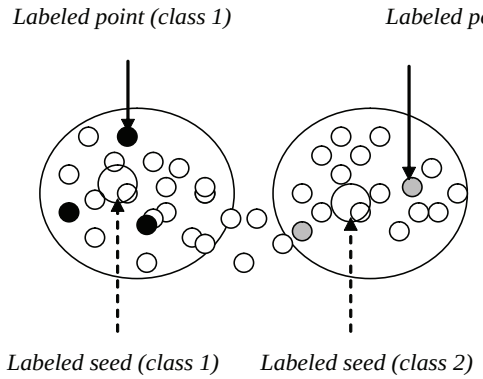
Co-training was introduced in (Blum & Mitchell, 1998). The idea of co-training is to split the features describing the data into two (or more) independent subsets. Each of these is used to train an algorithm. Co-training belongs to the class of *ensemble methods* where individual classifiers are trained and combined to predict the label of data. To this class belong also hybrid approaches like democratic Co-learning (Zhou & Goldman, 2004), and 2v-EM (Ghani, 2002).

Graph-based algorithms consider the problem of learning from hybrid data as a graph problem (Fig.5(a)). The data samples represent the nodes of a graph interconnected by weighted edges. Most of the

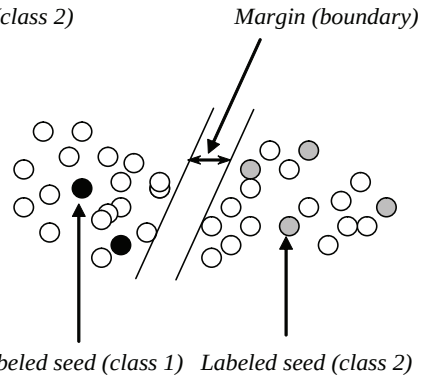
Figure 5. Some LPS methods: (a) graph-based, (b) CPS, (c) Boundary classification (empty circles (unlabeled points))



(a) Data points connected by edges of a graph



(b) Two clusters with two labeled seeds



(c) Two classes separated by a margin

graph-based algorithms are formulated as an objective function consisting of two terms: a loss function and a regularizer. To this category belong many transductive methods such as the *mincut* (Blum et al., 2004), and *random walk-based* (Szummer & Jaakkola, 2002) approaches.

Boundary classification methods (Fig.5(c)), which include *transductive support vector machines* (Yeung & Chang, 2007), *LPS based on Gaussian processes* (Lawrence & Jordan, 2005), and *entropy-based methods* (Jaakkola et al., 1999), rely on the notion of low data density assumption stipulating that the class boundary tends to be of low density.

A slightly different scheme of LPS is *clustering with partial supervision* -CPS- (or s*emi-supervised clustering)* (Fig.5(b))*;* which aims at incorporating some labeled samples before clustering the entire data. The few algorithms developed in this framework are essentially objective function-based including *genetic algorithms* (Demiriz et al., 1999) and *Fuzzy C-Means-based CPS* (Bouchachia & Pedrycz, 2006a). The objective function consists of two terms: one is clustering-oriented and the other is classification-oriented (see next section). Moreover, part of the CPS class are *seed-based* methods (Basu et al., 2002), where the labeled samples are used to generate seeds around which the unlabeled samples are clustered.

MAIN FOCUS

As outlined earlier, in (Bouchachia & Pedrycz, 2006a), a new CPS algorithm has been developed. It is based on an extension of the objective function of Fuzzy C-Means (Bezdek, 1981) to systematically combine labeled and unlabeled data. The objective function consists of two terms. The first term, that is a clustering term, aims at discovering the hidden structure of data. The second term takes the visible structure reflected by the available labels into account. The objective function looks as follows:

$$Objective = Clustering\ Term + \alpha * Classification\ Term$$

where α is a tuning parameter to set the balance between the two terms of the objective function. Higher value indicates more confidence in the labeled data. The outcome of optimizing this function leads to derive the expression of the cluster centers and the membership matrix (membership degree of points to each of the clusters).

This algorithm has shown that by increasing the amount of labeled data, the accuracy of the four proposed approaches increases. Furthermore, unlabeled data does also improve the accuracy. However, the amount of improvement depends on the method used. However, the performance of clustering and classification algorithms is typically influenced by their free parameters. As investigated in (Bouchachia & Pedrycz, 2006b), the effect of distance measures on the performance of CPS is investigated. In this study, the Euclidean distance and three more versatile and adaptive distances: a weighted Euclidean distance, a full adaptive distance, and a kernel-based distance were applied. A comprehensive assessment has shown how the fully adaptive distance allows better performance results but also how the fuzzy C-means based CPS algorithm outperforms other algorithms.

While in most studies, the issue has always been only to check the effect of increasing labeled data on the accuracy of LPS algorithms, it is important to check also the effect of unlabeled data on the accuracy as done in (Bouchachia, 2007). The reason behind the restriction to only the first check is that most of the LPS research is concentrating on semi-supervised classification or transductive learning and therefore, the most important aspect there is the amount of labeled data. On the other hand, the basic assumption that underlies the second check is that the amount of unlabeled data is far bigger than that of labeled data and therefore, the application of clustering techniques should be strongly promoted.

The *cluster assumption* is at the heart of LPS, be it classification or clustering. Indeed, it is worth noting that other assumptions such as the *boundary* (or low data density) assumption, *smoothness and continuity* assumption all implicitly based upon or refer to clustering. Consider the following definitions:

- **Cluster assumption:** Samples lying in the same cluster tend to have the same label.
- **Smoothness assumption:** Samples which are closer to each other in the input space, are likely to be mapped onto the same label in the output space (Zhu et al., 2003).
- **Boundary assumption:** Classes are represented as high density regions separated by valleys (low density regions) (Chapelle & Zien, 2005).

It is easy to see that all of these assumptions convey indirectly the same meaning. Assume that a class consists of many clusters (Bouchachia & Pedrycz, 2006a), then both assumptions: smoothness and low-density separation are taken into account. Nevertheless, these assumptions are seen differently depending on the computational model used in the algorithms; hence, our motivation for approaching the LPS problem from a clustering perspective.

However, despite the well-defined principles and assumptions behind the LPS algorithms, it is still hard to cope with the problem of learning from hybrid data when the amount of labeled data is very small. The reason for that is simple. Few labeled points cannot reflect the distribution of the classes in the input space. This complexity of the task becomes severe if some classes are unknown. A further problem lies in the absence of a thorough evaluation of all available algorithms that would enable the practitioners of data mining and pattern recognition to make the best choice among the available algorithms.

At the current stage of investigation of LPS, one can formulate some key questions:

Question 1: *Is it possible to make a definite choice among all available algorithms?*

Answers 1: As mentioned earlier, there is no single algorithm that can be preferred. The choice can only be motivated by various factors:

- Familiarity of the practitioner with the computational models used by the LPS algorithms, be it probabilistic, graphical, boundary–based or pre-labeling
- Existence of some comparative studies (which, if they exist, are at the current state of affairs are limited to one computational model)
- Sufficient knowledge about the structure of the data (statistical properties). It is important to note that in many approaches, there are strong statistical assumptions about the data that are not true (Cozman & Cohen, 2002)
- Availability of reasonable amount of labeled data reflecting the different regions in each class
- The number of free parameters of each LPS algorithm. The higher the number of free parameters, the higher the tuning effort and the risks of misclassification

Question 2: *Do unlabeled data increase the accuracy of LPS algorithms?*

Answers 2: Most of the authors report that unlabeled data have a positive effect on the accuracy of the LPS algorithms. However, in formal probabilistic terms (Seeger, 2001), many LPS algorithms (e.g., generative and graph-based) show the utility of unlabeled data only if the probability p(x) of unlabeled data does influence the computation of the posterior probability p(y|x). Most of us expect somehow that an improvement, be it minor, in the accuracy as the size of labeled and unlabeled data is increased, since the more the data, the smaller the variance of estimates, and the smaller the classification error. However, this might not be completely true as shown in several studies (Cozman & Cohen, 2002).

Question 3: *Do labeled data increase the accuracy of LPS algorithms?*

Answers 3: Similar to Answer 2, one can a-priori expect that increasing the size of labeled data increases the accuracy. This has been outlined in most LPS studies. Castelli and Cover (1995) have shown that the labeled data contribute exponentially faster than unlabeled data to the reduction of the classification error under some assumptions. However, it has been shown in at least one study (Schohn & Cohn, 2000) that the misclassification error in an active learning setting increases as the size of the labeled data exceeds a certain threshold. To our knowledge, this is the only study that shows that labeled data can harm.

FUTURE TRENDS

It is worth mentioning that LPS is a challenging task. Despite the large variety of LPS algorithms, there are still many open questions. Several axes for future work can be suggested for further investigation:

- Full assessment of the plethora of already proposed algorithms
- Development of further LPS algorithms is expected, advisable and desirable
- Hybrid algorithms are very likely to be investigated. Such algorithms usually tend to avoid making strong assumptions about the models and data

- Semi-automatic LPS algorithms will have a larger share of the algorithms. Semi-automatic here means involving experts in labeling further samples to provide a clearer tendency of the distribution of the labeled data. This refers to active learning. There exist, but very few, approaches relying on active learning to deal with partly labeled data
- Ensemble clusterers and classifiers are widely investigated in the machine learning literature and have proven to outperform individual clustering and classification algorithms. It is, therefore, interesting to consider *ensemble LPS algorithms*. Some initial work in this direction can be found in (D'Alchè-Buc, 2002; Bouchachia, 2007)

CONCLUSION

LPS is very relevant for many applications in the domain of data mining, pattern recognition, and machine learning. LPS has witnessed in recent years much attention from the research community. Its impact will be crucial on the future of such applications since its success reduces the effort and cost invested on labeling. This is especially relevant to particular applications (e.g., chemical, physics, text and data mining) in which labeling is very expensive. However, LPS remains a challenging, but also an exciting, research domain. More investigations are expected to be carried out as outlined in the previous section.

KEY TERMS

Classification: The process of assigning samples to known classes. In classification, each sample comes in the form of a pair (feature vector, label). If samples are continuous (i.e. signal), the process is known as regression.

Cluster Assumption: The assumption that samples lying in the same cluster tend to have the same label.

Clustering: The process of assigning unlabeled samples to clusters using some similarity measure. Ideally, two criteria have to be satisfied, intra-cluster similarity and inter-cluster dissimilarity.

Induction: The process of inducing a general decision function valid for the whole underlying data set of a learning task.

Semi-Supervised Classification: The process of training a classifier using labeled and unlabeled data, where the unlabeled samples are used to help discover the hidden structure of data and boost the classification accuracy.

Semi-Supervised Clustering: The process of clustering labeled and unlabeled data, where the labeled samples are used to guide the process of grouping and to boost the accuracy of unsupervised clustering.

Semi-Supervised Learning: The process of combining labeled and unlabeled data in order to build a learning system. Usually, the amount of labeled samples is small, while that of unlabeled ones is large.

Transduction: The process of decision making on a particular test set where the aim is to minimize misclassification of those particular points. From the perspective of LPS, the testing set coincides with the set of unlabeled points.

Legal and Technical Issues of Privacy Preservation in Data Mining

INTRODUCTION

To paraphrase Winograd (1992), we bring to our communities a tacit comprehension of right and wrong that makes social responsibility an intrinsic part of our culture. Our **ethics** are the moral principles we use to assert social responsibility and to perpetuate safe and just societies. Moreover, the introduction of new technologies can have a profound effect on our ethical principles. The emergence of very large databases, and the associated automated data analysis tools, present yet another set of ethical challenges to consider.

Socio-ethical issues have been identified as pertinent to data mining and there is a growing concern regarding the (ab)use of sensitive information (Clarke, 1999; Clifton et al., 2002; Clifton and Estivill-Castro, 2002; Gehrke, 2002). Estivill-Castro et al., discuss surveys regarding public opinion on personal privacy that show a raised level of concern about the use of private information (Estivill-Castro et al., 1999). There is some justification for this concern; a 2001 survey in InfoWeek found that over 20% of companies store customer data with information about medical profile and/or customer demographics with salary and credit information, and over 15% store information about customers' legal histories.

BACKGROUND

Data mining itself is not ethically problematic. The ethical and legal dilemmas arise when mining is executed over data of a personal nature. Perhaps the most immediately apparent of these is the invasion of privacy. Complete **privacy** is not an inherent part of any society because participation in a society necessitates communication and negotiation, which renders absolute privacy unattainable. Hence, individual members of a society develop an independent and unique perception of their own privacy. Privacy therefore exists within a society only because it exists as a perception of the society's members. This perception is crucial as it partly determines whether, and to what extent, a person's privacy has been violated.

An individual can maintain their **privacy** by limiting their accessibility to others. In some contexts, this is best achieved by restricting access to personal information. If a person considers the type and amount of information known about them to be inappropriate, then they perceive their privacy to be at risk. Thus, privacy can be violated when information concerning an individual is obtained, used, or disseminated, especially if this occurs without their knowledge or consent.

Huge volumes of detailed personal data are regularly collected and analysed by marketing applications (Fienberg, S. E. 2006; Berry and Linoff, 1997), in

which individuals may be unaware of the behind-the-scenes use of data, are now well documented (John, 1999). However, privacy advocates face opposition in their push for legislation restricting the secondary use of personal data, since analysing such data brings collective benefit in many contexts. DMKD has been instrumental in many scientific areas such as biological and climate-change research and is also being used in other domains where privacy issues are relegated in the light of perceptions of a common good. These include genome research (qv. (Tavani, 2004)), combating tax evasion and aiding in criminal investigations (Berry and Linoff, 1997) and in medicine (Roddick et al., 2003).

As **privacy** is a matter of individual perception, an infallible and universal solution to this dichotomy is infeasible. However, there are measures that can be undertaken to enhance privacy protection. Commonly, an individual must adopt a proactive and assertive attitude in order to maintain their privacy, usually having to initiate communication with the holders of their data to apply any restrictions they consider appropriate. For the most part, individuals are unaware of the extent of the personal information stored by governments and private corporations. It is only when things go wrong that individuals exercise their rights to obtain this information and seek to excise or correct it.

MAIN FOCUS

Data Accuracy

Mining applications involve vast amounts of data, which are likely to have originated from diverse, possibly external, sources. Thus the quality of the data cannot be assured. Moreover, although data pre-processing is undertaken before the execution of a mining application to improve data quality, people conduct transactions in an unpredictable manner, which can cause personal data to expire. When mining is executed over expired data inaccurate patterns are more likely to be revealed.

Likewise, there is a great likelihood of errors caused by mining over poor quality data. This increases the threat to the data subject and the costs associated with the identification and correction of the inaccuracies. The fact that data are often collected without a preconceived hypothesis shows that the data analysis used in DMKD are more likely to be **exploratory** (as opposed to the **confirmatory analysis** exemplified by many statistical techniques). This immediately implies that results from DMKD algorithms require further confirmation and/or validation. There is a serious danger of inaccuracies that cannot be attributed to the algorithms *per se*, but to their exploratory nature.

This has caused some debate amongst the DMKD community itself. Freitas (2000) has argued that mining association rules is a deterministic problem that is directly dependent on the input set of transactions and thus association rules are inappropriate for prediction, as would be the case of learning classifiers. However, most uses of association rule mining are for extrapolation to the future, rather than characterisation of the past.

The sharing of corporate data may be beneficial to organisations in a relationship but allowing full access to a database for mining may have detrimental results. The adequacy of traditional database security controls are suspect because of the nature of inference. Private and confidential information can be inferred from public information.

The following measures have thus been suggested to prevent unauthorised mining:

- **Limiting access to the data.** By preventing users from obtaining a sufficient amount of data, consequent mining may result in low confidence levels. This also includes query restriction, which attempts to detect when compromise is possible through the combination of queries (Miller and Seberry, 1989).
- **Anonymisation.** Any identifying attributes are removed from the source dataset. A variation on this can be a filter applied to the ruleset to suppress rules containing identifying attributes.
- Dynamic **Sampling**. Reducing the size of the available data set by selecting a different set of source tuples for each query.
- **Authority control** and cryptographic techniques. Such techniques effectively hide data from unauthorised access but allow inappropriate use by authorised (or naive) users (Pinkas, 2002).
- **Data perturbation**. Altering the data, by forcing aggregation or slightly altering data values, useful mining may be prevented while still enabling the planned use of the data. Agrawal and Srikant (2000) explored the feasibility of privacy-preservation by using techniques to perturb sensitive values in data.

- **Data swapping.** Attribute values are interchanged in a way that maintains the results of statistical queries (Evfimievski et al., 2002).
- **The elimination of unnecessary groupings.** By assigning unique identifiers randomly; they serve only as unique identifiers. This prevents meaningful groupings based on these identifiers yet does not detract from their intended purpose.
- **Data augmentation**. By adding to the data in non-obvious ways, without altering their usefulness, reconstruction of original data can be prevented.
- **Alerting.** Labelling potentially sensitive attributes and attribute values and from this calculating an estimate of the sensitivity of a rule (Fule and Roddick, 2004).
- **Auditing.** The use of auditing does not enforce controls, but could detect misuse so that appropriate action may be taken.

Issues relating to the computational cost of privacy preservation are discussed by Agrawal et al. (2004).

Legal Liability

When personal data have been collected it is generally decontextualised and separated from the individual, improving privacy but making misuse and mistakes more likely (Gammack and Goulding, 1999). Recently, there has been a trend to treat personal data as a resource and offer it for sale. Information is easy to copy and re-sell. The phrase *data mining* uses the metaphor of the exploitation of natural resources, further contributing to the perception of data as commodity. Moreover, the question of whether it is appropriate in terms of human rights to trade in personal data has seen insufficient academic and legal debate. The negative consequences of such trade are similar to those of data mining: transgression of privacy and the negative impacts of inaccurate data. However, the repercussions of inaccurate data are more serious for organisations trading in personal data, as the possibility of legal liability is introduced. There is the potential for those practising data trade or data mining to make mistakes and as a consequence lose heavily in the courts.

Compensation may be ordered against any organisation that is found to have harmed (or failed to prevent harm to) an individual to whom it owed a duty of care. Once liability (the tort of negligence) has been established, the plaintiff can claim financial compensation for any consequential losses caused by the negligent act (Samuelson, 1993). The extent and exact nature of the losses is, for the most part, unique to each plaintiff, but the boundaries of negligence are never closed. A mining exercise might erroneously declare an individual a poor credit risk, and decisions may be made prejudicial to that individual on that basis.

In some cases, algorithms may classify correctly, but such classification could be on the basis of controversial (ie. ethically sensitive) attributes such as sex, race, religion or sexual orientation. This could run counter to **Anti-Discrimination legislation**. In some cases, such as artificial neural networks, SVMs and nearest neighbour classifiers, which do not make their knowledge explicit in rules, the use of controversial classification attributes may be hard to identify. Even with methods that make transparent their classification, such as decision trees, there is little to prevent a corporation using rules based on controversial attributes if that improves accuracy of the classification. Individuals who suffer denial of credit or employment on the basis of race, sex, ethnicity or other controversial attributes in a context where this is contrary to law are in a strong position to demonstrate harm *only* if they illustrate the artificial classifiers are using such attributes. The question is how they obtain access to the classifier results.

In the event that the person loses money or reputation as a result of this, courts may award damages. Moreover, since the potential for inaccuracies involved in the exercise is great, it is conceivable that the courts might apply a higher than usual standard of care in considering whether an organisation has breached its duty to a plaintiff sufficiently to amount to **negligence**. Only time will tell.

Another legal issue is whether organisations manipulating personal data can be considered capable of defaming a person whose data they have mined. It is quite conceivable that since mining generates previously unknown information, the organisation using the mining tool can be considered the author of the information for the purposes of defamation law. Moreover, it can be argued that organisations trading in personal data are analogous to publishers, as they are issuing collections of data for sale and distribution. Hence, if the information is capable of being deemed defamatory by the courts, the data mining organisations are capable of being found liable for damages in this tort also. One difficulty is that the terms *author* and *publisher* have

long been associated with text or music, not data. Note that census data also faces this challenge and other technologies are complicating the issue still further. Consider aerial/satellite photography that can now achieve resolution to within a few metres and which can be freely purchased over the Internet. What is the resolution that makes such data be considered personal data? How can individuals living at identifiable houses decide if the aerial photo is to be used for a potential beneficial analysis, such as bush fire risk analyses of their property, or an analysis that could be considered **defamatory** or **discriminatory**?

Market analysts often see privacy concerns as unreasonable. Privacy is an obstacle to understanding customers and to supplying better suited products. Hundreds of millions of personal records are sold annually in the US by 200 **superbureaux** to direct marketers, private individuals, investigators, and government agencies (Laudon, 1996).

We are in urgent need of an extended interpretation of existing tort doctrine, or preferably a broadening of the boundaries of the current doctrines. Indeed, Samuelson (1993) warns that the engineered, technological nature of electronic information dissemination suggests a greater liability for its disseminators. Commonly, the conveyers of information are excused from liability if they are simply the carriers of the information from the publishers to the public—a book store selling a book that carries defamatory material will be excused from liability that might rightly attach to the author and the publisher. It is quite possible that a mining exercise, particularly one that had mined inaccurate data, might be deemed by the courts to be an exercise in publishing, not just in dissemination.

SOLUTIONS AND FUTURE TRENDS

Anonymisation of Data

One solution to the invasion of privacy problem is the **anonymisation** of personal data. This has the effect of providing some level of privacy protection for data subjects. However, this would render obsolete legitimate mining applications that are dependent on identifiable data subjects, and prevent many mining activities altogether. A suggested compromise is the empowerment of individuals to dictate the amount and type of personal data they consider appropriate for an organisation to mine.

While anonymisation of data is a step in the right direction, it is the weakest of the possible options. It is well known that additional information about an individual can easily be used to obtain other attributes. Moreover, grouping two sets of anonymised information can result in disclosure. Identifier removal (such as name, address, phone number and social security number) can be insufficient to ensure privacy (Klosgen, 1995). Anonymisation is a form of cell suppression, a technique applied on statistical databases. Indeed, the research agenda is still far from closed since most of the solutions proposed so far in the DMKD community (Piatetsky-Shapiro, 1995) are easily translated to existing methods for statistical databases.

Data perturbation is thus a promising alternative. Clifton and Marks (1996; 1999) indicated new and renewed threats to privacy from mining technology and Estivill-Castro and Brankovic (1999) indicated the potential of data perturbation methods which was subsequently adopted by Agrawal and Srikant (2000).

Inaccurate Data

The data quality issue is more difficult to resolve. Inaccurate data remains undetected by the individual until he or she experiences some associated repercussion, such as a denial of credit. It is also usually undetected by the organisation, which lacks the personal knowledge necessary for the exposure of inaccuracies. The adoption of data quality management strategies by the organisation, coupled with the expedient correction of inaccuracies reported by individuals and intermittent data cleansing may go some way to resolving the dilemma.

Legal Solutions

Legal regulation of applied technology is currently one of the more pressing needs facing policy-makers. But how does one approach the development of what is needed? Legislative reform may be unsuitable as it is an unwieldy tool in a rapidly expanding technical environment. Common law change is probably a more appropriate and suitable mechanism of legal regulation as it can be creatively applied to novel situations. The disadvantage of the common law, however, is that there needs to be a number of precedent court cases upon which to build common law principles, and litigation in this age of mediated dispute resolution and in con-

fidence settlements is becoming a rare phenomenon. Furthermore, the common law's record on subjects such as the protection of privacy and dealing with the legal implications of applied technologies is weak. This is a rapidly expanding socio-economic landscape, and the law is not keeping pace. Public awareness of legal suits alleging negligence and defamation may possibly have some prophylactic effect upon the potential transgressions of contemporary technology.

Another weakness of legal regulation is the fact that the jurisdictional boundaries that determine the limits of our legal system were decided in ignorance of technological developments that render these boundaries virtually irrelevant, given the international structure of many organisations and the burgeoning international presence of an individual on the Internet. If an Australian were to conduct a transaction and provide data for a multinational organisation registered in Europe via a web site physically situated in the United States, which legal system governs the transaction and its legal repercussions? This is a legal dilemma not lost on international lawyers, and one that does not readily admit of a simple solution.

CONCLUSION

The primary consideration of any future research should be at least maintenance, and preferably enhancement, of ethical flexibility. Solutions reconciling any issues must not only be applicable to the ever-changing technological environment, but also flexible with regard to specific contexts and disputes. Moreover, we must be able to identify ethical dilemmas as they arise and derive solutions in a timely, preferably concurrent manner. Many ethical issues overlap and have effects on each other. We need to identify any commonalities and differences that exist and exploit them to derive solutions that enable us to uphold, or extend, our ethical standards.

In terms of practical issues, the equality of access argument (the technological *haves and have-nots* (Baase 1997)) has not been considered in this chapter. Indeed, data mining may be one context in which the have-nots hold the advantage.

We exist in an environment in which technology has increasing social relevance. The challenge now is to implement methods of assessing the social impact of an emergent technology, providing us with the capacity to use the tools technology provides wisely and with consideration for our culture and its future.

KEY TERMS

Authority control: Various methods of controlling access to data.

Data Anonymisation: The removal of attribute values that would allow a third party to identify the individual.

Data Perturbation: Altering data, by forcing aggregation or slightly altering data values.

Multi Level Security (MLS): Extends conventional security measures by classifying data according to its confidentiality.

Sampling: The selection of a subset of data for analysis.

Spyware: Software that covertly gathers user information.

Statistical Compromise: A situation in which a series of queries may reveal confidential information.

Leveraging Unlabeled Data for Classification

Yinghui Yang
University of California, Davis, USA

Balaji Padmanabhan
University of South Florida, USA

INTRODUCTION

Classification is a form of data analysis that can be used to extract models to predict categorical class labels (Han & Kamber, 2001). Data classification has proven to be very useful in a wide variety of applications. For example, a classification model can be built to categorize bank loan applications as either safe or risky. In order to build a classification model, training data containing multiple independent variables and a dependant variable (class label) is needed. If a data record has a known value for its class label, this data record is termed "labeled". If the value for its class is unknown, it is "unlabeled". There are situations with a large amount of unlabeled data and a small amount of labeled data. Using only labeled data to build classification models can potentially ignore useful information contained in the unlabeled data. Furthermore, unlabeled data can often be much cheaper and more plentiful than labeled data, and so if useful information can be extracted from it that reduces the need for labeled examples, this can be a significant benefit (Balcan & Blum 2005). The default practice is to use only the labeled data to build a classification model and then assign class labels to the unlabeled data. However, when the amount of labeled data is not enough, the classification model built only using the labeled data can be biased and far from accurate. The class labels assigned to the unlabeled data can then be inaccurate.

How to leverage the information contained in the unlabeled data to help improve the accuracy of the classification model is an important research question. There are two streams of research that addresses the challenging issue of how to appropriately use unlabeled data for building classification models. The details are discussed below.

BACKGROUND

Research on handling unlabeled data can be approximately grouped into two streams. These two streams are motivated by two different scenarios.

The first scenario covers applications where the modeler can acquire, but at a cost, the labels corresponding to the unlabeled data. For example, consider the problem of predicting if some video clip has suspicious activity (such as the presence of a "most wanted" fugitive). Vast amounts of video streams exist through surveillance cameras, and at the same time labeling experts exist (in law enforcement and the intelligence agencies). Hence labeling any video stream is possible, but is an expensive task in that it requires human time and interpretation (Yan et al 2003). A similar example is in the "speech-to-text" task of generating automatic transcriptions of speech fragments (Hakkani-Tur et al 2004, Raina et al 2007). It is possible to have people listen to the speech fragments and generate text transcriptions which can be used to label the speech fragments, but it is an expensive task. The fields of active learning (e.g. MacKay (1992), Saar-Tsechansky & Provost (2001)) and optimal experimental design (Atkinson 1996) addresses how modelers can selectively acquire the labels for the problems in this scenario. Active learning acquires labeled data incrementally, using the model learned so far to select particularly helpful additional training examples for labeling. When successful, active learning methods reduce the number of instances that must be labeled to achieve a particular level of accuracy (Saar-Tsechansky & Provost (2001)). Optimal experimental design studies the problem of deciding which subjects to experiment on (e.g. in medical trials) given limited resources (Atkinson 1996).

The second scenario, the focus in this chapter, covers applications where it is not possible to acquire the

unknown labels or such acquisition is not an option. The extreme cases of the previous scenario where the costs are prohibitively high can also be considered in this set. For example, consider the problem of predicting the academic performance (i.e. the graduating GPA) of thousands of current applicants to an undergraduate program. Ample data exists from the performance of ex-students in the program, but it is impossible to "acquire" the graduating GPA of current applicants. In this case is the unlabeled data (i.e. the independent variables of the current applicants) of any use in the process of building a model? A stream of recent research (Blum & Mitchell (1998), Joachims (1999), Chapelle (2003)) addresses this problem and presents various methods for making use of the unlabeled data for this context.

To some extent, approaches used to learning with missing values can be applied to learning the labels of the unlabeled data. One standard approach to learning with missing values is the EM algorithm (Dempster et al. 1977). The biggest drawback of such approaches is that they need to assume the class label follows a certain distribution.

A second approach for this (Blum & Mitchell, 1998) is co-training (and variants (Yarowsky, 1995)) which was initially applied to Web page classification, since labeling Web pages involves human intervention and is expensive. The idea is to first learn multiple classifiers from different sets of features. Each classifier is then used to make predictions on the unlabeled data and these predictions are then treated as part of the training set for the other classifiers. This approach works well for Web page categorization since one classifier can be trained based on words within pages while another (using different features) can be trained on words in hyperlinks to the page. This approach is in contrast with self-training where a classifier uses its own (selected) predictions on the unlabeled data to retrain itself.

Another approach is to use clustering and density estimation to first generate a data model from both the labeled and unlabeled data (e.g. Chapelle, 2003). The labels are then used for labeling entire clusters of data, or estimating class conditional densities which involves labeling of the unlabeled data dependent on their relative placement in the data space with respect to the original labeled data. A popular approach for implementing this idea is using generative mixture models and the EM algorithm. The mixture models are identified using unlabeled data, and then the labeled data is used to determine the classes to assign to the (soft) clusters generated from the combined data.

There is also work on integrating these ideas into a specific classifier, such as the development of Transductive Support Vector Machines (Joachims 1999). Extending the concept of finding optimal boundaries in a traditional SVM, this work develops methods to learn boundaries that avoid going through dense regions of points both in labeled as well as unlabeled data.

To summarize, the prior research on learning with unlabeled data focuses either on selecting unlabeled data to acquire labels, or use models built on labeled data to assign labels to unlabeled data.

MAIN FOCUS OF THE CHAPTER

In this chapter, we focus on an approach for using the unlabeled data in the case where labels cannot be acquired. This approach is different from the ones discussed above in that it does not involve assigning labels to the unlabeled data. Instead, this approach augments the features (independent variables) of the labeled data to capture information in the unlabeled data. This approach is based on the intuition that the combined labeled and unlabeled data can be used to estimate the joint distribution of attributes among the independent variables better, than if this was estimated from the labeled data alone. Specifically, if interactions (or patterns) among variables turn out to be useful features for modeling, such patterns may be better estimated using all available data.

The Approach

The approach and alternatives for comparison are pictorially illustrated in Figure 1. The approach presented is the path on the right (#3). First the column represented by the target attribute (Y) is removed, and the labeled and unlabeled data are combined into one large dataset. Then a pattern discovery procedure (e.g. a procedure to discover frequent itemsets) is applied to learn a set of patterns from this data. Let the number of patterns learned from just the independent variables of both the labeled and unlabeled data be Q_2. Each of these patterns then is used to create binary variables P_1, P_2, … , P_{Q2} indicating whether each given pattern is present in each record of the dataset. For example, for pattern number Q_2, we check whether a data record contains

this pattern. If it does, then the value for the newly created attribute P_{Q2} is 1, otherwise it is 0. A classifier is then built using the labeled data which now has the original variables augmented with features learned from the combined data.

The following example illustrates how the approach works. Assume there are two independent variables (X_1 and X_2) in the data (both labeled and unlabeled). The labeled data has a dependent variable Y, but the unlabeled data doesn't. We take X_1 and X_2 in both the labeled data and unlabeled data and find frequent patterns in them (for example, $\{X_1=2, X_2=4\}$ occurs in many data records, so it's a frequent pattern). Then, a new independent variable $P_1=\{X_1=2, X_2=4\}$ is created to augment the existing ones. If a data record has the pattern $\{X_1=2, X_2=4\}$, then $P_1=1$, otherwise 0. At last, we use X_1, X_2, $\{X_1=2, X_2=4\}$ and Y in the labeled data to build classification models.

The intuition behind this approach is founded on three observations. First, there are often systematic interactions among independent variables in large high dimensional datasets. Second, often a subset of

Figure 1. Pictorial illustration of the approach (#3) and two comparison approaches (#1 and #2)

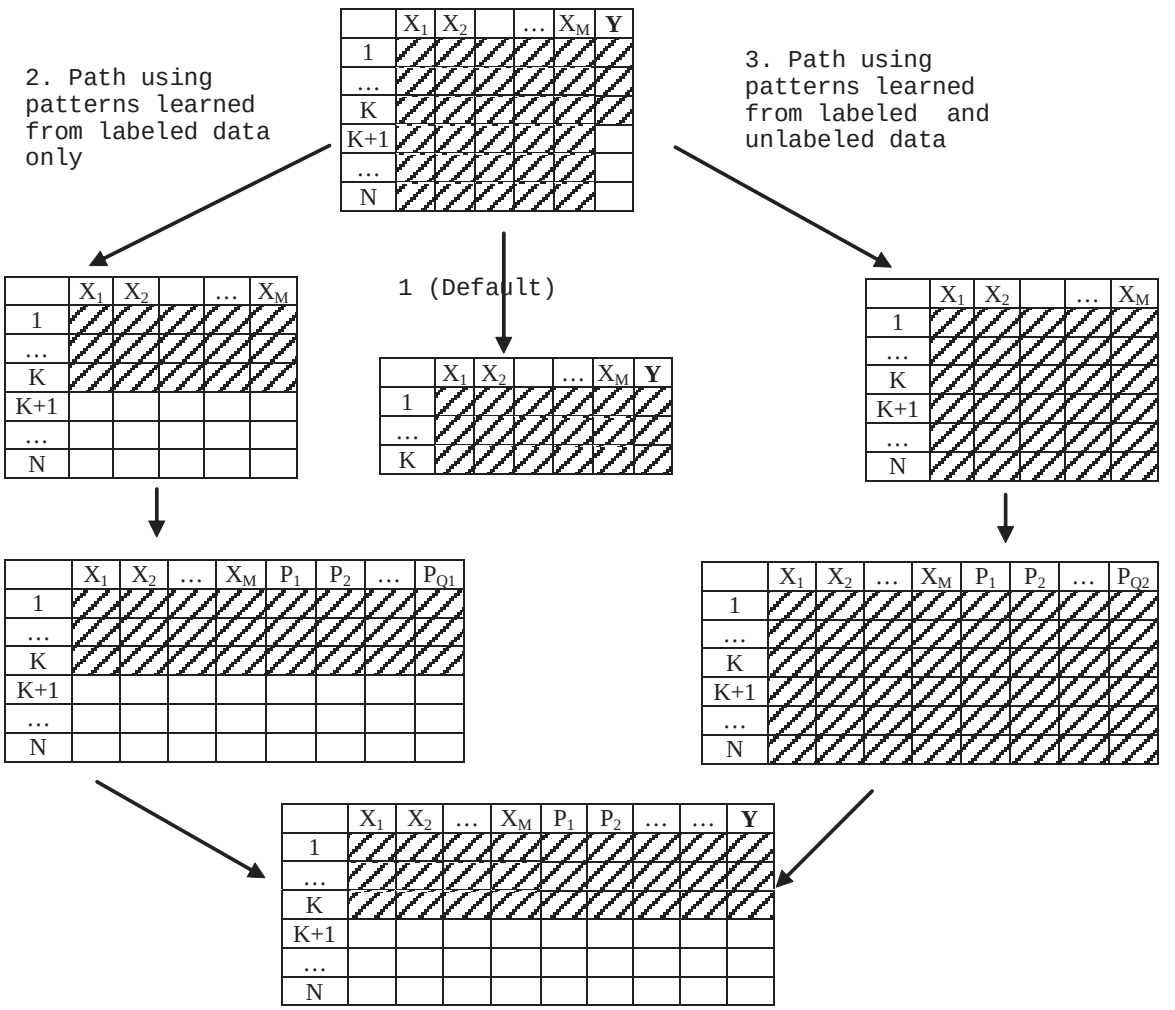

Figure 2. A generic algorithm for using patterns to exploit unlabeled data for classification

Input: Labeled data $D_L = \{t_1, t_2, \ldots, t_k\}$, Unlabeled data $D_{UL} = \{t_{k+1}, t_{k+2}, \ldots, t_N\}$, Pattern Discovery Procedure Γ, Classifier M, Feature Selection Procedure F.

Output: A specific classification model m.

1. $D = D_L \cup D_{UL}$ /* combine unlabeled with labeled data for pattern discovery */
2. Let $P = \Gamma(D)$ /* learn patterns among the explanatory variables */
3. $Q_2 = |P|$ /* index corresponds to path 3 in figure 1 */
4. For all $t_i \in D_L$ {
5. $t_i = t_i \cup \{b_1, b_2, \ldots, b_{Q2}\}$
   where b_j=1 if pattern $p_j \in P$ is present in t_i or b_j=0 otherwise
6. } /* all transactions in labeled data are now augmented with features learned from the combined data */
7. $D_{new} = F(D_L)$
8. $m = M(D_{new})$
9. output m

these patterns is useful in predicting the desired target variable. These two observations actually form the basis for a large body of work on feature construction or feature discovery (Fawcett 1993). Third, given the large search space of interactions, having more data will typically help in learning a more stable (or true) set of patterns. Hence for applications where there is a lot of unlabeled data, learning patterns from the entire data and then building a model is likely to make effective use of all available data. This is based on similar ideas (but not specific to patterns) in the literature that vast unlabeled data is often more likely to be representative of a general true underlying distribution than limited labeled data (Seeger 2001, Peng et al. 2003).

The method is formalized in Figure 2 Steps 1-3 learn the set of patterns using combined data. Steps 4-6 create new binary features in the data corresponding to the patterns learned. Given that this may result in a large number of variables created, step 7 applies a feature selection procedure to select the relevant features before the model is built (step 8).

In order to test if our approach really does exploit the unlabeled data, we highlight alternative approaches in Figure 1. The main comparison should be done with the path on the left (#2), that uses exactly the same process outlined above, except that even the process of learning patterns is only done using only the labeled data – hence this approach also uses patterns for feature construction, but does not use any unlabeled data. Path #1 in the middle is a "default" approach where the labeled data given is directly used to build the model.

To implement the method presented in Section 2 we chose itemsets (Agrawal et al 1995) as the representation for patterns and use standard itemset discovery algorithms to learn the patterns; we also use J4.8, a standard decision tree model in the open source data mining package weka , as the underlying classifier.

We use Web browsing datasets in these experiments. Each dataset consists of a set of sessions from different users mixed together, and the target variable in these is to predict the user corresponding to each session. To generate these datasets we randomly pick and combine (known) user sessions from a master database of user sessions. Note that most Web sites have some user sessions in which they know exactly who the user was (perhaps where the user signed in, made a purchase, or came in with an old cookie), but they also have several (unlabeled) sessions in which user activity is observed without precise identifying information on the user, and hence this particular application also falls under the general type of problems motivated in the introduction.

We compare three ways of building predictive models:

M1: The "default" method, where just the original attributes are used as independent variables.
M2: This is path #2 in Figure 1 where patterns, and features, are generated only from labeled data.
M3: This is path #3 in Figure 1 where both the labeled and unlabeled data were used as described.

The difference between M2 and M3 is that in M3 the frequent patterns are generated from the entire data set, including both labeled and unlabeled data. Hence this difference represents how well the unlabeled data was used. For each dataset we vary the percentage of labeled data assumed to be available to test how the method performs for different amounts of labeled/unlabeled data. The detailed results can be found in Yang & Padmanabhan (2007). On average the improvement is significant in all cases, and the improvement is significant mostly when the amount of labeled data is low. This corresponds well to the observation that when there is enough labeled data to measure the interactions appropriately then unlabeled data is less likely to be useful. Also when the average model accuracy on unlabeled data is high, the improvements are likely to be lower (since all the models perform well), but when the accuracy on unlabeled data is low, the improvement is greater. There are also a few negative numbers for the improvements, and this is certainly possible due to the specific sample, dataset and model built. While these results suggest the potential benefits that can be had in using unlabeled data when the percentage of labeled data is low, certainly further experiments across a larger number of datasets and with multiple runs are needed to get a more complete picture of the benefits and the exact circumstances in which the unlabeled data is useful.

FUTURE TRENDS

The problem of exploiting unlabeled data is relatively new, and is one that can have several applications. For instance, the co-training method was really motivated by the fact that millions of unlabeled Web pages exist and can be used in models. In marketing such situations arise when firms have a database of (potentially) millions of individuals to, say, offer a credit card to, but their labeled data may consist of a much smaller set of customers. While the potential of using unlabeled data exists, much research is needed to understand the specific circumstances when it should be used, and the specific methods for exploiting unlabeled data that should be used.

CONCLUSION

There are situations with a large amount of unlabeled data and a small amount of labeled data. Using only labeled data to build classification models can potentially ignore useful information contained in the unlabeled data. How to leverage the information contained in the unlabeled data to help improve the accuracy of the classification model is an important research question. Prior research on learning with unlabeled data focuses either on selecting unlabeled data to acquire labels, or use models built on labeled data to assign labels to unlabeled data. After discussing various approaches in handling unlabeled data for more accurate classification, this chapter focuses on one approach which augments the features of the labeled data to capture information in the unlabeled data in order to achieve higher classification accuracy. The problem of exploiting unlabeled data is relatively new, and is one that can have a wide variety of applications. Further research is needed to understand unaddressed issues for leveraging unlabeled data for more accurate classification.

KEY TERMS

Active Learning: It's a goal-directed data acquisition method for incomplete data. The usual scenario considered in active learning is that all explanatory variables are known, but the value for the target variable is often unknown and expensive to acquire. The problem is to determine which points to acquire this target value from with the specific goal of improving model performance at manageable cost.

Classification: Classification is a form of data analysis that can be used to extract classification models to predict categorical class labels.

Decision Tree: It's a predictive model. In the produced tree structure, leaves represent classifications and branches represent conjunction of features that lead to those classifications.

EM Algorithm: It's used in statistics for finding maximum likelihood estimates of parameters in probabilistic models, where the model depends on unobserved latent variables.

Itemset: A set of items. It's often used in association rule mining. The occurrence frequency of an itemset (a set of items) is the number of transactions that contain the itemset.

Labeled Data: If a data record has a known value for its class label, this data record is called a labeled data.

Unlabeled Data: If the value for a data record's class is unknown, it's called an unlabeled data.

Locally Adaptive Techniques for Pattern Classification

Carlotta Domeniconi

Dimitrios Gunopulos
University of California, USa

INTRODUCTION

Pattern classification is a very general concept with numerous applications ranging from science, engineering, target marketing, medical diagnosis and electronic commerce to weather forecast based on satellite imagery. A typical application of pattern classification is mass mailing for marketing. For example, credit card companies often mail solicitations to consumers. Naturally, they would like to target those consumers who are most likely to respond. Often, demographic information is available for those who have responded previously to such solicitations, and this information may be used in order to target the most likely respondents. Another application is electronic commerce of the new economy. E-commerce provides a rich environment to advance the state-of-the-art in classification because it demands effective means for text classification in order to make rapid product and market recommendations.

Recent developments in data mining have posed new challenges to pattern classification. Data mining is a knowledge discovery process whose aim is to discover unknown relationships and/or patterns from a large set of data, from which it is possible to predict future outcomes. As such, pattern classification becomes one of the key steps in an attempt to uncover the *hidden knowledge* within the data. The primary goal is usually predictive accuracy, with secondary goals being speed, ease of use, and interpretability of the resulting predictive model.

While pattern classification has shown promise in many areas of practical significance, it faces difficult challenges posed by real world problems, of which the most pronounced is Bellman's *curse of dimensionality*: it states the fact that the sample size required to perform accurate prediction on problems with high dimensionality is beyond feasibility. This is because in high dimensional spaces data become extremely sparse and are apart from each other. As a result, severe bias that affects any estimation process can be introduced in a high dimensional feature space with finite samples.

Learning tasks with data represented as a collection of a very large number of features abound. For example, microarrays contain an overwhelming number of genes relative to the number of samples. The Internet is a vast repository of disparate information growing at an exponential rate. Efficient and effective document retrieval and classification systems are required to turn the ocean of bits around us into useful information, and eventually into knowledge. This is a challenging task, since a word level representation of documents easily leads 30000 or more dimensions.

This chapter discusses classification techniques to mitigate the curse of dimensionality and reduce bias, by estimating feature relevance and selecting features accordingly. This issue has both theoretical and practical relevance, since many applications can benefit from improvement in prediction performance.

BACKGROUND

In a classification problem an observation is characterized by q feature measurements $\boldsymbol{x} = \left(x_1, \cdots, x_q\right) \in \Re^q$ and is presumed to be a member of one of J classes, L_j, $j = 1, \cdots, J$. The particular group is unknown, and the goal is to assign the given object to the correct group using its measured features $\boldsymbol{x}$.

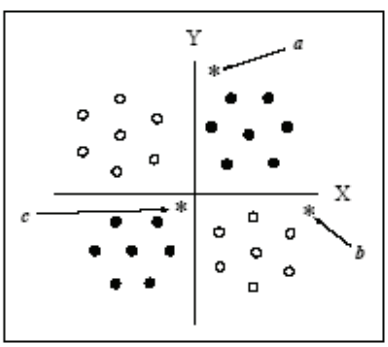
Feature relevance has a *local* nature. Therefore, any chosen fixed metric violates the assumption of locally constant class posterior probabilities, and fails to make correct predictions in different regions of the input space. In order to achieve accurate predictions, it becomes crucial to be able to estimate the different degrees of relevance that input features may have in various locations of the feature space.

Consider, for example, the rule that classifies a new data point with the label of its closest training point in the measurement space (*1-Nearest Neighbor rule*). Suppose each instance is described by 20 features, but only three of them are relevant to classifying a given instance. In this case, two points that have identical values for the three relevant features may nevertheless be distant from one another in the 20-dimensional input space. As a result, the similarity metric that uses all 20 features will be misleading, since the distance between neighbors will be dominated by the large number of irrelevant features. This shows the effect of the curse of dimensionality phenomenon, that is, in high dimensional spaces distances between points within the same class or between different classes may be similar. This fact leads to highly biased estimates. Nearest neighbor approaches (Ho, 1998; Lowe, 1995) are especially sensitive to this problem.

In many practical applications things are often further complicated. In the previous example, the three relevant features for the classification task at hand may be dependent on the location of the query point, i.e. the point to be classified, in the feature space. Some features may be relevant within a specific region, while other features may be more relevant in a different region. Figure 1 illustrates a case in point, where class boundaries are parallel to the coordinate axes. For query *a*, dimension *X* is more relevant, because a slight move along the *X* axis may change the class label, while for query *b*, dimension *Y* is more relevant. For query *c*, however, both dimensions are equally relevant.

These observations have two important implications. Distance computation does not vary with equal strength or in the same proportion in all directions in the feature space emanating from the input query. Moreover, the value of such strength for a specific feature may vary from location to location in the feature space. Capturing such information, therefore, is of great importance to any classification procedure in high dimensional settings.

Figure 1. Feature relevance varies with query locations



MAIN THRUST

Severe bias can be introduced in pattern classification in a high dimensional input feature space with finite samples. In the following we introduce adaptive metric techniques for distance computation, capable of reducing the bias of the estimation.

Friedman (Friedman, 1994) describes an adaptive approach (the Machete and Scythe algorithms) for classification that combines some of the best features of kNN learning and recursive partitioning. The resulting hybrid method inherits the flexibility of recursive partitioning to adapt the shape of the neighborhood $N(\mathbf{x}_0)$ of query $(\mathbf{x}_0)$, as well as the ability of nearest neighbor techniques to keep the points within $N(\mathbf{x}_0)$ close to the point being predicted. The method is capable of producing nearly continuous probability estimates with the region $N(\mathbf{x}_0)$ centered at $(\mathbf{x}_0)$, and the shape of the region separately customized for each individual prediction point.

The major limitation concerning the Machete/Scythe method is that, like recursive partitioning methods, it applies a "greedy" strategy. Since each split is conditioned on its "ancestor" split, minor changes in an early split, due to any variability in parameter estimates, can have a significant impact on later splits, thereby producing different terminal regions. This makes the predictions highly sensitive to the sampling fluctuations associated with the random nature of the process that produces the training data, and therefore may lead to high variance predictions.

In (Hastie & Tibshirani, 1996), the authors propose a discriminant adaptive nearest neighbor classification method (DANN) based on linear discriminant analysis. Earlier related proposals appear in (Myles & Hand, 1990; Short & Fukunaga, 1981). The method in (Hastie & Tibshirani, 1996) computes a local distance metric as a product of weighted within and between sum of squares matrices. The authors also describe a method to perform global dimensionality reduction, by pooling the local dimension information over all points in

the training set (Hastie & Tibshirani, 1996; Hastie & Tibshirani, 1996a).

While sound in theory, DANN may be limited in practice. The main concern is that in high dimensions one may never have sufficient data to fill in $q \times q$ (within and between sum of squares) matrices (where q is the dimensionality of the problem). Also, the fact that the distance metric computed by DANN approximates the weighted *Chi-squared* distance only when class densities are Gaussian and have the same covariance matrix may cause a performance degradation in situations where data do not follow Gaussian distributions or are corrupted by noise, which is often the case in practice.

A different adaptive nearest neighbor classification method (ADAMENN) has been introduced to try to minimize bias in high dimensions (Domeniconi, Peng, & Gunopulos, 2002), and to overcome the above limitations. ADAMENN performs a *Chi-squared* distance analysis to compute a flexible metric for producing neighborhoods that are highly adaptive to query locations. Let $\mathbf{x}$ be the nearest neighbor of a query $\mathbf{x}_0$ computed according to a distance metric $D(\mathbf{x},\mathbf{x}_0)$. The goal is to find a metric $D(\mathbf{x},\mathbf{x}_0)$ that minimizes $E[r(\mathbf{x},\mathbf{x}_0)]$, where $r(\mathbf{x}_0,\mathbf{x}) = \sum_{j=1}^{J} \Pr(j \mid \mathbf{x}_0)(1-\Pr(j \mid \mathbf{x}))$. Here $\Pr(j|\mathbf{x})$ is the class conditional probability at $\mathbf{x}$. That is, $r(\mathbf{x}_0,\mathbf{x})$ is the finite sample error risk given that the nearest neighbor to $\mathbf{x}_0$ by the chosen metric is $\mathbf{x}$. It can be shown (Domeniconi, Peng, & Gunopulos, 2002) that the weighted *Chi-squared* distance

$$D(\mathbf{x},\mathbf{x}_0) = \sum_{j=1}^{J} \frac{[\Pr(j \mid \mathbf{x}) - \Pr(j \mid \mathbf{x}_0)]^2}{\Pr(j \mid \mathbf{x}_0)}. \quad (1)$$

approximates the desired metric, thus providing the foundation upon which the ADAMENN algorithm computes a measure of local feature relevance, as shown below.

The first observation is that $\Pr(j|\mathbf{x})$ is a function of $\mathbf{x}$. Therefore, one can compute the conditional expectation of $\Pr(j|\mathbf{x})$, denoted by $\overline{\Pr}(j \mid x_i = z)$, given that x_i assumes value z, where x_i represents the ith component of $\mathbf{x}$. That is, $\overline{\Pr}(j \mid x_i = z) = E[\Pr(j \mid \mathbf{x}) \mid x_i = z] = \int \Pr(j \mid \mathbf{x})\, p(\mathbf{x} \mid x_i = z) d\mathbf{x}$. Here $p(\mathbf{x}|x_i = z)$ is the conditional density of the other input variables defined as $p(\mathbf{x} \mid x_i = z) = p(\mathbf{x})\delta(x_i - z) / \int p(\mathbf{x})\delta(x_i - z) d\mathbf{x}$, where $\delta(x-z)$ is the Dirac delta function having the properties $\delta(x-z) = 0$ *if* $x \neq z$ and $\int_{-\infty}^{\infty} \delta(x-z)dx = 1$. Let

$$r_i(\mathbf{z}) = \sum_{j=1}^{J} \frac{[\Pr(j \mid \mathbf{z}) - \overline{\Pr}(j \mid x_i = z_i)]^2}{\overline{\Pr}(j \mid x_i = z_i)}. \quad (2)$$

$r_i(\mathbf{z})$ represents the ability of feature i to predict the $\Pr(j|\mathbf{z})$ s at $x_i = z_i$. The closer $\overline{\Pr}(j \mid x_i = z_i)$ is to $\Pr(j|\mathbf{z})$, the more information feature i carries for predicting the class posterior probabilities locally at $\mathbf{z}$.

We can now define a measure of feature relevance for $\mathbf{x}_0$ as

$$\bar{r}_i(\mathbf{x}_0) = \frac{1}{K} \sum_{\mathbf{z} \in N(\mathbf{x}_0)} r_i(\mathbf{z}), \quad (3)$$

where $N(\mathbf{x}_0)$ denotes the neighborhood of $\mathbf{x}_0$ containing the K nearest training points, according to a given metric. $\bar{r}_i$ measures how well on average the class posterior probabilities can be approximated along input feature i within a local neighborhood of $\mathbf{x}_0$. Small $\bar{r}_i$ implies that the class posterior probabilities will be well approximated along dimension i in the vicinity of $\mathbf{x}_0$. Note that $\bar{r}_i(\mathbf{x}_0)$ is a function of both the test point $\mathbf{x}_0$ and the dimension i, thereby making $\bar{r}_i(\mathbf{x}_0)$ a local relevance measure in dimension i.

The relative relevance, as a weighting scheme, can then be given by $w_i(\mathbf{x}_0) = \frac{R_i(\mathbf{x}_0)^t}{\sum_{l=1}^{q} R_l(\mathbf{x}_0)^t}$, where $t = 1,2$, giving rise to linear and quadratic weightings respectively, and $R_i(\mathbf{x}_0) = \max_{j=1}^{q}\{\bar{r}_j(\mathbf{x}_0)\} - \bar{r}_i(\mathbf{x}_0)$ (i.e., the larger the R_i, the more relevant dimension i). We propose the following exponential weighting scheme

$$w_i(\mathbf{x}_0) = \exp(cR_i(\mathbf{x}_0)) / \sum_{l=1}^{q} \exp(cR_l(\mathbf{x}_0)) \quad (4)$$

where c is a parameter that can be chosen to maximize (minimize) the influence of $\bar{r}_i$ on w_i. When $c = 0$ we have $w_i = 1/q$, which has the effect of ignoring any difference among the $\bar{r}_i$'s. On the other hand, when c is large a change in $\bar{r}_i$ will be exponentially reflected in w_i. The exponential weighting is more sensitive to changes in local feature relevance and in general gives rise to better performance improvement. In fact, it is more stable because it prevents neighborhoods from extending infinitely in any direction, i.e., zero weight. This, however, can occur when either linear or quadratic weighting is used. Thus, equation (4) can be used to compute the weight associated with each feature, resulting in the weighted distance computation:

$$D(\mathbf{x},\mathbf{y}) = \sqrt{\sum_{i=1}^{q} w_i (x_i - y_i)^2}. \quad (5)$$

The weights $\mathbf{w}_i$ enable the neighborhood to elongate less important feature dimensions, and, at the same time, to constrict the most influential ones. Note that the technique is *query-based* because the weights depend on the query (Aha, 1997; Atkeson, Moore, & Shaal, 1997).

An intuitive explanation for (2) and, hence, (3), goes as follows. Suppose that the value of $r_i(\mathbf{z})$ is small, which implies a large weight along dimension *i*. Consequently, the neighborhood is shrunk along that direction. This, in turn, penalizes points along dimension *i* that are moving away from z_i. Now, $r_i(\mathbf{z})$ can be small only if the subspace spanned by the other input dimensions at $x_i = z_i$ likely contains samples similar to $\mathbf{z}$ in terms of the class conditional probabilities. Then, a large weight assigned to dimension *i* based on (4) says that moving away from the subspace, hence from the data similar to $\mathbf{z}$, is not a good thing to do. Similarly, a large value of $r_i(\mathbf{z})$, hence a small weight, indicates that in the vicinity of z_i along dimension *i* one is unlikely to find samples similar to $\mathbf{z}$. This corresponds to an elongation of the neighborhood along dimension *i*. Therefore, in this situation in order to better predict the query, one must look farther away from z_i.

One of the key differences between the relevance measure (3) and Friedman's is the first term in the squared difference. While the class conditional probability is used in (3), its expectation is used in Friedman's. This difference is driven by two different objectives: in the case of Friedman's, the goal is to seek a dimension along which the expected variation of $\Pr(j|\mathbf{x})$ is maximized, whereas in (3) a dimension is found that minimizes the difference between the class probability distribution for a given query and its conditional expectation along that dimension (2). Another fundamental difference is that the machete/scythe methods, like recursive partitioning, employ a greedy peeling strategy that removes a subset of data points permanently from further consideration. As a result, changes in an early split, due to any variability in parameter estimates, can have a significant impact on later splits, thereby producing different terminal regions. This makes predictions highly sensitive to the sampling fluctuations associated with the random nature of the process that produces the training data, thus leading to high variance predictions. In contrast, ADAMENN employs a "patient" averaging strategy that takes into account not only the test point $\mathbf{x}_0$ itself, but also its K_0 nearest neighbors. As such, the resulting relevance estimates (3) are in general more robust and have the potential to reduce the variance of the estimates.

In (Hastie & Tibshirani, 1996), the authors show that the resulting metric approximates the weighted *Chi-squared* distance (1) by a Taylor series expansion, given that class densities are Gaussian and have the same covariance matrix. In contrast, ADAMENN does not make such assumptions, which are unlikely in real world applications. Instead, it attempts to approximate the weighted *Chi-Squared* distance (1) directly. The main concern with DANN is that in high dimensions we may never have sufficient data to fill in $q \times q$ matrices. It is interesting to note that the ADAMENN algorithm can potentially serve as a general framework upon which to develop a unified adaptive metric theory that encompasses both Friedman's work and that of Hastie and Tibshirani.

FUTURE TRENDS

Almost all problems of practical interest are high dimensional. With the recent technological trends, we can expect an intensification of research effort in the area of feature relevance estimation and selection. In bioinformatics, the analysis of microarray data poses challenging problems. Here one has to face the problem of dealing with more dimensions (genes) than data points (samples). Biologists want to find "marker genes" that are differentially expressed in a particular set of conditions. Thus, methods that simultaneously cluster genes and samples are required to find distinctive "checkerboard" patterns in matrices of gene expression data. In cancer data, these checkerboards correspond to genes that are up- or down-regulated in patients with particular types of tumors. Increased research effort in this area is needed and expected.

Clustering is not exempted from the curse of dimensionality. Several clusters may exist in different subspaces, comprised of different combinations of features. Since each dimension could be relevant to at least one of the clusters, global dimensionality reduction techniques are not effective. We envision further investigation on this problem with the objective of developing robust techniques in presence of noise.

Recent developments on kernel-based methods suggest a framework to make the locally adaptive techniques discussed above more general. One can perform feature relevance estimation in an induced

feature space, and then use the resulting kernel metrics to compute distances in the input space. The key observation is that kernel metrics may be non-linear in the input space, but are still linear in the induced feature space. Hence, the use of suitable non-linear features allows the computation of locally adaptive neighborhoods with arbitrary orientations and shapes in input space. Thus, more powerful classification techniques can be generated.

CONCLUSIONS

Pattern classification faces a difficult challenge in finite settings and high dimensional spaces due to the curse of dimensionality. In this chapter we have presented and compared techniques to address data exploration tasks such as classification and clustering. All methods design adaptive metrics or parameter estimates that are local in input space in order to dodge the curse of dimensionality phenomenon. Such techniques have been demonstrated to be effective for the achievement of accurate predictions.

KEY TERMS

Classification: The task of inferring concepts from observations. It is a mapping from a measurement space into the space of possible meanings, viewed as finite and discrete target points (class labels). It makes use of training data.

Clustering: The process of grouping objects into subsets, such that those within each cluster are more closely related to one another than objects assigned to different clusters, according to a given similarity measure.

Curse of Dimensionality: Phenomenon that refers to the fact that in high dimensional spaces data become extremely sparse and are far apart from each other. As a result, the sample size required to perform an accurate prediction in problems with high dimensionality is usually beyond feasibility.

Kernel Methods: Pattern analysis techniques that work by embedding the data into a high dimensional vector space, and by detecting linear relations in that space. A kernel function takes care of the embedding.

Local Feature Relevance: Amount of information that a feature carries to predict the class posterior probabilities at a given query.

Nearest Neighbor Methods: Simple approach to the classification problem. It finds the *K* nearest neighbors of the query in the training set, and then predicts the class label of the query as the most frequent one occurring in the *K* neighbors.

Pattern: A structure that exhibits some form of regularity, able to serve as a model representing a concept of what was observed.

Recursive Partitioning: Learning paradigm that employs local averaging to estimate the class posterior probabilities for a classification problem.

Subspace Clustering: Simultaneous clustering of both row and column sets in a data matrix.

Training Data: Collection of observations (characterized by feature measurements), each paired with the corresponding class label.

INTRODUCTION

Systems biology aims to understand biological systems on a comprehensive scale, such that the components that make up the whole are connected to one another and work in harmony. As a major component of systems biology, differential proteomics studies the differences between distinct but related proteomes such as normal versus diseased cells and diseased versus treated cells. High throughput mass spectrometry (MS) based analytical platforms are widely used in differential proteomics (Domon, 2006; Fenselau, 2007). As a common practice, the proteome is usually digested into peptides first. The peptide mixture is then separated using multidimensional liquid chromatography (MDLC) and is finally subjected to MS for further analysis. Thousands of mass spectra are generated in a single experiment. Discovering the significantly changed proteins from millions of peaks involves mass informatics. This paper introduces data mining steps used in mass informatics, and concludes with a descriptive examination of concepts, trends and challenges in this rapidly expanding field.

BACKGROUND

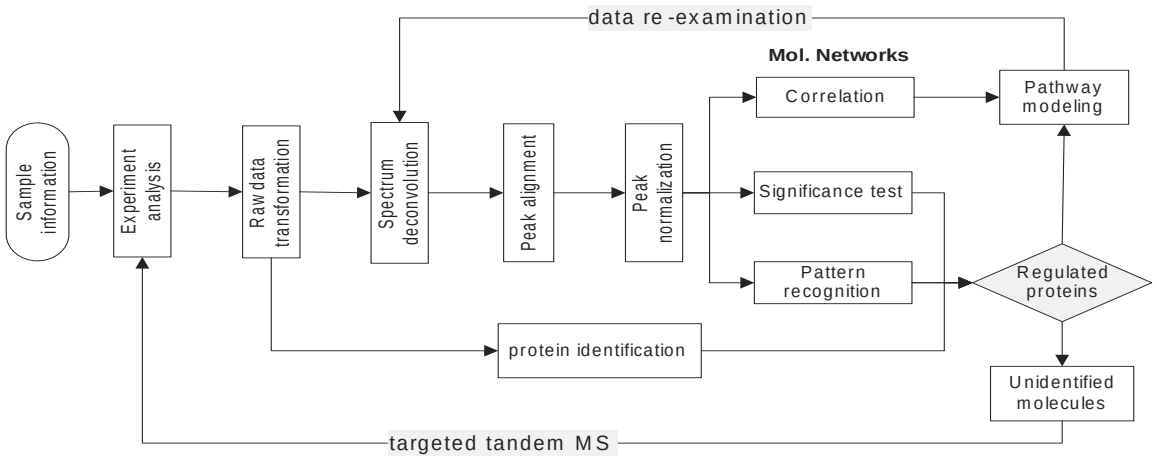
Proteomics was initially envisioned as a technique to globally and simultaneously characterize all components in a proteome. In recent years, a rapidly emerging set of key technologies is making it possible to identify large numbers of proteins in a mixture or complex, to map their interactions in a cellular context, and to analyze their biological activities. Several MS based technologies have emerged for identifying large numbers of proteins expressed in cells and globally detecting the differences in levels of proteins in different cell states (Asara, 2006).

Due to the complexity of the proteome, a major effort in proteomics research is devoted to fractionation of proteins and peptides prior to MS. One way to fractionate peptide mixtures to the extent required for MS analysis of the component peptides is to couple multiple chromatography columns in tandem (Hattan, 2005; Qui, 2007). The fractionated peptide mixture is then subjected to MS for further separation and mass analysis. Thousands of mass spectra will be generated in a single differential proteomics experiment. Mass informatics is involved in identifying the significantly changed proteins from millions of peptide peaks.

DATA MINING FRAMEWORK

A variety of mass spectrometers are commercially available. Each of these mass spectrometers stores raw mass spectra in a proprietary format. The raw spectra have to be transformed into common data format first. As in any study of biological phenomena, it is crucial that only relevant observations are identified and related to each other. The interpretation and comprehension of the collection of mass spectra presents major challenges and involve several data mining steps. The aim of mass informatics is to reduce data dimensionality and to extract relevant knowledge from thousands of mass spectra (Arneberg, 2007). Figure 1 shows an overall framework for mass informatics in differential proteomics. Most of the components of this framework

Figure 1. Information flow chart in differential proteomics



will be discussed in this paper with the exception of the pathway modeling.

Spectra Deconvolution

The purpose of spectra deconvolution is to differentiate signals arising from the real analyte as opposed to signals arising from contaminants or instrumental noise, and to reduce data dimensionality which will benefit down stream statistical analysis. Therefore, spectra deconvolution extracts peak information from thousands of raw mass spectra. The peak information is reported in a simple peak table. As an example, GISTool (Zhang, 2005a) is a software package using chemical noise filtering, charge state fitting, and de-isotoping for the analysis of complex peptide samples. Overlapping peptide signals in mass spectra are deconvoluted by correlating the observed spectrum with modeled peptide isotopic peak profiles. Isotopic peak profiles for peptides were generated *in silico* from a protein database producing reference model distributions. Several other spectra deconvolution packages such as RelEx (MacCoss, 2003), MSQuant (http://msquant.sourceforge.net/), and ASAPRatio (Li, 2003) have been developed to find quantitative information about proteins and peptides.

Protein Identification

Two methods are currently used for protein identification: database searching and *de novo* sequencing. Database searching correlates the spectra with protein sequences. The database-searching algorithm starts with spectrum reduction to remove chemical noise. A list of peptides is generated *in silico* from the protein database using enzyme specificity. After applying potential chemical modifications, *in silico* peptides that have similar molecular weight to the precursor ions of tandem mass spectrum (MS/MS) are selected as candidate peptides. A theoretical spectrum is then created for each candidate peptide and these theoretical spectra are compared with the experimental spectrum. A final ranking list is generated using different scoring functions. Disadvantages of the database searching strategy are very well understood: the protein of interest might not be present in the sequence database, prediction errors are present in gene-finding programs, the protein database may not be available in some cases, genes might undergo alternative splicing resulting in novel proteins, and amino acids may mutate and undergo unknown modifications. SEQUEST (Eng, 1994) and MASCOT (Perkins, 1999) are two database searching software packages used most frequently.

de novo sequencing derives the peptide sequence directly from the tandem mass spectrum (Kanazawa, 2007). Lutefisk (Taylor, 1997) is a popular *de novo*

sequencing software. The Lutefisk algorithm translates the spectrum into a "spectrum graph" where the nodes in the graph correspond to peaks in the spectrum; two nodes are connected by an edge if the mass difference between the two corresponding peaks is equal to the mass of an amino acid. The software then attempts to find a path that connects the N- and C-termini, and to connect all the nodes corresponding to the y-ions or b-ions. After all the sequences are obtained, a scoring procedure is used to rank the sequences. The advantage of *de novo* sequencing is that it does not rely on a protein database. However, it requires high mass accuracy. Furthermore, it cannot correctly assign peptides because of amino acid mass equivalence.

Peak Alignment

Ideally, the same peptide detected on the same analytical system should have the same value of the measurement. For example, if a peptide is measured on a liquid chromatography mass spectrometry (LC-MS) system, retention time and molecular weight of this peptide, in different samples, should be the same. However, this may not be the case due to experimental variation. The objective of peak alignment is to recognize peaks of the same molecule occurring in different samples from millions of peaks detected during the course of an experiment. XAlign software (Zhang, 2005b) uses a two-step alignment approach. The first step addresses systematic retention time shift by recognizing and aligning significant peaks. A significant peak refers to a peak that is present in every sample and is the most intense peak in a certain m/z and retention time range. Discrete convolution is used in the second step to align overlapped peaks. The other alignment software packages include LCMSWARP (Jaitly, 2006) and PETAL (Wang, 2007).

Normalization

To allow multi-experiment analyses, it is important to first normalize the data to make the samples comparable. Normalization step targets to quantitatively filter overall peak intensity variations due to experimental errors such as varying amounts of samples loaded onto LC-MS. Several normalization methods have been proposed. One is to choose an analysis run as reference and individually normalize all others relative to this reference, one at a time (Wang, 2003). The intensity ratio of each aligned peak pair of a given analysis run and the reference is calculated. The normalization constant for the analysis run being considered is then taken as the median of the ratios of intensities for all components between the analysis run in question and the reference analysis run. Zhu et al. normalized the MS data by dividing the intensity at each m/z value by the average intensity of the entire spectrum (Zhu, 2003). The log linear model method (Hartemink, 2001) assumes primarily multiplicative variation. The maximum likelihood and maximum *a posteriori* estimates for the parameters characterizing the multiplicative variation were derived to compute the scaling factors needed for normalization.

Statistical Significance Test

The purpose of statistical significance test is to identify peptide peaks that make significant contributions to the protein profile of a sample, or that distinguish a group of samples from others. The procedure can be summarized into the following criteria for biomarker discovery:

Qualitative analysis for significant peaks that are present in one group but not in the other. Qualitative difference indicates the situation in which a peak is present only in few samples, e.g. less than 50% of the samples, in one group but is present in most of the samples in the other group. In this situation, a binary variable is used to denote the presence of this peak in each sample. The comparison between two groups is then performed through a contingency table, whose columns and rows correspond to groups versus presence/absence, respectively. A chi-square test provides an adequate test statistic about whether the presence of this peak is significantly different between the two groups or not.

Statistical tests for quantitatively different peaks between two groups. In addition to qualitative differences, some peaks may be present in multiple sample groups but their intensity might differ between the groups. The quantitative difference indicates the situation in which a peak is present in most (or all) of the samples, but has different intensities between the groups. In this situation, the standard two-sample t-test or the Wilcoxon-Mann-Whitney rank test can be used to compare the group differences.

Pattern Recognition

Many types of pattern recognition systems fall into two main categories, supervised and unsupervised. Supervised systems require knowledge or data in which the outcome or classification is known ahead of time, so that the system can be trained to recognize and distinguish outcomes. Unsupervised systems cluster or group records without previous knowledge of outcome or classification.

The most frequently used approach of unsupervised pattern recognition is principal component analysis (PCA). PCA's main function is to reduce dimensions of the multivariate, multi-channeled data to a manageable subset, a new set of uncorrelated variables called principle components (PCs). These PCs serves as an approximation to the original data and allows an analyst to overview the data in the reduced dimension space and study the major constituents of the overall variability in the data. Other unsupervised methods include hierarchical clustering, k-means, and self organizing maps (SOM).

Many algorithms perform supervised learning, such as discriminant function analysis, partial least square, artificial neural networks, nearest-neighbor. The most popular supervised learning system used in differential proteomics is support vector machine (SVM). The SVM is fundamentally a binary classifier. It operates by mapping the given training set into a possible high-dimensional feature space and attempting to locate in that space a hyperplane that separates the positive examples from the negative ones. Having found such a plane, the SVM can then predict the classification of an unlabeled example by mapping it into the feature space and determining on which side of the separating plane the example lies. Much of the SVM's power comes from its criterion for selecting a separating hyperplane when candidate planes exist: the SVM chooses the plane that maintains a maximum margin from any point in the training set.

Protein Correlation Networks

Protein correlation studies the relationships between protein concentrations. For example, two proteins will have a negative correlation if the concentration of one protein increases while the other decreases in the same sample. Protein correlation not only reveal important relationships among the various proteins, but also provides information about the biochemical processes underlying the disease or drug response. Correlations of biological molecules may be linear or non-linear in nature; a common evaluation approach is to estimate molecular correlations by calculating the Pearson's correlation coefficient.

Interactive visualization of protein correlation networks is one of the major informatic components in differential proteomic data analysis. Many software packages have been developed for interactive visualization such as Cytoscape (Shannon, 2003), Graphviz (http://www.graphviz.org/), CFinder (Adamcsek, 2006), and Tom Sawyer (http://www.tomsawyer.com). These programs can be used to display protein correlation networks. However, these software packages are limited in providing data mining capability. SysNet (Zhang, 2007) is an interactive visual data mining application for 'omics expression data analysis, which is able to integrate molecular expression data obtained from different 'omics experiments, interactively analyze intermolecular correlations using different statistical models, and perform interactive analysis of time lapse data to assess molecular evolution.

FUTURE TRENDS AND CHALLENGES

The study of differential proteomics has much to offer to scientists with high confidence. Intelligent data mining facilities, however, still need to be developed to prevent important results from being lost in the massive information. There is much less work done in bridging the wet laboratory research and data mining. This kind of research includes experimental design, quality assurance, preliminary data analysis, etc. Differential proteomics also requires informatics tools to accurately and rapidly query databases to select relevant results. Biological databases are characterized by large quantities of data exhibiting different characteristics, e.g. data models, attributes grouping, and semantics. The technology to organize, search, integrate, and evolve these sources has not kept pace with the rapid growth of the available information space. Scientists usually go from one database to another and manually query them and consolidate the results of their queries. The efficient sharing of data is especially challenging in such environments where the information sources are largely autonomous, heterogeneous, fragmented and evolve dynamically.

Differential proteomics also faces challenge in high confidence protein identification. Typically ~10-20% of tandem spectra from LC-MS/MS analyses can be confidently identified while the remaining spectra are typically ignored or discarded. Several factors contribute to this inefficiency: imperfect scoring schema, criteria that constrain the protein database search, incorrect mass and charge assignment, and low-quality MS/MS spectra. To date, the physical properties of peptides exploited for peptide selection, or fractionation are not widely considered or utilized for protein identification even though these methods are routinely used in proteomics. Another problem confounding current proteomics efforts is false positive protein identifications. In the recent years, it became apparent that peptide and protein assignments obtained from protein database searches using tandem MS data were subject to the assignment of many false positives within a dataset.

Data visualization is another challenge in bioinformatics. Results in differential proteomics are extremely complicated even after data mining. Presenting findings in a way that biologists can easily understand and extract the information by themselves is crucial for the success of differential proteomics. A good example of this is bio-networks. In a single differential proteomics experiment, bio-informatician can build a bio-network that contains thousands of correlated proteins and related chemical components. It will be a nightmare for a biologist to extract useful information from this massive network unless an intelligent informatic tool is provided.

CONCLUSION

High throughput mass spectrometry based analytical platforms generate massive amount of data for differential proteomics research. Several data mining steps are involved in extracting scientific information from such data. These data mining steps include spectrum deconvolution, protein identification, peak alignment, normalization, statistical significance test, pattern recognition, and protein correlation networks. Each of these data mining steps faces a variety of challenges toward efficient and accurate data analysis. Many ongoing efforts to overcome these generic inefficiencies have achieved varying degrees of success. However, challenges in this rapidly expanding field of mass informatics are still preventing scientists from fully understanding the proteome.

KEY TERMS

Differential Proteomics: A research field that qualitatively and quantitatively compares proteomes under different conditions to further unravel biological processes.

Interactive Data Mining: A data mining process that discovers scientific knowledge through interactive communication between human and computer.

Liquid Chromatography: An analytical chromatographic technique that is useful for separating ions or molecules that are dissolved in a solvent.

Mass Informatics: Bioinformatics research that focuses on data mining of experimental data generated from mass spectrometry.

Mass Spectrometry: An analytical technique used to measure the mass-to-charge ratio of ions.

Protein Biomarkers: Naturally occurring proteins that can be used for measuring the prognosis and/or progress of diseases and therapies.

Proteome: The entire complement of proteins expressed by a genome, cell, tissue or organism at a particular time and under specific conditions.

Systems Biology: A field in biology aiming at system level understanding of biological systems by studying the interactions between their different components. It attempts to create predictive models of cells, organs, biochemical processes and complete organisms.

Materialized View Selection for Data Warehouse Design

INTRODUCTION

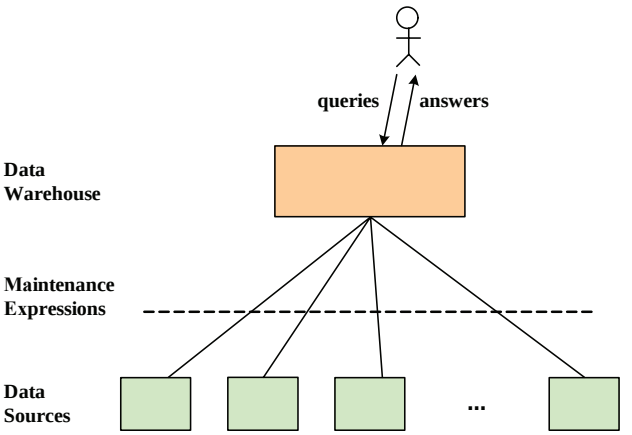
A Data Warehouse (DW) is a repository of information retrieved from multiple, possibly heterogeneous, autonomous, distributed databases and other information sources for the purpose of complex querying, analysis and decision support. Data in the DW are selectively collected from the sources, processed in order to resolve inconsistencies, and integrated in advance (at design time) before data loading. DW data are usually organized multidimensionally to support On-Line Analytical Processing (OLAP). A DW can be abstractly seen as a set of materialized views defined over the source relations. During the initial design of a DW, the DW designer faces the problem of deciding which views to materialize in the DW. This problem has been addressed in the literature for different classes of queries and views and with different design goals.

BACKGROUND

Figure 1 shows a simplified DW architecture. The DW contains a set of materialized views. The users address their queries to the DW. The materialized views are used partially or completely for evaluating the user queries. This is achieved through partial or complete rewritings of the queries using the materialized views.

When the source relations change, the materialized views need to be updated. The materialized views are usually maintained using an incremental strategy. With such a strategy, the changes to the source relations are propagated to the DW. The changes to the materialized views are computed using the changes of the source relations, and are eventually applied to the materialized views. The expressions used to compute the view changes involve the changes of the source relations,

Figure 1. A simplified DW architecture



and are called maintenance expressions. Maintenance expressions are issued by the DW against the data sources and the answers are sent back to the DW. When the source relation changes affect more than one materialized view, multiple maintenance expressions need to be evaluated. The techniques of multiquery optimization can be used to detect ``common subexpressions'' among maintenance expressions in order to derive an efficient global evaluation plan for all the maintenance expressions.

MAIN THRUST OF THE CHAPTER

When selecting views to materialize in a DW, one attempts to satisfy one or more design goals. A design goal is either the minimization of a cost function or a constraint. A constraint can be classified as user oriented or system oriented. Attempting to satisfy the constraints can result in no feasible solution to the view selection problem. The design goals determine the design of the algorithms that select views to materialize from the space of alternative view sets.

Minimization of Cost Functions

Most approaches comprise in their design goals the minimization of a cost function. The following are examples of cost functions to be minimized:

- **Query evaluation cost.** Often, the queries that the DW has to satisfy are given as input to the view selection problem. The overall query evaluation cost is the sum of the cost of evaluating each input query rewritten (partially or completely) over the materialized views. This sum can also be weighted, each weight indicating the frequency or importance of the corresponding query. Several approaches aim at minimizing the query evaluation cost (Harinarayan et al., 1996; Shukla et al 1998; Gupta & Mumick, 1999).
- **View maintenance cost.** The view maintenance cost is the sum of the cost of propagating each source relation change to the materialized views. This sum can be weighted, each weight indicating the frequency of propagation of the changes of the corresponding source relation. The maintenance expressions can be evaluated more efficiently if they can be partially rewritten over views already materialized at the DW: the evaluation of parts of the maintenance expression is avoided since their materializations are present at the DW. Moreover, access of the remote data sources and expensive data transmissions are reduced. Materialized views that are added to the DW for reducing the view maintenance cost are called *auxiliary views* (Ross et al., 1996; Theodoratos & Sellis, 1999). The auxiliary views can be materialized permanently or transiently. Transiently materialized views are used during the maintenance process and discarded afterwards (Mistry et al., 2001). Obviously, maintaining the auxiliary views incurs additional maintenance cost. However, if this cost is less than the reduction to the maintenance cost of the initially materialized views, it is worth keeping the auxiliary views in the DW. Ross et al. (1996) derive auxiliary views to permanently materialize in order to minimize the view maintenance cost.
- **Operational cost.** Minimizing the query evaluation cost and the view maintenance cost are conflicting requirements. Low view maintenance cost can be obtained by replicating source relations at the DW. In this case, though, the query evaluation cost is high since queries need to be computed from the replicas of the source relations. Low query evaluation cost can be obtained by materializing at the DW all the input queries. In this case, all the input queries can be answered by a simple lookup but the view maintenance cost is high since complex maintenance expressions over the source relations need to be computed. The input queries may overlap, that is, they may share many common subexpressions. By materializing common subexpressions and other views over the source relations, it is possible, in general, to reduce the view maintenance cost. These savings must be balanced against higher query evaluation cost. For this reason, one can choose to minimize a linear combination of the query evaluation and view maintenance cost which is called *operational cost*. Most approaches endeavor to minimize the operational cost (Gupta, 1997; Baralis et al., 1997; Yang et al., 1997; Theodoratos & Sellis, 1999).
- **Total view size.** In a distributed DW where the materialized views are stored remotely, the performance bottleneck is usually the data transmission time over the network. In this case, the designer

is interested to minimize the size of the set of materialized views that answer all input queries (Chirkova et al., 2006).

System Oriented Constraints

System oriented constraints are dictated by the restrictions of the system, and are transparent to the users.

- **Space constraint.** Although the degradation of the cost of disk space allows for massive storage of data, one cannot consider that the disk space is unlimited. The space constraint restricts the space occupied by the selected materialized views not to exceed the space allocated to the DW for this end. Space constraints are adopted in many works (Harinarayan et al; 1996, Gupta, 1997; Theodoratos & Sellis, 1999; Golfarelli & Rizzi, 2000).
- **View maintenance cost constraint.** In many practical cases the refraining factor in materializing all the views in the DW is not the space constraint but the view maintenance cost. Usually, DWs are updated periodically, e.g. at nighttime, in a large batch update transaction. Therefore the update window must be sufficiently short so that the DW is available for querying and analysis during daytime. The view maintenance cost constraint states that the total view maintenance cost should be less than a given amount of view maintenance time. Gupta & Mumick, (1999), Golfareli & Rizzi (2000), and Lee & Hammer (2001) consider a view maintenance cost constraint in selecting materialized views.
- **Self Maintainability.** A materialized view is self-maintainable if it can be maintained, for any instance of the source relations over which it is defined, and for all source relation changes, using only these changes, the view definition, and the view materialization. The notion is extended to a set of views in a straightforward manner. By adding auxiliary views to a set of materialized views, one can make the whole view set self-maintainable. There are different reasons for making a view set self-maintainable: (a) The remote source relations need not be contacted in turn for evaluating maintenance expressions during view updating. (b)''Anomalies'' due to concurrent changes are eliminated and the view maintenance process is simplified. (c) The materialized views can be maintained efficiently even if the sources are not able to answer queries (e.g. legacy systems), or if they are temporarily unavailable (e.g. in mobile systems). By adding auxiliary views to a set of materialized views, the whole view set can be made self-maintainable. Self-maintainability can be trivially achieved by replicating at the DW all the source relations used in the view definitions. Self-maintainability viewed as a constraint requires that the set of materialized views taken together is self-maintainable. Quass et al (1996), Akinde et al (1998), Liang et al (1999) and Theodoratos (2000) aim at making the DW self-maintainable.
- **Answering the input queries using exclusively the materialized views.** This constraint requires the existence of a complete rewriting of the input queries (which are initially defined over the source relations) over the materialized views. Clearly, if this constraint is satisfied, the remote data sources need not be contacted for evaluating queries. This way, expensive data transmissions from the DW to the sources and conversely are avoided. Some approaches assume a centralized DW environment where the source relations are present at the DW site. In this case the answerability of the queries from the materialized views is trivially guaranteed by the presence of the source relations. The answerability of the queries can also be trivially guaranteed by appropriately defining select-project views on the source relations, and replicating them at the DW. This approach guarantees at the same time the self-maintainability of the materialized views. Theodoratos & Sellis (1999) do not assume a centralized DW environment or replication of part of the source relations at the DW, and explicitly impose this constraint in selecting views for materialization.

User Oriented Constraints

User oriented constraints express requirements of the users.

- **Answer data currency constraints.** An answer data currency constraint sets an upper bound on the time elapsed between the point in time the answer to a query is returned to the user and the

point in time the most recent changes of a source relation that are taken into account in the computation of this answer are read (this time reflects the currency of answer data). Currency constraints are associated with every source relation in the definition of every input query. The upper bound in an answer data currency constraint (minimal currency required) is set by the users according to their needs. This formalization of data currency constraints allows stating currency constraints at the query level and not at the materialized view level as is the case in some approaches. Therefore, currency constraints can be exploited by DW view selection algorithms where the queries are the input, while the materialized views are the output (and therefore are not available). Furthermore, it allows stating different currency constraints for different relations in the same query.

- **Query response time constraints.** A query response time constraint states that the time needed to evaluate an input query using the views materialized at the DW should not exceed a given bound. The bound for each query is given by the users and reflects their needs for fast answers. For some queries fast answers may be required, while for others the response time may not be predominant.

Search Space and Algorithms

Solving the problem of selecting views for materialization involves addressing two main tasks: (a) generating a search space of alternative view sets for materialization, and (b) designing optimization algorithms that select an optimal or near-optimal view set from the search space.

A DW is usually organized according to a star or snow-flake schema where a fact table is surrounded by a number of dimension tables. The dimension tables define hierarchies of aggregation levels. Typical OLAP queries involve star joins (key/foreign key joins between the fact table and the dimension tables) and grouping and aggregation at different levels of granularity. For queries of this type, the search space can be formed in an elegant way as a multidimensional lattice (Harinarayan et al., 1996; Baralis et al., 1997).

Gupta (1997) states that the view selection problem is NP-hard. Most of the approaches on view selection problems avoid exhaustive algorithms. The adopted algorithms fall in two categories: deterministic and randomized. In the first category belong greedy algorithms with performance guarantee (Harinarayan et al., 1996; Gupta, 1997), 0-1 integer programming algorithms (Yang et al., 1997), A* algorithms (Gupta & Mumick, 1999), and various other heuristic algorithms (Ross et al., 1996; Baralis et al., 1997; Shukla et al., 1998; Theodoratos & Sellis, 1999). In the second category belong simulated annealing algorithms (Theodoratos et al., 2001; Kalnis et al., 2002), iterative improvement algorithms (Kalnis et al., 2002) and genetic algorithms (Lee & Hammer, 2001). Both categories of algorithms exploit the particularities of the specific view selection problem and the restrictions of the class of queries considered.

FUTURE TRENDS

The view selection problem has been addressed for different types of queries. Research has focused mainly on queries over star schemas. Newer applications, e.g. XML or web based applications, require different types of queries. This topic has only been partially investigated (Labrinidis & Roussopoulos, 2000; Golfarelli et al., 2001).

A relevant issue that needs further investigation is the construction of the search space of alternative view sets for materialization. Even though the construction of such a search space for grouping and aggregation queries is straightforward (Harinarayan et al., 1966), it becomes an intricate problem for general queries (Golfarelli & Rizzi, 2001).

Indexes can be seen as special types of views. Gupta et al (1997) show that a two-step process that divides the space available for materialization and picks views first and then indexes can perform very poorly. More work needs to be done on the problem of automating the selection of views and indexes together.

DWs are dynamic entities that evolve continuously over time. As time passes, new queries need to be satisfied. A dynamic version of the view selection problem chooses additional views for materialization, and avoids the design of the DW from scratch (Theodoratos & Sellis, 2000). A system that dynamically materializes views in the DW at multiple levels of granularity in order to match the workload (Kotidis &

Roussopoulos, 2001; Lawrence, M. & Rau-Chaplin, 2006) is a current trend in the design of a DW. In some applications the workload comprises query and update statements that need to be executed in a certain order (that is, the workload is a sequence of statements). In this case, a view management scheme can be employed that exploits the statement sequence information, and dynamically creates and drops transiently materialized views. Such a scheme can achieve further reductions to the operational cost of the DW (Agrawal et al., 2006; Xu et al., 2007).

CONCLUSION

A DW can be seen as a set of materialized views. A central problem in the design of a DW is the selection of views to materialize in it. Depending on the requirements of the prospective users of the DW, the materialized view selection problem can be formulated with various design goals which comprise the minimization of cost functions and the satisfaction of user and system oriented constraints. Because of its importance, different versions of it have been the focus of attention of many researchers in recent years. Papers in the literature deal mainly with the issue of determining a search space of alternative view sets for materialization and with the issue of designing optimization algorithms that avoid examining exhaustively the usually huge search space. Some results of this research have already been used in commercial database management systems (Agrawal et al., 2004; Zilio et al. 2004).

KEY TERMS

Auxiliary View: A view materialized in the DW exclusively for reducing the view maintenance cost. An auxiliary view can be materialized permanently or transiently.

Materialized View: A view whose answer is stored in the DW.

Operational Cost: A linear combination of the query evaluation and view maintenance cost.

Query Evaluation Cost: The sum of the cost of evaluating each input query rewritten over the materialized views.

Self-Maintainable View: A materialized view that can be maintained, for any instance of the source relations, and for all source relation changes, using only these changes, the view definition, and the view materialization.

View: A named query.

View Maintenance Cost: The sum of the cost of propagating each source relation change to the materialized views.

Matrix Decomposition Techniques for Data Privacy

INTRODUCTION

Data mining technologies have now been used in commercial, industrial, and governmental businesses, for various purposes, ranging from increasing profitability to enhancing national security. The widespread applications of data mining technologies have raised concerns about trade secrecy of corporations and privacy of innocent people contained in the datasets collected and used for the data mining purpose. It is necessary that data mining technologies designed for knowledge discovery across corporations and for security purpose towards general population have sufficient privacy awareness to protect the corporate trade secrecy and individual private information. Unfortunately, most standard data mining algorithms are not very efficient in terms of privacy protection, as they were originally developed mainly for commercial applications, in which different organizations collect and own their private databases, and mine their private databases for specific commercial purposes.

In the cases of inter-corporation and security data mining applications, data mining algorithms may be applied to datasets containing sensitive or private information. Data warehouse owners and government agencies may potentially have access to many databases collected from different sources and may extract any information from these databases. This potentially unlimited access to data and information raises the fear of possible abuse and promotes the call for privacy protection and due process of law.

Privacy-preserving data mining techniques have been developed to address these concerns (Fung et al., 2007; Zhang, & Zhang, 2007). The general goal of the privacy-preserving data mining techniques is defined as to hide sensitive individual data values from the outside world or from unauthorized persons, and simultaneously preserve the underlying data patterns and semantics so that a valid and efficient decision model based on the distorted data can be constructed. In the best scenarios, this new decision model should be equivalent to or even better than the model using the original data from the viewpoint of decision accuracy. There are currently at least two broad classes of approaches to achieving this goal. The first class of approaches attempts to distort the original data values so that the data miners (analysts) have no means (or greatly reduced ability) to derive the original values of the data. The second is to modify the data mining algorithms so that they allow data mining operations on distributed datasets without knowing the exact values of the data or without direct accessing the original datasets. This article only discusses the first class of approaches. Interested readers may consult (Clifton et al., 2003) and the references therein for discussions on distributed data mining approaches.

BACKGROUND

The input to a data mining algorithm in many cases can be represented by a vector-space model, where a collection of records or objects is encoded as an $n \times m$ object-attribute matrix (Frankes, & Baeza-Yates, 1992). For example, the set of vocabulary (words or terms) in a dictionary can be the items forming the rows of the matrix, and the occurrence frequencies of all terms in a document are listed in a column of the matrix. A

collection of documents thus forms a term-document matrix commonly used in information retrieval. In the context of privacy-preserving data mining, each column of the data matrix can contain the attributes of a person, such as the person's name, income, social security number, address, telephone number, medical records, etc. Datasets of interest often lead to a very high dimensional matrix representation (Achlioptas, 2004). It is observable that many real-world datasets have nonnegative values for attributes. In fact, many of the existing data distortion methods inevitably fall into the context of matrix computation. For instance, having the longest history in privacy protection area and by adding random noise to the data, additive noise method can be viewed as a random matrix and therefore its properties can be understood by studying the properties of random matrices (Kargupta et al., 1991).

Matrix decomposition in numerical linear algebra typically serves the purpose of finding a computationally convenient means to obtain the solution to a linear system. In the context of data mining, the main purpose of matrix decomposition is to obtain some form of simplified low-rank approximation to the original dataset for understanding the structure of the data, particularly the relationship within the objects and within the attributes and how the objects relate to the attributes (Hubert, Meulman, & Heiser, 2000). The study of matrix decomposition techniques in data mining, particularly in text mining, is not new, but the application of these techniques as data distortion methods in privacy-preserving data mining is a recent interest (Xu et al., 2005). A unique characteristic of the matrix decomposition techniques, a compact representation with reduced-rank while preserving dominant data patterns, stimulates researchers' interest in utilizing them to achieve a win-win goal both on high degree privacy-preserving and high level data mining accuracy.

MAIN FOCUS

Data distortion is one of the most important parts in many privacy-preserving data mining tasks. The desired distortion methods must preserve data privacy, and at the same time, must keep the utility of the data after the distortion (Verykios et al., 2004). The classical data distortion methods are based on the random value perturbation (Agrawal, & Srikant, 2000). The more recent ones are based on the data matrix-decomposition strategies (Wang et al., 2006; Wang et al., 2007; Xu et al., 2006).

Uniformly Distributed Noise

The original data matrix A is added with a uniformly distributed noise matrix E_u. Here E_u is of the same dimension as that of A, and its elements are random numbers generated from a continuous uniform distribution on the interval from C_1 to C_2. The distorted data matrix A_u is denoted as: $A_u = A + E_u$.

Normally Distributed Noise

Similar to the previous method, here the original data matrix A is added with a normally distributed noise matrix E_n, which has the same dimension as that of A. The elements of E_n are random numbers generated from the normal distribution with a parameter mean μ and a standard deviation ρ. The distorted data matrix A_n is denoted as: $A_n = A + E_n$.

Singular Value Decomposition

Singular Value Decomposition (SVD) is a popular matrix factorization method in data mining and information retrieval. It has been used to reduce the dimensionality of (and remove the noise in the noisy) datasets in practice (Berry et al., 1999). The use of SVD technique in data distortion is proposed in (Xu et al., 2005). In (Wang et al., 2007), the SVD technique is used to distort portions of the datasets.

The SVD of the data matrix A is written as:

$$A = U\Sigma V^T$$

where U is an $n \times n$ orthonormal matrix, $\Sigma = \text{diag}[\sigma_1, \sigma_2, \cdots, \sigma_s]$ ($s = \min\{m,n\}$) is an $n \times m$ diagonal matrix whose nonnegative diagonal entries (the singular values) are in a descending order, and V^T is an $m \times m$ orthonormal matrix. The number of nonzero diagonal entries of Σ is equal to the rank of the matrix A.

Due to the arrangement of the singular values in the matrix Σ (in a descending order), the SVD transformation has the property that the maximum variation among the objects is captured in the first dimension, as $\sigma_1 \geq \sigma_i$ for $i \geq 2$. Similarly, much of the remaining variation is

captured in the second dimension, and so on. Thus, a transformed matrix with a much lower dimension can be constructed to represent the structure of the original matrix faithfully. Define:

$$A_k = U_k \Sigma_k V_k^T$$

where U_k contains the first k columns of U, Σ_k contains the first k nonzero singular values, and V_k^T contains the first k rows of V^T. The rank of the matrix A_k is k. With k being usually small, the dimensionality of the dataset has been reduced dramatically from $\min\{m,n\}$ to k (assuming all attributes are linearly independent). It has been proved that A_k is the best k dimensional approximation of A in the sense of the Frobenius norm.

In data mining applications, the use of A_k to represent A has another important implication. The removed part $E_k = A - A_k$ can be considered as the noise in the original dataset (Xu et al., 2006). Thus, in many situations, mining on the reduced dataset A_k may yield better results than mining on the original dataset A. When used for privacy-preserving purpose, the distorted dataset A_k can provide protection for data privacy, at the same time, it keeps the utility of the original data as it can faithfully represent the original data structure.

Sparsified Singular Value Decomposition

After reducing the rank of the SVD matrices, we can further distort the data matrices by removing their small size entries. This can be done with a threshold strategy. Given a threshold value ε, we set any data entry in the matrices U_k and V_k^T to be zero if its absolute value is smaller than ε. We refer to this operation as the dropping operation (Gao, & Zhang, 2003). For example, we set $u_{ij} = 0$ in U_k if $|u_{ij}| < \varepsilon$. Similar operation is applied to the entries in V_k^T. Let $\overline{U_k}$ denote U_k with dropped entries and $\overline{V_k^T}$ denote V_k^T with dropped entries, we can represent the distorted dataset as:

$$\overline{A_k} = \overline{U_k} \Sigma_k \overline{V_k^T}$$

The sparsified SVD method is equivalent to further distorting the dataset A_k. Denoting $E_\varepsilon = A_k - \overline{A_k}$, we have:

$$A = \overline{A_k} + E_k + E_\varepsilon$$

The dataset provided to the data mining analysts is $\overline{A_k}$, which is twice distorted in the sparsified SVD strategy. Without the knowledge of E_k and E_ε, it will be difficult for the data mining analysts to recover the exact values of A, based on the disclosed values of A_k.

Nonnegative Matrix Factorization

Given an $n \times m$ nonnegative matrix dataset A with $A_{ij} \geq 0$ and a prespecified positive integer $k \leq \min\{n,m\}$, the Nonnegative Matrix Factorization (NMF) finds two nonnegative matrices $W \in R^{n \times k}$ with $W_{ij} \geq 0$ and $H \in R^{k \times m}$ with $H_{ij} \geq 0$, such that $A \approx WH$ and the objective function:

$$f(W,H) = \frac{1}{2} \| A - WH \|_F^2$$

is minimized. Here $\|\bullet\|_F$ is the Frobenius norm. The matrices W and H may have many other desirable properties in data mining applications. Several algorithms to compute nonnegative matrix factorizations for some applications of practical interests are proposed in (Lee, & Seung, 1999; Pascual-Montano et al., 2006). Some of these algorithms are modified in (Wang et al., 2006) to compute nonnegative matrix factorizations for enabling privacy-preserving in datasets for data mining applications. Similar to the sparsified SVD techniques, sparsification techniques can be used to drop small size entries from the computed matrix factors to further distort the data values (Wang et al., 2006).

In text mining, NMF has an advantage over SVD in the sense that if the data values are nonnegative in the original dataset, NMF maintains their nonnegativity, but SVD does not. The nonnegativity constraints can lead to a parts-based representation because they allow only additive, not subtractive, combinations of the original basis vectors (Lee, & Seung, 1999). Thus, dataset values from NMF have some meaningful interpretations in the original sense. On the contrary, data values from SVD are no longer guaranteed to be nonnegative. There has been no obvious meaning for the negative values in the SVD matrices. In the context of privacy-preserving, on the other hand, the negative values in the dataset may actually be an advantage, as they further obscure the properties of the original datasets.

Utility of the Distorted Data

Experiments with both SVD and NMF data distortion techniques have been conducted on both synthetic and real-world datasets with a support vector machine classification algorithm. These datasets include some terrorist database, the well-known Wisconsin breast cancer database, and a random number matrix. In these experiments, only the numerical attribute values were distorted. Experimental results reported in (Wang et al., 2007; Wang et al., 2006; Xu et al., 2006; Xu et al., 2005) show that both SVD and NMF techniques provide much higher degree of data distortion than the standard data distortion techniques based on adding uniformly distributed noise or normally distributed noise. In terms of the accuracy of the data mining algorithm, techniques based on adding uniformly distributed noise or normally distributed noise sometimes degrade the accuracy of the classification results, compared with applying the algorithm on the original, undistorted datasets. On the other hand, both SVD and NMF techniques can generate distorted datasets that are able to yield better classification results, compared with applying the algorithm directly on the original, undistorted datasets. This is amazing, as people would intuitively expect that data mining algorithms applied on the distorted datasets may produce less accurate results, than applied on the original datasets.

It is not very clear why the distorted data from SVD and NMF are better for the data classification algorithm used to obtain the experimental results. The hypothesis is that both SVD and NMF may have some functionalities to remove the noise from the original datasets by removing small size matrix entries. Thus, the distorted datasets from SVD and NMF look like "cleaned" datasets. The distorted datasets from the techniques based on adding either uniformly distributed noise or normally distributed noise do not have this property. They actually generate "noisy" datasets in order to distort data values.

FUTURE TRENDS

Using matrix decomposition-based techniques in data distortion for privacy-preserving data mining is a relatively new trend. This class of data privacy-preserving approaches has many desirable advantages over the more standard privacy-preserving data mining approaches. There are a lot of unanswered questions in this new research direction. For example, a classical problem in SVD-based dimensionality reduction techniques is to determine the optimal rank of the reduced dataset matrix. Although in the data distortion applications, the rank of the reduced matrix does not seem to sensitively affect the degree of the data distortion or the level of the accuracy of the data mining results (Wang et al., 2007), it is still of both practical and theoretical interests to be able to choose a good rank size for the reduced data matrix.

Unlike the data distortion techniques based on adding either uniformly distributed noise or normally distributed noise, SVD and NMF does not maintain some statistical properties of the original sestets, such as the mean of the data attributes. Such statistical properties may or may not be important in certain data mining applications. It would be desirable to design some matrix decomposition-based data distortion techniques that maintain these statistical properties.

The SVD and NMF data distortion techniques have been used with the support vector machine based classification algorithms (Xu et al., 2006). It is not clear if they are equally applicable to other data mining algorithms. It is certainly of interest for the research community to experiment these data distortion techniques with other data mining algorithms.

There is also a need to develop certain techniques to quantify the level of data privacy preserved in the data distortion process. Although some measures for data distortion and data utility are defined in (Xu et al., 2006), they are not directly related to the concept of privacy-preserving in datasets.

CONCLUSION

We have presented two classes of matrix decomposition-based techniques for data distortion to achieve privacy-preserving in data mining applications. These techniques are based on matrix factorization techniques commonly practiced in matrix computation and numerical linear algebra. Although their application in text mining is not new, their application in data distortion with privacy-preserving data mining is a recent attempt. Previous experimental results have demonstrated that these data distortion techniques are highly effective for high accuracy privacy protection, in the sense that they can provide high degree of data distortion and

maintain high level data utility with respect to the data mining algorithms.

The computational methods for SVD and NMF are well developed in the matrix computation community. Very efficient software packages are available either in standard matrix computation packages such as MATLAB or from several websites maintained by individual researchers. The availability of these software packages greatly accelerates the application of these and other matrix decomposition and factorization techniques in data mining and other application areas.

KEY TERMS

Data Distortion: A systematic perturbation of data values in a database in order to mask the original data

values, but allow certain properties of the database to be preserved.

Data Utility: A dataset's ability to maintain its performance with data mining algorithms after the data distortion process.

Matrix Decomposition: A factorization of a matrix into some canonical form, usually in the form of a product of two or more matrices.

Nonnegative Matrix Factorization: A class of algorithms that factor a (usually nonnegative) matrix into the product of two matrices, both have nonnegative entries. This type of factorization of matrices is not unique by incorporating different constraints.

Privacy-Preserving Data Mining: Extracting valid knowledge and information from the datasets without learning the underlying data values or data patterns, or without revealing the values or patterns of the private data.

Singular Value Decomposition: The factorization of a rectangular matrix into the product of three matrices. The first and the third matrices are orthonormal. The second matrix is diagonal and contains the singular values of the original matrix.

Measuring the Interestingness of News Articles

Raymond K. Pon
University of California - Los Angeles, USA

Alfonso F. Cardenas
University of California - Los Angeles, USA

David J. Buttler
Lawrence Livermore National Laboratory, USA

INTRODUCTION

An explosive growth of online news has taken place. Users are inundated with thousands of news articles, only some of which are interesting. A system to filter out uninteresting articles would aid users that need to read and analyze many articles daily, such as financial analysts and government officials.

The most obvious approach for reducing the amount of information overload is to learn keywords of interest for a user (Carreira et al., 2004). Although filtering articles based on keywords removes many irrelevant articles, there are still many uninteresting articles that are highly relevant to keyword searches. A relevant article may not be interesting for various reasons, such as the article's age or if it discusses an event that the user has already read about in other articles.

Although it has been shown that collaborative filtering can aid in personalized recommendation systems (Wang et al., 2006), a large number of users is needed. In a limited user environment, such as a small group of analysts monitoring news events, collaborative filtering would be ineffective.

The definition of what makes an article interesting – or its "interestingness" – varies from user to user and is continually evolving, calling for adaptable user personalization. Furthermore, due to the nature of news, most articles are uninteresting since many are similar or report events outside the scope of an individual's concerns. There has been much work in news recommendation systems, but none have yet addressed the question of what makes an article interesting.

BACKGROUND

Working in a limited user environment, the only available information is the article's content and its metadata, disallowing the use of collaborative filtering for article recommendation. Some systems perform clustering or classification based on the article's content, computing such values as TF-IDF weights for tokens (Radev et al., 2003). Corso (2005) ranks articles and new sources based on several properties, such as mutual reinforcement and freshness, in an online method. However, Corso does not address the problem of personalized news filtering, but rather the identification of interesting articles for the general public. Macskassy and Provost (2001) measure the interestingness of an article as the correlation between the article's content and real-life events that occur after the article's publication. Using these indicators, they can predict future interesting articles. Unfortunately, these indicators are often domain specific and are difficult to collect for the online processing of articles.

The online recommendation of articles is closely related to the adaptive filtering task in TREC (Text Retrieval Conference), which is the online identification of articles that are most relevant to a set of topics. The task is different from identifying interesting articles for a user because an article that is relevant to a topic may not necessarily be interesting. However, relevancy to a set of topics of interest is often correlated to interestingness. The report by Robertson and Soboroff (2002) summarizes the results of the last run of the TREC filtering task. Methods explored in TREC11 include a Rocchio variant, a second-order perceptron, a SVM, a Winnow classifier, language modelling, probabilistic models of terms and relevancy, and the Okapi Basic Search System.

The recommendation of articles is a complex document classification problem. However, most classification methods have been used to bin documents into topics, which is a different problem from binning documents by their interestingness. Traditional classification has focused on whether or not an article is relevant to a topic of interest, such as the work done in TREC. Typical methods have included the Rocchio (1971) algorithm, language models (Peng et al., 2003), and latent Dirichlet allocation (Newman et al., 2006; Steyvers, 2006). Despite the research done in topic relevancy classification, it is insufficient for addressing the problem of interestingness. There are many reasons why an article is interesting besides being relevant to topics of interests. For example, an article that discusses content that a user has never seen may be interesting but would be undetectable using traditional IR techniques. For example, the events of the September 11 attacks had never been seen before but were clearly interesting. Furthermore, redundant yet relevant articles would not be interesting as they do not provide the user any new information. However, traditional IR techniques are still useful as a first step towards identifying interesting articles.

MAIN FOCUS

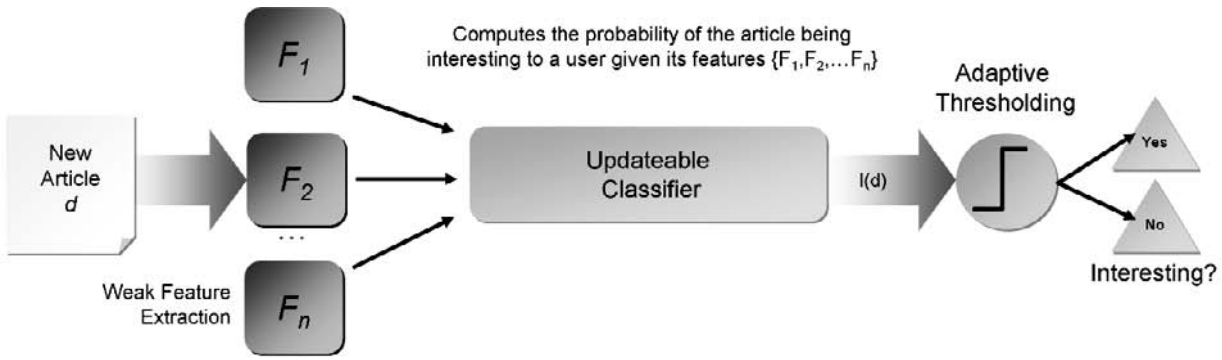
The problem of recommending articles to a specific user can be addressed by answering what makes an article interesting to the user. A possible classification pipeline is envisioned in Figure 1. Articles are processed in a streaming fashion, like the document processing done in the adaptive filter task in TREC. Articles are introduced to the system in chronological order of their publication date. The article classification pipeline consists of four phases. In the first phase, a set of feature extractors generate a set of feature scores for an article. Each feature extractor addresses an aspect of interestingness, such as topic relevancy. Then a classifier generates an overall classification score, which is then thresholded by an adaptive thresholder to generate a binary classification, indicating the interestingness of the article to the user. In the final phase, the user examines the article and provides his own binary classification of interestingness (i.e., label). This feedback is used to update the feature extractors, the classifier, and the thresholder. The process continues similarly for the next document in the pipeline.

Interestingness Issues

The "interestingness" of an article varies from user to user and is often complex and difficult to measure. Consequently, several issues arise:

1. There are a variety of reasons why an article is interesting. There is no single attribute of a document that definitively identifies interesting articles. As a result, using only traditional IR techniques for document classification is not sufficient (Pon et al, 2007).
2. Some interestingness features are often contradictory. For example, an interesting article should be relevant to a user's known interests but should yield new information. On the other hand, random events may be new and unique but may not necessarily be of interest to all users.

Figure 1. Article classification pipeline



3. The breaking news of an important event is difficult to discriminate from the breaking news of an unimportant one.
4. Because what makes an article interesting varies from user to user, the ideal set of features for a user can not be determined until the system is in use by a user. Useless features will be present in the classification process, which will degrade the performance of a classifier (Forman, 2004), especially its accuracy with classifying on early articles.
5. The definition of the interestingness may change for a user over time. Consequently, an online learner must be able to adapt to the changing utility of features.
6. User-feedback must be continually incorporated in the classification process so that any machine learning algorithm can learn efficiently over time what makes an article interesting for a user. A classifier must be incrementally accurate, updateable, and robust against noisy and potentially useless features.
7. Users are often interested in a multitude of topics that may be drastically different from one another. For example, a user may be interested in news about an election and football. To represent a user using a single profile may not be sufficient while multiple profiles may be costly to maintain (Pon et al., 2007b).
8. A successful news recommendation system must give accurate recommendations with very little training. Users will deem a system useless if it cannot provide useful recommendations almost immediately.

Possible Document Features for Interestingness

There is no single feature that definitively identifies interesting articles. Pon et al. (2007) describes a set of possible aspects regarding interestingness:

1. *Topic Relevancy*: Although an article that is relevant to a topic of interest may not necessarily be interesting, relevancy to such topics is often a prerequisite for interestingness for a certain class of users. Traditional IR techniques can be used for this purpose.
2. *Uniqueness*: Articles that yield little new information compared to articles already seen may not be interesting. In contrast, an article that first breaks a news event may be interesting. Articles that describe a rare event may also be interesting. For example, Rattigan and Jensen (2005) claim that interesting articles may be produced by rare collaborations among authors. Methods for outlier detection include using mixture models (Eskin, 2000), generating solving sets (Angiulli et al., 2005) and using k-d trees (Chaudhary et al., 2002).
3. *Source Reputation*: An article's interestingness can be estimated given its source's past history in producing interesting articles. Articles from a source known to produce interesting articles tend to be more interesting than articles from less-reputable sources.
4. *Writing Style*: Most work using the writing style of articles has mainly been for authorship attribution (Koppel et al., 2006). Instead of author attribution, the same writing style features can be used to infer interestingness. For example, the vocabulary richness (Tweedie & Baayen, 1998) of an article should suit the user's understanding of the topic (e.g., a layman versus an expert). Also writing style features may help with author attribution, which can be used for source reputation, where attribution is unavailable.
5. *Freshness*: Articles about recent events tend to be labeled as more interesting than articles about older events. Also articles about the same event are published around the time the event has occurred. This may also be the case for interesting events, and consequently interesting articles.
6. *Subjectivity and Polarity*: The sentiment of an article may also contribute to a user's definition of interestingness. For example, "bad news" may be more interesting than "good news" (i.e., the polarity of the article). Or, subjective articles may be more interesting than objective articles. Polarity identification has been done with a dictionary approach (Mishne, 2005). Others have looked at subjectivity labeling, using various NLP techniques (Wiebe et al., 2004).

The above list is not an exhaustive list of interestingness features. There is currently ongoing work on

the identification and the measurement of new features that correlate with interestingness.

Ensembles

Because of the complexity of the problem of recommending articles, a solution to this problem could leverage multiple existing techniques to build a better recommendation system. In other problems, this approach has worked well, such as in webpage duplication (Henzinger, 2006).

One ensemble approach to ranking items, such as articles, is to combine multiple ranking functions through probabilistic latent query analysis (Yan & Hauptmann, 2006). Another approach uses a weighted majority algorithm to aggregate expert advice from an ensemble of classifiers to address concept drift in real-time ranking (Beckier & Arias, 2007). A simpler ensemble approach is taken by Pon et al. (2007a). Different techniques, which are relevant to determining the "interestingness" of an article, are combined together as individual features for a naïve Bayesian classifier. Pon et al. show that this achieves a better "interestingness" judgment. However, naïve Bayesian classifiers assume that features are independent. As discussed earlier, "interestingness" is complex and allows for the possibility of conditionally dependent features. For example, an article may be interesting if it is unique but relevant to topics of interest. The search for an updateable yet efficient and complete classifier for "interestingness" remains open.

Additionally, because the definition of interestingness varies from user to user (Pon et al., 2007a) and may even change over time, it is not possible to use traditional offline feature selection algorithms, such as the ones described by Guyon and Eliseeff (2003), to identify which features are important before deploying the system. So, all features are included for classification. The ideal approach to dealing with this problem is by embedding a feature selection algorithm within an updateable classifier. Some approaches have included using Winnow (Carvalho & Cohen 2006), but lack the generality for handling features with different semantic meanings. Utgoff et al.'s (1997) incremental decision tree algorithm addresses this problem but is not appropriate for an online environment due to its growing storage requirements. A different approach taken by Nurmi and Floreen (2005) identify and remove redundant features using the properties of time series data. However, this approach is not applicable to articles as articles are not necessarily dependent upon the article that immediately precedes it in the document stream.

FUTURE TRENDS

With the advent of blogs that specialize in niche news markets, readers can expect to see an explosive growth on the availability of information where only a small fraction may be of interest to them. In contrast to traditional news sources, such as CNN, blogs focus on specific topics that may be of interest to only a handful of users as opposed to the general public. This phenomenon is often referred to as the long tail market phenomenon (Anderson, 2007). Instead of building news filters that cater to the mass public, future research will focus more on personalized news recommendation. Personalization research is also present in other media, as evident in the Netflix Prize competition (2007) and the related KDD Cup 2007 competition (Bennett et al., 2007), in which teams compete to improve the accuracy of movie recommendations.

Traditional corpora, such as the ones used in TREC, are ill equipped to address the problems in personalized news recommendation. Current corpora address the traditional problems of topic relevancy and do not address the problem of interestingness. Furthermore, such corpora are not user-focused. At best, such corpora label articles that a general audience would find to be interesting as opposed to a specific user. Even the Yahoo! news articles used by Pon et al. (2007) address the problem of identifying interesting articles to a large community of users instead of a specific user. Further research in personalized news recommendation will need to be evaluated on a large test data collection that has been collected using many individual users. Such data can be collected by tracking individual user behavior on the Internet or on news bulletin boards, such as Digg (2007).

CONCLUSION

The online recommendation of interesting articles for a specific user is a complex problem, having to draw from many areas of machine learning, such as feature selection, classification, and anomaly detection. There

is no single technique that will be able to address the problem of interestingness by itself. An ensemble of multiple techniques is one possible solution to addressing this problem. Because of the growth of research in recommendation systems, more user-focused test collections should be made available for system evaluation and comparison.

KEY TERMS

Conditionally Dependent Features: Features whose values are dependent upon the values of other features.

Ensemble: The combination of multiple techniques to achieve better results for a common task.

General Audience Recommendation: Recommendations made for the mass public, usually related to what is popular.

Interestingness: How interesting the referred item is to a specific user. This measure is complex and subjective, varying from user to user.

Online Feature Selection: The problem of selecting a subset of useful features from a set of given features for online classification by machine learning algorithms. As instances are classified sequentially, the appropriate set of features is selected for classifying each instance.

Online News Recommendation: The problem of recommending news articles to a specific user by machine learning algorithms. Such algorithms must provide a recommendation for an article when it arrives in a document stream in real-time. Once a decision on an article is made, the decision cannot be changed.

User-Focused Recommendation: Recommendations made for a specific user or a niche community.

Metaheuristics in Data Mining

INTRODUCTION

The *Metaheuristics* are general strategies for designing heuristic procedures with high performance. The term metaheuristic, which appeared in 1986 for the first time (Glover, 1986), is compound by the terms: "meta", that means over or behind, and "heuristic". Heuristic is the qualifying used for methods of solving optimization problems that are obtained from the intuition, expertise or general knowledge (Michalewicz & Fogel, 2000).

Nowadays a lot of known strategies can be classified as metaheuristics and there are a clear increasing number of research papers and applications that use this kind of methods. Several optimization methods that already existed when the term appeared have been later interpreted as metaheuristics (Glover & Kochenberger, 2003). Genetic Algorithms, Neural Networks, Local Searches, and Simulated Annealing are some of those classical metaheuristics. Several modern metaheuristics have succeeded in solving relevant optimization problems in industry, business and engineering. The most relevant among them are Tabu Search, Variable Neighbourhood Search and GRASP. New population based evolutionary metaheuristics such as Scatter Search and Estimation Distribution Algorithms are also quite important. Besides Neural Networks and Genetic Algorithms, other nature-inspired metaheuristics such as Ant Colony Optimization and Particle Swarm Optimization are also now well known metaheuristics..

BACKGROUND

The ***Metaheuristic*** methods are general strategies for designing heuristic procedures for solving an optimization problem. An optimization problem is characterized by a search space S of feasible solutions and an objective function f. Solving the problem consists of finding an *optimal* solution s^*; i.e., a feasible solution that optimizes f in S. Given a set of transformations or moves on the solution space, the *neighbourhood* of s, denoted by $N(s)$, is the set of solutions that are reachable from s with one of these moves. A *local optimum* is a solution s that optimizes f in its neighbourhood $N(s)$. A *Local Search* is a procedure that iteratively applies an improving move to a solution (Pirlot, 1996; Yagiura & Ibaraki, 2002). The main objection to local searches is that they are trapped in a local optimum. The first metaheuristics arose looking for ways to escape from local optima in order to reach an optimal solution. There are an increasing number of books and reviews on the whole field of Metaheuristics (Reeves, 1993, Michalewicz & Fogel, 2000; Glover & Kochenberger, 2003; Blum & Roli, 2003)

Data mining (DM) is a constantly growing area. DM tools are confronted to a particular problem: the great number of characteristics that qualify data samples. They are more or less victims of the abundance of information. DM needs benefits from the powerful metaheuristics that can deal with huge amounts of data in Decision Making contexts. Several relevant tasks in DM; such as clustering, classification, feature selection and data reduction, are formulated as optimization

problems. The solutions for the corresponding problem consist of the values for the parameters that specify the role designed for performing the task. In nearest-neighbour clustering and classification, the solutions consist of the possible selections of cases for applying the rule. The objective functions are the corresponding performance measures. In Feature Selection and Data Reduction, the solutions are set of variables or cases and, if the size of set of features or the amount of data is fixed, the objective is to maximize the (predictive) performance. However in general, there are, at least, two objectives: the accuracy and the simplicity. They are usually contradictory and generally referred by the performance and the amount of information used for prediction. The accuracy is to be maximized and the amount of information is to be minimized. Therefore, multi-objective metaheuristics are appropriated to get the adequate tradeoff.

MAIN FOCUS

The main focus in the metaheuristics field related to DM is in the application of the existing and new methods and in the desirable properties of the metaheuristics. Most metaheuristic strategies have already been applied to DM tasks but there are still open research lines to improve their usefulness.

Main Metaheuristics

The *Multi-start* considers the ways to get several initial solutions for the local searches in order to escape from local optima and to increase the probability of reaching the global optimum (Martí, 2003; Fleurent & Glover, 1999). *GRASP* (*Greedy Randomized Adaptive Search Procedures*) comprises two phases, an adaptive construction phase and a local search (Feo & Resende, 1995; Resende & Ribeiro, 2003). The distinguishing feature of *Tabu Search* (Glover, 1989, 1990, Glover & Laguna, 1997) is the use of adaptive memory and special associated problem-solving strategies. *Simulated Annealing* (Kirkpatrick et al., 1983; Vidal, 1993) is derived from a local search by allowing also, probabilistically controlled, not improving moves. *Variable Neighbourhood Search* is based on systematic changes of neighbourhoods in the search for a better solution (Mladenović & Hansen, 1997; Hansen and Mladenović, 2003). *Scatter Search* (Glover, 1998; Laguna & Martí, 2002) uses an evolving reference set, with moderate size, whose solutions are combined and improved to update the reference set with quality and dispersion criteria. *Estimation of Distribution Algorithms* (Lozano & Larrañaga, 2002) is a population-based search procedure in which a new population is iteratively obtained by sampling the probability distribution on the search space that estimates the distribution of the good solutions selected from the former population. *Ant Colony Optimization* (Dorigo & Blum, 2005; Dorigo & Di Caro, 1999; Dorigo & Stützle, 2004) is a distributed strategy where a set of agents (artificial ants) explore the solution space cooperating by means of the pheromone. *Particle Swarm Optimization* (Clerc, 2006, Kennedy & Eberhart, 1995; Eberhart & Kennedy, 1995; Kennedy & Eberhat, 2001) is an evolutionary method inspired by the social behaviour of individuals within swarms in nature where a swarm of particles fly in the virtual space of the possible solutions conducted by the inertia, memory and the attraction of the best particles.

Most metaheuristics, among other optimization techniques (Olafsson et al., 2006), have already been applied to DM, mainly to Clustering and Feature Selection Problems. For instance, *Genetic Algorithms* has been applied in (Freitas, 2002), *Tabu Search* in (Tahir et al., 2007; Sung & Jin, 2000), *Simulated Annealing* in (Debuse & Rayward-Smith, 1997, 1999), *Variable Neighbourhood Search* in (Hansen and Mladenović, 2001; Belacel et al., 2002; García-López et al., 2004a), *Scatter Search* in (García-López et al., 2004b, 2006; Pacheco, 2005), *Estimation of Distribution Algorithms* in (Inza et al., 2000, 2001), *Ant Colony Ooptimization* in (Han & Shi, 2007; Handl et al., 2006; Admane et al., 2004; Smaldon & Freitas, 2006) and *Particle Swarm Optimization* in (Correa et al., 2006; Wang et al., 2007). Applications of *Neural Networks* in DM are very well known and some review or books about modern metaheuristics in DM have also already appeared (De la Iglesia et al., 1996; Rayward-Smith, 2005; Abbass et al., 2002)

Desirable Characteristics

Most authors in the field have used some of desirable properties of metaheuristics to analyse the proposed methods and few of them collected a selected list of them (Melián et al., 2003). The desirable characteristics

of the metaheuristics, from the theoretical and practical points of view, provide ways for the improvement in the field. A list of them follows:

1. ***Simplicity***: the metaheuristics should be based on a simple and clear principle, easy to understand.
2. ***Precise***: the steps or phases of the metaheuristic must be stated in precise terms, without room for the ambiguity.
3. ***Coherence***: the steps of the algorithms for particular problems should follow naturally from the principles of the metaheuristic;
4. ***Efficiency***: the procedures for particular problems should provide good solutions (optimal or near-optimal) in moderate computational time;
5. ***Efficacy***: the algorithms should solve optimally most problems of benchmarks, when available;
6. ***Effectiveness***: the procedures for particular problems should provide optimal or near-optimal solutions for most realistic instances.
7. ***Robustness***: the metaheuristics should have good performance for a variety of instances, i.e., not just be fine-tuned to some data and less good elsewhere;
8. ***Generality***: the metaheuristics should lead to good heuristics for a large variety of problems.
9. ***Adaptable***: the metaheuristics should include elements to adapt to several contexts or field of applications or different kind of models
10. ***User-friendliness***: the metaheuristics should be easy to use; without parameters or such they are easily understood and tuned.
11. ***Innovation***: the principles of the metaheuristics, and/or their use, should lead to new types of applications.
12. ***Interactivity***: the metaheuristics should allow the user to incorporate his knowledge in order to improve the performance of the procedure.
13. ***Multiplicity***: the methods should be able to present several near optimal solutions among which the user can choose.
14. ***Autonomous***: the metaheuristics should allow implementations without parameters or such that they are automatically tuned.
15. ***Applicability***: the metaheuristics should be widely applicable to several fields.

FUTURE TRENDS

Several of the future trends in metaheuristics will have a big impact in DM because they incorporate the methodologies of intelligent systems to solve the difficulties for efficiently dealing with high amount of data.

Hybrid Metaheuristics

Metaheuristics can get the benefits from the hybridization methodologies (Almeida et al., 2006; Talbi, 2002). This new emerging field includes combinations of components from different metaheuristics, low-level and high-level hybridization, portfolio techniques, expert systems, co-operative search and co-evolution techniques.

Cooperative Metaheuristics

The cooperative metaheuristics consider several search agents that implement metaheuristics and cooperate by interchanging information on the search. The cooperative scheme can be centralized or decentralized depending on the existence of a control of the communications and the way the agents use the information. They are usually obtained from the population search strategies where each individual gets search capabilities and communicates with other individuals in the population (García-Pedrajas et al., 2001; Huang, 2006; Grundel et al., 2004; Melián-Batista et al., 2006).

The Learning Metaheuristics

The performance of the metaheuristics improves by using Machine Learning tools that incorporate the knowledge obtained by the algorithm while it runs. These tools should allow a metaheuristic to tune their parameters to get the best possible performance on a set of instances (Cadenas et al., 2006; Guo, 2003).

Nature-Inspired Metaheuristics

The number and success of the metaheuristics derived from the studies of some natural phenomena are increasing in the last years. In addition to the classical *Neural Networks* and *Genetic Algorithms* other metaheuristic strategies are being consolidated in the field such as

Ant Colony Optimization and *Particle Swarm Optimization*. However recent proposals like *Artificial Immune Systems* (Timmis, 2006), *Membrane Systems* (Paun, 2002) or *Swarm Intelligence* (Engelbrecht, 2005) have not been enough studied (Forbes, 2005).

Multiple Objective Metaheuristics

Since most of the real problems in DM are multiobjective problems (where several contradictory objective functions involved), the adaptation or capabilities of metaheuristics for these problems are very relevant in real applications (Baños et al., 2006).

Parallel Metaheuristics

With the proliferation of parallel computers and faster community networks, parallel metaheuristics (Alba, 2005) is already being now an effective alternative to speed up metaheuristics searches in DM and allow efficiently dealing with high amount of data.

CONCLUSIONS

Modern metaheuristics have succeeded in solving optimization problems in relevant fields. Several relevant tasks in DM are formulated as optimization problems. Therefore, metaheuristics should provide promising tools for improving DM tasks. Some examples of this already have appeared in the specialized literature. In order to extend this success, the knowledge of the good characteristics of the successful metaheuristic is important. The relevance of the future trends of the field for DM applications depends of this knowledge.

KEY TERMS

Diversification: The capability of the search methods to explore different zones of the search space.

Heuristic: A procedure to provide a good solution of an optimization problem that is obtained from the intuition, expertise or general knowledge.

Intensification: The capability of the search methods for improving the solutions of an optimization problem.

Local Optimum: A solution of an optimization problem that is better that any other solution of its neighbourhood.

Local Search: A heuristic method consisting of iteratively applying an improving move to a solution until a stopping criterion is met.

Memory: The capability of some search methods for using the information on the solutions examined in the search process and their objective values.

Metaheuristics: The metaheuristics are general strategies for designing heuristic procedures with high performance.

Neighbourhood: Given a set of moves or transformations in the solution space of an optimization problem, the neighbourhood of a solution is the set of solutions that can be obtained from it by one of these moves or transformations.

Optimization Problem: Given a set S of alternative solutions and an objective function *f*, the corresponding optimization problem consists in finding the solution *s* that optimizes *f*.

Population Method: A solution method, based on a set of solutions (the population), that searches for the optimum in the solution space of an optimization problem.

INTRODUCTION

The application of Machine Learning (ML) and Data Mining (DM) tools to classification and regression tasks has become a standard, not only in research but also in administrative agencies, commerce and industry (e.g., finance, medicine, engineering). Unfortunately, due in part to the number of available techniques and the overall complexity of the process, users facing a new data mining task must generally either resort to trial-and-error or consultation of experts. Clearly, neither solution is completely satisfactory for the non-expert end-users who wish to access the technology more directly and cost-effectively.

What is needed is an informed search process to reduce the amount of experimentation with different techniques while avoiding the pitfalls of local optima that may result from low quality models. Informed search requires meta-knowledge, that is, knowledge about the performance of those techniques. Meta-learning provides a robust, automatic mechanism for building such meta-knowledge. One of the underlying goals of meta-learning is to understand the interaction between the mechanism of learning and the concrete contexts in which that mechanism is applicable. Meta-learning differs from base-level learning in the scope of adaptation. Whereas learning at the base-level focuses on accumulating experience on a specific learning task (e.g., credit rating, medical diagnosis, mine-rock discrimination, fraud detection, etc.), learning at the meta-level is concerned with accumulating experience on the performance of multiple applications of a learning system.

The meta-knowledge induced by meta-learning provides the means to inform decisions about the precise conditions under which a given algorithm, or sequence of algorithms, is better than others for a given task. While Data Mining software packages (e.g., SAS Enterprise Miner, SPSS Clementine, Insightful Miner, PolyAnalyst, KnowledgeStudio, Weka, Yale, Xelopes) provide user-friendly access to rich collections of algorithms, they generally offer no real decision support to non-expert end-users. Similarly, tools with emphasis on advanced visualization help users understand the data (e.g., to select adequate transformations) and the models (e.g., to tweak parameters, compare results, and focus on specific parts of the model), but treat algorithm selection as a post-processing activity driven by the users rather than the system. Data mining practitioners need systems that guide them by producing explicit advice automatically. This chapter shows how meta-learning can be leveraged to provide such advice in the context of algorithm selection.

BACKGROUND

STABB is an early precursor of meta-learning systems in the sense that it was the first to show that a learner's bias can be adjusted dynamically (Utgoff, 1986). VBMS may be viewed as the first simple meta-learning system (Rendell et al., 1989). It learns to choose one of three symbolic learning algorithms as a function of the number of training instances and the number of features. The StatLog project extended VBMS significantly by considering a larger number of

dataset characteristics, together with a broad class of candidate models and algorithms for selection (Brazdil & Henery, 1994). The aim was to characterize the space in which a given algorithm achieves positive generalization performance.

The MLT project focused on the practice of machine learning and produced a toolbox consisting of a number of learning algorithms, datasets, standards and know-how (Kodratoff et al., 1992; Craw et al., 1992). Considerable insight into many important machine learning issues was gained during the project, much of which was translated into meta-rules that formed the basis of a kind of user-guidance expert system called Consultant-2.

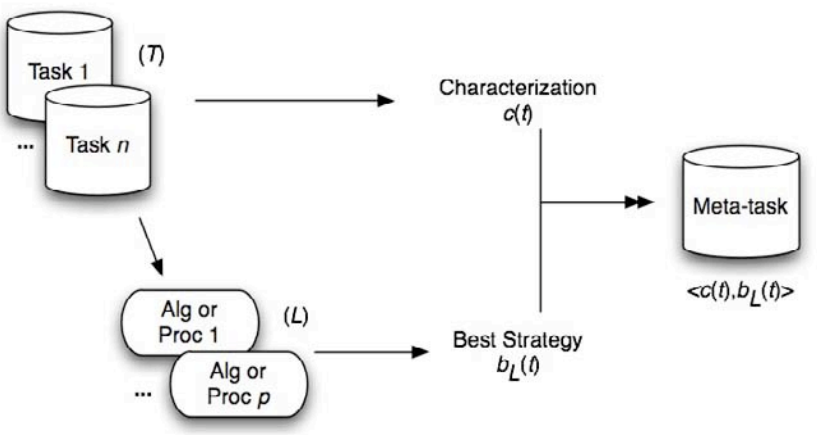
Born out of practical challenges faced by researchers at Daimler Benz AG (now), CITRUS is perhaps the first implemented system to offer user guidance for the complete data mining process, rather than for a single phase of the process (Engels, 1996; Wirth et al., 1997). Algorithm selection takes place in two stages, consisting of: 1) mapping tasks to classes of algorithms, and 2) selecting an algorithm from the selected class. The mapping stage is driven by decomposition and guided by high-level pre/post-conditions (e.g., interpretability). The selection stage consists of using data characteristics (inspired by the Statlog project) together with a process of elimination (called "strike-through"), where algorithms that do not work for the task at hand are successively eliminated until the system finds one applicable algorithm. Although there is no meta-learning in the traditional sense in CITRUS, there is still automatic guidance beyond the user's own input.

Finally, theoretical results, such as the NFL theorems and their consequences have helped in identifying limitations and opportunities for meta-learning (Schaffer, 1994; Wolpert & Macready, 1995; Wolpert, 2001). Additionally, extensive empirical studies have confirmed the theory, and provided additional insight into learning that may serve both as a source of direct meta-knowledge and as input to meta-learning (Aha, 1992; Holte, 1993; Lim et al., 2000).[1]

MAIN FOCUS

Meta-learning, in the context of model selection, consists of applying learning mechanisms to the problem of mapping learning tasks to algorithms. Let L be a set of learning algorithms and T be a set of learning tasks such that for each t in T, $b_L(t)$ represents the algorithm in L that performs best on t for some user-defined performance criterion (e.g., predictive accuracy, execution time).[2] Since learning tasks may be unwieldy to handle

Figure 1. Meta-dataset construction



directly, some type of task characterization is used and the meta-learner actually learns a mapping from characterizations to algorithms. For each learning task t, let $c(t)$ denote the characterization of t by some fixed mechanism. The set $\{<c(t), b_L(t)>: t \text{ in } T\}$ constitutes a meta-task or meta-dataset, as depicted in Figure 1.

A meta-learner can then take the meta-dataset $\{<c(t), b_L(t)>: t \text{ in } T\}$ as a training set and induce a meta-model that, for each new learning task, predicts the model from L that will perform best. Alternatively, one may build a meta-model that predicts a ranking of algorithms from L (Berrer et al., 2000; Brazdil et al., 2003). The ranking approach reduces the brittleness of the meta-model. Assume, for example, that the model predicted best for some new learning task results in what appears to be a poor performance. In the single-model prediction approach, the user has no further information as to what other model to try. In the ranking approach, the user may try the second best, third best, and so on, in an attempt to improve performance. Furthermore, ranking makes it easier to include additional (possibly qualitative) criteria, such as comprehensibility, in the selection process (Giraud-Carrier, 1998).

Clearly, one of the challenges of meta-learning is the construction of the meta-dataset, i.e, $<c(t), b_L(t)>$ pairs for some base level learning tasks. This raises issues with: 1) the choice of the characterization mechanism c, 2) the choice of the set of learners L, 3) the collection of representative tasks, and 4) the cost of computing $c(t)$ and $b_L(t)$ for each task. We briefly discuss each of these issues in the following sections.

Characterization Mechanism

As in any learning task, the characterization of the examples plays a crucial role in enabling learning. The central idea is that high-quality dataset characteristics or meta-features provide useful information to discriminate among the performances of a set of given learning strategies. Typical characterization techniques belong to one of the following classes.

- *Statistical and Information-Theoretic Characterization.* A number of statistical and information-theoretic measures are extracted from the dataset, such as number of classes, number of features, ratio of examples to features, degree of correlation between features and target concept, average class entropy and class-conditional entropy, skewness, kurtosis, signal–to-noise ratio, etc. (Aha, 1992; Michie et al., 1994; Engels & Theusinger, 1998; Sohn, 1999; Köpf et al., 2000; Kalousis, 2002).
- *Model-Based Characterization*. Models induced on the dataset are used as indicators of the underlying properties of the dataset. To date, only decision trees have been used for the extraction of characteristics such as nodes per feature, maximum tree depth, shape, tree imbalance, etc. (Bensusan et al., 2000; Peng et al., 2002).
- *Landmarking*. The performances of simple learners, known as landmarkers, are computed on the dataset using cross-validation (Bensusan & Giraud-Carrier, 2000; Pfahringer et al., 2000). The idea is that landmarkers serve as signposts of the performance of the full-fledged target learners in L. Alternatively, one can exploit accuracy results obtained on simplified versions of the data (e.g., samples), known as sub-sampling landmarks (Fürnkranz & Petrak, 2001; Soares et al., 2001).

Choice of Base-level Learners

Although no learner is universal, each learner has its own area of expertise, which can be informally defined as the set of learning tasks on which it performs well. Since the role of the meta-model is to predict which algorithm is most likely to perform best on each new task, one should select base learners with complementary areas of expertise. In principle, one should seek the smallest set of learners that is most likely to ensure a reasonable coverage of the base-level learning space. One way to ensure diversity is by choosing representative learners from varied model classes. The more varied the biases, the greater the coverage.

Meta-Dataset Construction

The number of accessible, documented, real-world learning tasks is relatively small, which poses a challenge for learning. This challenge may be addressed either by augmenting the meta-dataset through systematic generation of synthetic base level tasks, or by taking the view that the model selection task is inherently incremental and treating it as such. The second approach results in slower learning since learning tasks become available over time. On the other hand, it naturally adapts to reality, extending to new areas

of the base level learning space only when tasks from these areas actually arise.

Computational Cost

The computational cost is the price to pay to be able to perform model selection learning at the meta-level. However, in order to be justifiable, the cost of computing $c(t)$ should be significantly lower than the cost of computing $b_L(t)$. Otherwise, even if the meta-model is very accurate, it has little value as the user would be better off trying all algorithms and selecting the best one, which clearly defeats the purpose of meta-learning. The characterization mechanisms listed above all include many measures that satisfy this condition.

Although much remains to be done, results suggest the suitability of meta-learning for model selection (Brazdil & Soares, 2000; Bensusan & Kalousis, 2001; Hilario & Kalousis, 2001). We briefly describe two recent, successful systems as an illustration. One is a strict meta-learning system and offers ranking advice for model selection. The other is based on an ontology, but produces ranking advice for the complete KDD process.

Data Mining Advisor

The Data Mining Advisor (DMA) is the main product of the ESPRIT METAL research project (see http://www.metal-kdd.org). The DMA is a Web-based meta-learning system for the automatic selection of model building algorithms in the context of classification and regression tasks. Given a dataset and goals defined by the user in terms of accuracy and training time, the DMA returns a list of algorithms that are ranked according to how well they are predicted to meet the stated goals.

The DMA guides the user through a wizard-like step-by-step process consisting of 1) uploading a target dataset (with some user-defined level of privacy), 2) characterizing the dataset automatically using statistical and information-theoretic measures, 3) setting the selection criteria and the ranking method, 4) producing the ranking advice, and 5) executing user-selected algorithms on the dataset. Although the induced models themselves are not returned, the DMA reports 10-fold cross-validation accuracy, true rank and score, and, when relevant, training time. A simple example of the ranking produced by the DMA is shown in Figure 2, where some algorithms were selected for execution.

The DMA's choice of providing rankings rather than "best-in-class" is motivated by a desire to give as much information as possible to the user, as discussed above. In some sense, one can argue that the ranking approach subsumes the "best-in-class" approach. Interestingly, empirical evidence suggests that the best algorithm is generally within the top 3 in the DMA rankings (Brazdil et al., 2003).

Intelligent Discovery Assistant

The notion of Intelligent Discovery Assistant (IDA) provides a template for building ontology-driven, pro-

cess-oriented assistants for KDD (Bernstein & Provost, 2001; Bernstein et al., 2005). IDAs encompass the three main algorithmic steps of the KDD process, namely, pre-processing, model building and post-processing. In IDAs, any chain of operations consisting of one or more operations from each of these steps is called a Data Mining (DM) process. The goal of an IDA is to propose to the user a list of ranked DM processes that are both valid and congruent with user-defined preferences (e.g., speed, accuracy).

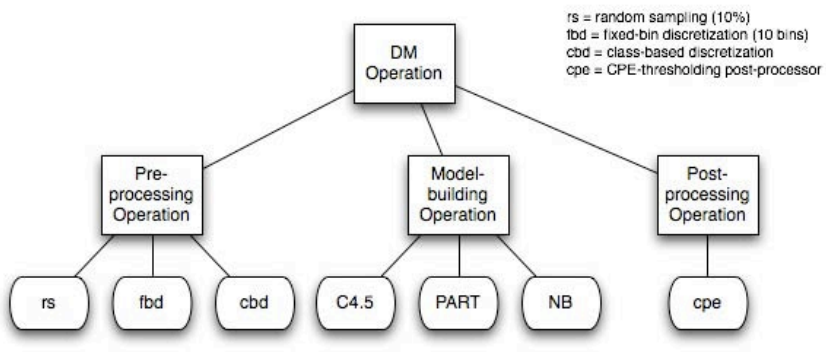
The IDA's underlying ontology is essentially a taxonomy of DM operations or algorithms, where the leaves represent implementations available in the corresponding IDA. Operations are characterized by pre-conditions, post-conditions and heuristic indicators. Clearly, the versatility of an IDA is a direct consequence of the richness of its ontology. The typical organization of an IDA consists of 1) the plan generator, that uses the ontology to build a list of (all) valid DM processes that are appropriate for the task at hand, and 2) the heuristic ranker, that orders the generated DM processes according to preferences defined by the user.

The plan generator takes as input a dataset, a user-defined objective (e.g., build a fast, comprehensible classifier) and user-supplied information about the data, i.e., information that may not be obtained automatically. Starting with an empty process, it systematically searches for an operation whose pre-conditions are met and whose indicators are congruent with the user-defined preferences. Once an operation has been found, it is added to the current process, and its post-conditions become the system's new conditions from which the search resumes. The search ends once a goal state has been found or when it is clear that no satisfactory goal state may be reached. The plan generator's search is exhaustive: all valid DM processes are computed. Figure 3 shows the output of the plan generator for a small ontology of only 7 operations, when the input dataset is continuous-valued and comprehensible classifiers are to be preferred.

The restriction of the plan generator to valid processes congruent with user-defined objectives is generally sufficient to make an exhaustive search feasible. The main advantage of this exhaustivity is that no valid DM process is ever overlooked, as is likely to be the case with most users, including experts. As a result, an IDA may, and evidence suggests that it does, uncover novel processes that experts had never thought about before, thus enriching the community's meta-knowledge (Bernstein & Provost, 2001).

Once all valid DM processes have been generated, a heuristic ranker is applied to assist the user further, by organizing processes in descending order of ``return'' on user-specified goals. For example, the processes in Figure 3 are ordered from simplest (i.e., least number of steps) to most elaborate. The ranking relies on the knowledge-based heuristic indicators. If speed rather than simplicity were the objective, for example, then

Figure 3. Sample list of IDA-generated DM processes



Plan #1: C4.5
Plan #2: PART
Plan #3: rs, C4.5
Plan #4: rs, PART
Plan #5: fbd, C4.5
Plan #6: fbd, PART
Plan #7: cbd, C4.5
Plan #8: cbd, PART
Plan #9: rs, fbd, C4.5
Plan #10: rs, fbd, PART
Plan #11: rs, cbd, C4.5
Plan #12: rs, cbd, PART
Plan #13: fbd, NB, cpe
Plan #14: cbd, NB, cpe
Plan #15: rs, fbd, NB, cpe
Plan #16: rs, cbd, NB, cpe

Plan #3 would be bumped to the top of the list, and all plans involving random sampling would also move up. In the current implementation of IDAs, rankings rely on fixed heuristic mechanisms. However, IDAs are independent of the ranking method and thus, they could possibly be improved by incorporating meta-learning to generate rankings based on past performance.

FUTURE TRENDS

One important research direction in meta-learning consists in searching for improved meta-features in the characterization of datasets. A proper characterization of datasets can elucidate the interaction between the learning mechanism and the task under analysis. Current work has only started to unveil relevant meta-features; clearly much work lies ahead. For example, many statistical and information-theoretic measures adopt a global view of the dataset under analysis; meta-features are obtained by averaging results over the entire training set, implicitly smoothing the actual distribution. There is a need for alternative and more detailed descriptors of the example distribution in a form that highlights the relationship to the learner's performance.

Similarly, further research is needed in characterizing learning algorithms. Recent efforts in model composition may prove useful. In this paradigm, instead of seeking to combine several whole algorithms or to find one algorithm among several that would perform best on a given task, the system breaks the learning process down into sub-components and, for each task, composes a custom, possibly novel, learning system from a combination of these components (Suyama et al., 1998; Abe & Yamaguchi, 2002).

Recently proposed agent-based data mining architectures offer unique ways to increase the versatility, extensibility and usability of meta-learning (Botía et al., 2001; Hernansaez et al., 2004; Zhong et al., 2001).

Finally, the increased amount and detail of data available about the operations of organizations is leading to a demand for a much larger number of models, up to hundreds or even thousands. This kind of application has been called Extreme Data Mining (Fogelman-Soulié, 2006). Current DM methodologies, which are largely dependent on human efforts, are not suitable for this kind of extreme settings because of the large amount of human resources required. Meta-learning can be used to reduce the need for human intervention in model development and thus, we expect that it will play a major role in these large-scale Data Mining applications.

CONCLUSION

From a practical standpoint, meta-learning helps solve important problems in the application of data mining tools. First, the successful use of these tools outside the boundaries of research is conditioned upon the appropriate selection of a suitable predictive model, or combination of models, according to the domain of application. Without some kind of assistance, model selection and combination can turn into solid obstacles to non-expert end-users. Second, a problem commonly observed in the practical use of data mining tools is how to profit from the repetitive use of predictive models over similar tasks. The successful application of models in real-world scenarios requires continuous adaptation to new needs. Rather than starting afresh on new tasks, one would expect the learning mechanism itself to re-learn, taking into account previous experience. Again, meta-learning systems can help control the process of exploiting cumulative expertise by searching for patterns across tasks, thus improving the utility of data mining. Interestingly, generalizations of meta-learning for algorithm selection in other areas, such as cryptography, sorting and optimization, have recently been proposed (Smith-Miles, 2007).

KEY TERMS

Data Mining: Application of visualization, statistics and machine learning to the discovery of patterns in databases. There is general consensus that patterns found by data mining should in some way be novel and actionable.

Landmarking: A task characterization that replaces a learning task by the performances of a number of simple and efficient learning algorithms on that task.

Meta-Dataset: Dataset consisting of task characterizations (or meta-features) together with their associated best strategy (i.e., learning algorithm or data mining process that gives the best performance on the task).

Meta-Features: Features used to characterize datasets, that serve as inputs to meta-learning. These features may take the form of statistics, landmarkers or model-based attributes.

Meta-Learning: Application of learning techniques at the meta-level. Any use of learning methods to help inform the process of machine learning. Learning about learning.

Task Characterization: A method for extracting features, then known as meta-features, from the dataset associated with a learning task.

ENDNOTES

[1] Note that, although it is sometimes viewed as a form of meta-learning, we purposely omit from this discussion the notion of model combination. Model combination consists of creating a single learning system from a collection of learning algorithms. It has been shown that in many cases improved performance is obtained by combining the strengths of several learning algorithms. These approaches reduce the probability of misclassification based on any single induced model by increasing the system's area of expertise through combination. However, from the meta-learning perspective, they can be regarded as single algorithms.

[2] It is easy to extend the notion of best learning algorithm for *t* to best data mining process for *t*.

A Method of Recognizing Entity and Relation

Xinghua Fan
Chongqing University of Posts and Telecommunications, China

INTRODUCTION

Entity and relation recognition, i.e. assigning semantic classes (e.g., person, organization and location) to entities in a given sentence and determining the relations (e.g., born-in and employee-of) that hold between the corresponding entities, is an important task in areas such as information extraction (IE) (Califf and Mooney, 1999; Chinchor, 1998; Freitag, 2000; Roth and Yih, 2001), question answering (QA) (Voorhees, 2000; Changki Lee et al., 2007) and story comprehension (Hirschman et al., 1999). In a QA system, many questions ask for the specific entities involved in some relations. For example, the question that "Where was Poe born?" in TREC-9 asks for the location entity in which Poe was born. In a typical IE extraction task such as constructing a jobs database from unstructured text, the system has to extract many meaning entities like title and salary, ideally, to determine whether the entities are associated with the same position.

BACKGROUND

In all earlier works as we know of, except for Roth and Yih' work (2002), the entity and relation recognition task is treated as two separate subtasks, which are typically carried out sequentially, i.e. firstly, use an entity recognizer to identify entities, and then use a relation classifier to determine the relations. This procedure is problematic: firstly, errors made by the entity recognizer are propagated to the relation classifier with an accumulative effect and may degrade its performance significantly. For example, if "Boston" is mislabeled as a person, it will never be classified as the location of Poe's birthplace. Secondly, some relation information can be available only during the relation recognition, and the information is sometimes crucial to resolve ambiguity of entity recognition. For example, if we know that the class of an entity corresponds to the first argument X in the relation born-in (X, China), the class of the entity cannot be a location but a person.

To resolve the first problem described above, Roth and Yih (2002) developed a method, in which the two subtasks are carried out simultaneously. Firstly, two classifiers are trained for entities and relations independently, and their outputs are treated as the conditional probability distributions for each entity and relation. Secondly, this information together with the constraint knowledge induced among relations and entities are represented in a belief network (Pearl, 1998) and used to make global inferences for all entities and relations of interest. The idea of making global inferences is very good because it blocks the errors propagation. But the approach has still several problems. Firstly, the belief network cannot fully model the entity and relation recognition question since it allows no cycles, and the question need a probability model that can deal with loop. For example, relation R_{12} and R_{21} actually depend on each other (e.g., if R_{12} is born-in, then R_{21} will not be born-in), so there exists a loop between entity E_1 and E_2 through R_{12} and R_{21}. Secondly, the method cannot use some constraint knowledge that is only available during relation recognition and helpful to improve the precision of entity recognition.

To overcome the shortages described above, Fan and Sun (2005, 2006) presented a solution, which includes (1) to present the model dubbed "entity relation propagation diagram" and "entity relation propagation tree", and (2) to develop a method for this task based on the model. The presented method allows subtasks entity recognition and relation recognition to be linked more closely together. At the same time, the method can model the loopy dependencies among entities and relations, and can use two kinds of constraint knowledge learned from the annotated dataset.

MAIN FOCUS

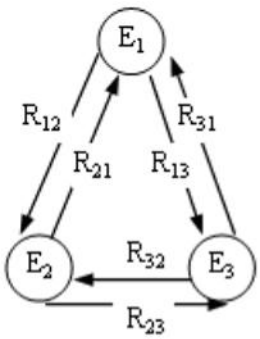
The Problem of Entity and Relation Recognition

For readability, an example sentence is illustrated as Figure 1. Conceptually, the entities and relations in a sentence can be viewed, while taking account of the mutual dependencies among them, as the labeled graph in Figure 2. In Figure 2(a), a node represents an entity and a link denotes the relation held between two entities. The arrowhead of a link represents the direction of the relation. Each entity or relation has several attributes respectively, which are denoted as a corresponding table (Figure 2(b) and Figure 2(c)). These attributes can be classified into two classes. Some of them that are easy to acquire via learned classifiers, such as words inside an entity and parts of speech of words in the context, are called local attribute; and other attributes that are difficult to acquire, such as semantic classes of phrases and relations among them, are called decision attribute. The question of recognizing entity and relation is to determine a unique value for each decision attribute of all entities and relations, while taking account of the local attributes of all entities and all relations. To describe the problem in a formal way, some basic definitions are given as follows.

Figure 1. A sentence that has three entities

Dole (E_1)'s wife, Elizabeth (E_2), is a native of Salisbury, N.C. (E_3)

Figure 2. Conceptual view of entity and relation



(a)

Entity Name	E_1	E_2	E_3
Attribute-1 (words)	Dole	Elizabeth	Salisbury, N.C.
Attribute-2 (POS)	Noun	Noun	Noun
…	…	…	…
Attribute-m	…	…	…

(b)

Relation Name	R_{12}	R_{23}
Attribute-1 (special pattern)	E_1's wife, E_2	E_2 be naïve of E_3
…	…	…
Attribute-n	…	…

(c)

Definition 1 (Entity): An entity can be a single word or a set of consecutive words with a predefined boundary. A sentence is a linked list, which consists of words and entities. Entities in a sentence are denoted as E_1, E_2 … according to their order, and they take values that range over a set of entity class C^E. For example, the sentence in Figure 1 has three entities: E_1= "Dole", E_2= "Elizabeth" and E_3= "Salisbury, N.C.".

Definition 2 (Relation): In this chapter, we only consider the relation between two entities. An entity pair (E_i, E_j) represents the relation R_{ij} from entity E_i and E_j, where E_i is the first argument and E_j is the second argument. Relation R_{ij} take values that range over a set of relation class C^R. Note that (E_i, E_j) is an ordered pair, and there exists two relations $R_{ij} = (E_i, E_j)$ and $R_{ji} = (E_j, E_i)$ between entities E_i and E_j.

Definition 3 (Class): The class of an entity or relation is its decision attribute, which is one of the predefined class set and cannot be known before recognizing them. We denote the sets of predefined entity class and relation class as C^E and C^R respectively. All elements in C^E or C^R are mutually exclusive respectively.

Definition 4 (Constraint): A constraint is a 5-tuple $(r, \varepsilon^1, \varepsilon^2, \alpha_R, \alpha_\varepsilon)$. The symbols are defined as follows. $r \in C^R$ represents the class of a relation R_{ij}. $\varepsilon^1, \varepsilon^2 \in C^E$ represent the classes of the first argument E_i and the second argument E_j in the relation R_{ij} respectively. $\alpha_R \in [0,1]$ is real number that represents a joint conditional probability distribution of the classes of its two arguments, given the class r of the relation R_{ij}, i.e. $\alpha_R = \Pr\{\varepsilon^1, \varepsilon^2 \mid r\}$. $\alpha_\varepsilon \in [0,1]$ is real number that represents a conditional probability distribution of the class of a relation, given the classes of its two arguments ε^1 and ε^2, i.e. $\alpha_\varepsilon = \Pr\{r \mid \varepsilon^1, \varepsilon^2\}$. Note that α_R and α_ε can be easily learned from an annotated training dataset.

Definition 5 (Observation): We denote the observations of an entity and a relation in a sentence as O^E and O^R respectively. O^E or O^R represents all the "known" local properties of an entity or a relation, e.g., the spelling of a word, part-of-speech, and semantic related attributes acquired from external resources such as WordNet. The observations O^E and O^R can be viewed as random event, and $\Pr\{O^E\} = \Pr\{O^R\} \equiv 1$ because O^E and O^R in a given sentence are known.

Based on the above definitions, the question of entity and relation recognition can be described in a formal way as follows. Suppose in a given sentence, the set of entities is $\{E_1, E_2 \ldots E_n\}$, the set of relations is $\{R_{12}, R_{21}, R_{13}, R_{31}, \ldots, R_{1n}, R_{n1}, \ldots, R_{n-1,n}, R_{n,n-1}\}$, the predefined sets of entity classes and relation classes are $C^E = \{e_1, e_2, \ldots e_m\}$ and $C^R = \{r_1, r_2, \ldots r_k\}$ respectively, the observation of entity E_i is O_i^E, and the observation of relation R_{ij} is O_{ij}^R. n, m and k represent the number of entities, the number of the predefined entity classes and the number of the predefined relation classes respectively. The question is to search the most probable class assignment for each entity and relation of interest, given the observations of all entities and relations. In other words, the question is to solve the following two equations, using two kinds of constraint knowledge α_R and α_ε and the interaction among entities and relations illustrated as Figure 2.

$$e = \arg\max_d \Pr\{E_i = e_d \mid O_1^E, O_2^E, \cdots, O_n^E, O_{12}^R, O_{21}^R, \cdots, O_{1n}^R, O_{n1}^R, \cdots, O_{n-1,n}^R, O_{n,n-1}^R\} \quad (1)$$

$$r = \arg\max_d \Pr\{R_{ij} = r_d \mid O_1^E, O_2^E, \cdots, O_n^E, O_{12}^R, O_{21}^R, \cdots, O_{1n}^R, O_{n1}^R, \cdots, O_{n-1,n}^R, O_{n,n-1}^R\} \quad (2)$$

In equation (1), d =1, 2, …, m. And in equation (2), d=1, 2, …, k.

The Proposed Framework (Fan and Sun, 2005; Fan and Sun, 2006)

Because the class assignment of a single entity or relation depends not only on local attributes of itself, but also on those of all other entities and relations, the equation (1) and equation (2) cannot be solved directly. To simplify the problem, Fan and Sun presented the following method consisting of three stages:

At the first stage, the method employs two classifiers that perform subtasks entity recognition and relation recognition for each entity and each relation independently. Their outputs are used as conditional probability distributions $\Pr\{E|O^E\}$ and $\Pr\{R|O^R\}$ for each entity and relation, given the corresponding observations. Note that each of the local classifier could only depend on a large number of features, which are

not viewed as relevant to the latter inference process. The purpose at the first stage is to abstract away from the process of "inference with classifiers".

At the second stage, the class of each entity is determined by taking into account the classes of all the entities, as computed at the previous stage. This is achieved using the model dubbed "entity relation propagation diagram (**ERPD**)" and "entity relation propagation tree (**ERPT**)". During this stage, the constraint knowledge α_R in definition 4 and the conditional probability distribution $\Pr\{R|O^R\}$ for each relation, as computed at the first stage, are used.

At the third stage, each relation is recognized, while considering the classes of the involved entities produced during the second stage. During this stage, the constraint knowledge α_ε in definition 4 is used.

The procedure learning basic classifiers for entities and relations at the first stage is the same as Roth and YiH's approach (2002), which uses SnoW (Roth, 1998) as the prepositional learner. See, e.g., Roth and YiH (2002) for details. At the second stage, the aim of introducing ERPD is to estimate the conditional probability distribution $\Pr\{E|\,ERPD\}$ given the constraint α_R in definition 4 and the sets $\{\Pr\{E_i \mid O^{Ei}\}\}$ and $\{\Pr\{R_{ij} \mid O^{Rij}\}\}$ (i, j=1,…,n), as computed at the first stage.

For the readability, suppose $\Pr\{E|\,ERPD\}$ is given, the entity recognition equation (1) becomes the equation (3).

$$e = \begin{cases} \arg\max_j \Pr\{E_i = e_j \mid O_i^E\} & RV > \theta \\ \arg\max_j \Pr\{E_i = e_j \mid ERED\} & RV \le \theta \end{cases} \quad (3)$$

where, θ is a threshold determined experimentally. **RV** $\in$ [0, 1] is a real number, called the Reliable Value (**RV**), representing the belief degree of the output of the entity recognizer at the first stage. Suppose the maximum value of the conditional probability distribution of the target entity, given the observation, as Vm and the secondary maximum value as Vs, **RV** is defined as:

$$RV = \frac{V_m - V_s}{V_m + V_s} \quad (4)$$

The reason of introducing **RV** is due to a fact that only for ambiguous entities, it is effective by taking the classes of all entities in a sentence into account. **RV** measures whether an entity is ambiguous.

After we have recognized the classes of its two arguments in relation R, the relation can be recognized according to the following equation (5), i.e. the equation (2) becomes the following equation (5). The base idea is to search the probable relation among the different candidate relation classes given the observation, under satisfying the relation class constraint decided by the results of recognizing entity at the second stage.

$$r = \arg\max_k \Pr\{R = r^k \mid O_R\} \times W_R$$

$$W_R = \begin{cases} 1 & \text{if } \Pr\{r \mid \varepsilon^1, \varepsilon^2\} > 0 \\ 0 & \text{if } \Pr\{r \mid \varepsilon^1, \varepsilon^2\} = 0 \end{cases} \quad (5)$$

where, ε^1, ε^2 is the results of entity prediction at the second stage, $\Pr\{r|\ \varepsilon^1, \varepsilon^2\}$ is constraint knowledge α_ε in definition 4, and W_R is the weight of the constraint knowledge.

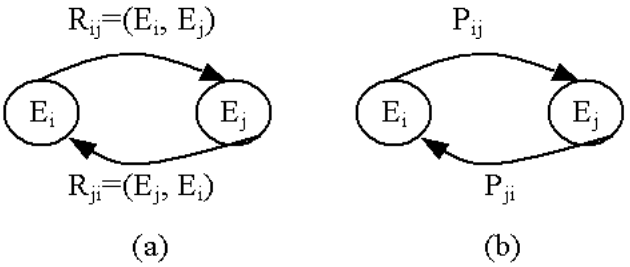
Entity Relation Propagation Diagram (Fan and Sun, 2005; Fan and Sun, 2006)

To fully represent the mutual dependencies, a model that can deal with cycles is designed for entity & relation recognition. Here, the model dubbed entity relation propagation diagram, which is similar to Causality Diagram (Fan, 2002; Fan et al., 2003) that has been applied on complex system fault diagnosis, is presented.

The classes of any two entities are dependent on each other through the relations, taking into account the relations between them. For example, the class of entity E_i in Figure 3(a) depends on the classes of relations R_{ij} and R_{ji} between entities E_i and E_j, and the classes of relations R_{ij} and R_{ji} depend on the classes of entities E_i and E_j. This means we can predict the class of the target entity according to the class of the neighboring entity, using the relations between them. Here, the relation reaction intensity is introduced to describe the prediction ability of this kind.

Definition 6 (Relation Reaction Intensity): We denote the relation reaction intensity from entity E_i to entity E_j as P_{ij}, which represents the ability that we can guess the class of E_j if we know the class of its neighboring entity E_i and the relation R_{ij} between them. The relation reaction intensity could be modeled using a condition probability

Figure 3. Illustration of the relation reaction between two entities



distribution $P_{ij}=Pr\{E_j|E_i\}$, and it is a matrix as follows.

$$\mathbf{P}_{ij}=\left[\mathbf{P}_{ij}^{1\bullet}\ \cdots\ \mathbf{P}_{ij}^{n\bullet}\right]=\begin{bmatrix} p_{ij}^{11} & \cdots & p_{ij}^{n1} \\ \vdots & \ddots & \\ p_{ij}^{n1} & \cdots & p_{ij}^{nn} \end{bmatrix}_{n\times n}$$

where n is the number of entity class. $\mathbf{P}_{ij}^{k\bullet}$ is the kth column of $\mathbf{P}_{ij}$, which represents the conditional probabilities of assigning different classes of entity E_j given the class of E_i as e_k.

According to the definition 3, all elements in C^E are mutually exclusive, thus we have

$$\sum_{l=1}^{n} p_{ij}^{kl}=1 \tag{6}$$

The element p_{ij}^{k} of P_{ij} represents the conditional probability $Pr\{E_j=e_l|E_i=e_k\}$, which is computed as follows.

$$\begin{aligned} p_{ij}^{kl} &= \Pr\{E_j=e_l \mid E_i=e_k\} \\ &= \sum_{t=1}^{N}\frac{\Pr\{R_{ij}=r_t\}\Pr\{E_i=e_k, E_j=e_l \mid R_{ij}=r_t\}}{\Pr\{E_i=e_k\}} \end{aligned}$$

According to definition 5, have

$$\Pr\{R_{ij}=r_t\}=\Pr\{R_{ij}=r_t \mid O_{ij}^{R}\},$$

$$\Pr\{E_i=e_k\}=\Pr\{E_i=e_k \mid O_i^{E}\}.$$

Then

$$p_{ij}^{kl}=\sum_{t=1}^{N}\frac{\Pr\{R_{ij}=r_t \mid O_{ij}^{R}\}\Pr\{E_i=e_k, E_j=e_l \mid R_{ij}=r_t\}}{\Pr\{E_i=e_k \mid O_i^{E}\}} \tag{7}$$

where $r_t \in C^R$, N is the number of relations in relation class set. In equation (7), $\Pr\{E_i=e_k, E_j=e_1 \mid R_{ij}=r_t\}$ represents the constraint knowledge α_R among entities and relations. $\Pr\{R_{ij}=r_t \mid O_{ij}^{R}\}$ and $\Pr\{E_i=e_k \mid O_i^{E}\}$ represent the outputs at the first stage.

Considering equation (7) together with equation (6), the result of computing according to equation (7) should be normalized according to equation (3). Thus, we have

$$\mathbf{P}_{ij}^{k\bullet}=\mathrm{Norm}\left(\begin{bmatrix} p_{ij}^{k1} \\ \vdots \\ p_{ij}^{kn} \end{bmatrix}\right) \tag{8}$$

where Norm(.) is a function which normalizes the vector in {}. For example,

$$\mathrm{Norm}\left(\begin{bmatrix} 0.5 \\ 0.7 \\ 0.8 \end{bmatrix}\right)=\begin{bmatrix} 0.5/(0.5+0.7+0.8) \\ 0.7/(0.5+0.7+0.8) \\ 0.8/(0.5+0.7+0.8) \end{bmatrix}=\begin{bmatrix} 0.25 \\ 0.35 \\ 0.4 \end{bmatrix}.$$

It is easy to see that $Pr\{E_i = e_k | O_i^E\}$ doesn't contribute to the normalized value. This means that the relation reaction intensity depends only on constraint knowledge α_R and the conditional probability distribution of the classes of relations given the observation.

Definition 7 (Observation Reaction Intensity): We denote the observation reaction intensity as the conditional probability distribution of an entity class, given the observation, i.e. $Pr\{E|O^E\}$, which is the output result at the first stage in the framework.

Entity Relation Propagation Diagram (ERPD) is a directed diagram, which allows cycles. As illustrated in Figure 4, the symbols used in the ERPD are defined as follows.

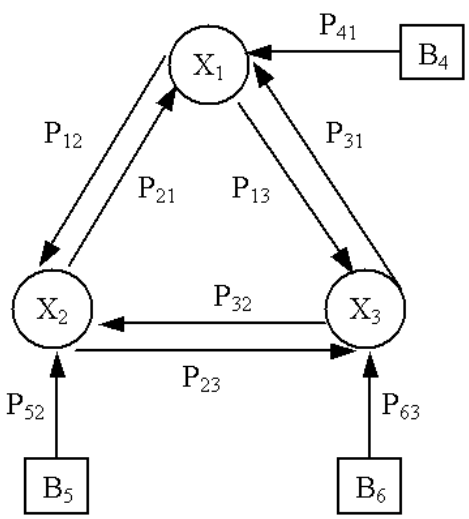
Circle: A node event variable that may equal any one of a set of mutually exclusive node events, which together cover the whole node sample space. Here, a node event variable represents an entity, a node event represents a predefined entity class, and the whole sample space represents the set of predefined entity classes. Box: A basic event is one of the independent sources of the linked node event variable. Here, a basic event represents the observation of an entity. Directed arc: A linkage event variable that may or may not enable an input event to cause the corresponding output event. Here, the linkage event variable from a node event variable to another node event variable represents relation reaction intensity in definition 6. And the linkage event variable from a basic event to the corresponding node event variable represents observation reaction intensity in definition 7. All arcs pointing to a node are logical OR relationship.

The method of computing the conditional probability distribution Pr{E| ERPD} based on the ERPD is described in the paper (Fan and Sun, 2006) for detail.

FUTURE TRENDS

The precision of recognizing entity affects directly the precision of recognizing relation between two entities. The future work will concentrate on how to improve the entity recognition. Based on the results in the paper (Fan and Sun, 2006), we think the possible solution is to define some additional relations between two entities. The additional relation is defined by experts and has the following characters: (1) it is easy to recognize by a relation classifier, i.e., its features are very rich and have strong discriminability. (2) This relation should

Figure 4. Illustration of an entity and relation propagation diagram



be helpful for the entity recognition. For example, the task is to recognize entity Clinton, White House and the relation between them. Suppose it is very difficult to recognize the entity Clinton and the relation between Clinton and White House, an additional relation spouse between Clinton and Hillary may be introduced because the relation spouse is easy to recognize and it is helpful to recognize entity Clinton.

CONCLUSION

Entity and relation recognition in text data is a key task in areas such as information extraction and question answering. The typically procedure for this question has several problems, (1) it cannot block errors propagation from entity recognizer to relation classifier, and (2) it cannot use some useful information that becomes available during relation recognition. The method based on the belief network has still several problems, (1) it cannot model the loopy dependencies among entities and relations, (2) it cannot use the constraint knowledge α_R, and (3) it cannot improve the entity recognition. The method based on entity relation propagation diagram (ERPD) has the following advantages, (1) entity relation propagation diagram can model the loopy dependencies among entities and relations, and (2) it can use two kinds of constraint knowledge α_R and α_ε learned from the annotated dataset. So, the method can improve not only relation recognition but also entity recognition in some degree.

KEY TERMS

Entity and Relation Recognition (ERR): The entity and relation recognition is the task of assigning semantic classes (e.g., person, organization and location) to entities in a given sentence (i.e., Named Entity Recognition) and determining the relations (e.g., born-in and employee-of) that hold between the corresponding entities.

Entity Relation Propagation Diagram (ERPD): It is a directed diagram that allows cycles, in which an entity is considered as a node event variable and denoted as a circle, a node event represents a predefined entity class; the observation of an entity, i.e., the "known" local properties of an entity such as the spelling of a word, part-of-speech, is considered as a basic event and denoted as a box; the relation between two entities is transformed into a relation reaction intensity, is denoted as a directed arc pointed from the input event to the output event. An ERPD integrates all entities, their "known" local properties and the relation between two entities.

Information Extraction (**IE**): It is a sub-discipline of language engineering, a branch of computer science. It aims to apply methods and technologies from practical computer science to the problem of processing unstructured textual data automatically, with the objective to extract structured knowledge regarding a predefined domain.

Knowledge Representation (**KR**): Knowledge representation is the study of how knowledge about the world can be represented and what kinds of reasoning can be done with that knowledge.

Named Entity Recognition (NER): Named entities are atomic elements in text belonging to predefined categories such as the names of persons, organizations, locations, expressions of times, quantities, monetary values, percentages, etc. Named entity recognition is the task of identifying such named entities.

Relation Reaction Intensity: It is a condition probability distribution matrix, which represents the ability that we can guess the class of entity E_j if we know the class of its neighboring entity E_i and the relation R_{ij} between them.

Microarray Data Mining

Li-Min Fu
Southern California University of Health Sciences, USA

INTRODUCTION

Based on the concept of simultaneously studying the expression of a large number of genes, a DNA microarray is a chip on which numerous probes are placed for hybridization with a tissue sample. Biological complexity encoded by a deluge of microarray data is being translated into all sorts of computational, statistical or mathematical problems bearing on biological issues ranging from genetic control to signal transduction to metabolism. Microarray data mining is aimed to identify biologically significant genes and find patterns that reveal molecular network dynamics for reconstruction of genetic regulatory networks and pertinent metabolic pathways.

BACKGROUND

The idea of microarray-based assays seemed to emerge as early as of the 1980s (Ekins & Chu, 1999). In that period, a computer-based scanning and image-processing system was developed to quantify the expression level in tissue samples of each cloned complementary DNA sequence spotted in a 2D array on strips of nitrocellulose, which could be the first prototype of the DNA microarray. The microarray-based gene expression technology was actively pursued in the mid-1990s (Schena et al., 1998) and has seen rapid growth since then (Bier et al., 2008).

Microarray technology has catalyzed the development of the field known as functional genomics by offering high-throughput analysis of the functions of genes on a genomic scale (Schena et al., 1998). There are many important applications of this technology, including elucidation of the genetic basis for health and disease, discovery of biomarkers of therapeutic response, identification and validation of new molecular targets and modes of action, and so on. The accomplishment of decoding human genome sequence together with recent advances in the biochip technology has ushered in genomics-based medical therapeutics, diagnostics, and prognostics.

MAIN THRUST

The laboratory information management system (LIMS) keeps track of and manages data produced from each step in a microarray experiment, such as hybridization, scanning, and image processing. As microarray experiments generate a vast amount of data, the efficient storage and use of the data require a database management system. While some databases are designed to be data archives only, other databases such as ArrayDB (Ermolaeva et al., 1998) and Argus (Comander, Weber, Gimbrone, & Garcia-Cardena, 2001) allow information storage, query and retrieval as well as data processing, analysis and visualization. These databases also provide a means to link microarray data to other bioinformatics databases (e.g., NCBI Entrez systems, Unigene, KEGG, OMIM). The integration with external information is instrumental to the interpretation of patterns recognized in the gene-expression data. To facilitate the development of microarray databases and analysis tools, there is a need to establish a standard for recording and reporting microarray gene expression data. The MIAME (Minimum Information about Microarray Experiments) standard includes a description of experimental design, array design, samples, hybridization, measurements and normalization controls (Brazma et al., 2001).

Data Mining Objectives

Data mining addresses the question of how to discover a gold mine from historical or experimental data, particularly in a large database. The goal of data mining and knowledge discovery algorithms is to extract implicit, previously unknown and nontrivial patterns, regularities, or knowledge from large data sets that can be used to improve strategic planning and decision-mak-

ing. The discovered knowledge capturing the relations among the variables of interest can be formulated as a function for making prediction and classification or as a model for understanding the problem in a given domain. In the context of microarray data, the objectives are identifying significant genes and finding gene expression patterns associated with known or unknown categories. Microarray data mining is an important topic in bioinformatics, a field dealing with information processing on biological data, particularly, genomic data.

Practical Factors Prior to Data Mining

Some practical factors should be taken into account prior to microarray data mining. At first, microarray data produced by different platforms vary in their formats and may need to be processed differently. For example, one type of microarray with cDNA as probes produces ratio data from two channel outputs whereas another type of microarray using oligonucleotide probes generates non-ratio data from a single channel. Also, different platforms may pick up gene expression activity with different levels of sensitivity and specificity. Moreover, different data processing techniques may be required for different data formats.

Normalizing data to allow direct array-to-array comparison is a critical issue in array data analysis since there are several variables in microarray experiments that can affect measured mRNA levels (Schadt, Li, Ellis, & Wong, 2001; Yang et al., 2002). Variations may occur during sample handling, slide preparation, hybridization, or image analysis. Normalization is essential for correct microarray data interpretation. In simple ways, data can be normalized by dividing or subtracting expression values by a representative value (e.g., mean or median in an array) or by taking a linear transformation to zero mean and unit variance. As an example, data normalization in the case of cDNA arrays may proceed as follows. The local background intensity is first subtracted from the value of each spot on the array; and the two channels are normalized against the median values on that array; and then the Cy5/Cy3 fluorescence ratios and $\log_{10}$-transformed ratios are calculated from the normalized values. In addition, genes that do not change significantly can be removed through a filter in a process called data filtration.

While data analysis is a central issue in data mining, experimental design is critical as well. In particular, the use of replication in controlled experiments can significantly improve the outcome (Lee, Kuo, Whitmore, & Sklar, 2000).

Differential Gene Expression

To identify genes differentially expressed across two conditions is one of the most important issues in microarray data mining. In cancer research, for example, we wish to understand what genes are abnormally expressed in a certain type of cancer, so we conduct a microarray experiment and collect the gene expression profiles of normal and cancer tissues, respectively, as the control and test samples. The information regarding differential expression is derived from comparing the test against control sample.

To determine which genes are differentially expressed, a common approach is based on fold-change. In this approach, we simply decide a fold-change threshold (e.g., 2X) and select genes associated with changes greater than that threshold. If a cDNA microarray is used, the ratio of the test over control expression in a single array can be converted easily to fold change in both cases of up-regulation (induction) and down-regulation (suppression). For oligonucleotide chips, fold-change is computed from two arrays, one for test and the other for control sample. In this case, if multiple samples in each condition are available, the statistical t-test or Wilcoxon tests can be applied but the catch is that the Bonferroni adjustment to the level of significance on hypothesis testing would be necessary to account for the presence of multiple genes. The t-test determines the difference in mean expression values between two conditions and identifies genes with significant difference. The non-parametric Wilcoxon test is a good alternative in the case of non-Gaussian data distribution. SAM (Significance Analysis of Microarrays) (Tusher, Tibshirani, & Chu, 2001) is a state-of-the-art technique based on balanced perturbation of repeated measurements and minimization of the false discovery rate (FDR). FDR is the expected proportion of false positives among all declared positives. FDR, as an alternative to the *p*-value, has been widely accepted for gene selection from microarray data (Yang & Yang, 2006). In addition, multivariate statistical analysis techniques, such as singular value decomposition (Alter, Brown, & Botstein, 2000) and multi-dimensional scaling, can be applied to reduce the high dimensionality of microarray data.

Coordinated Gene Expression

Identifying genes that are co-expressed across multiple conditions is an issue with significant implications in microarray data mining. For example, given gene expression profiles measured over time, we are interested in knowing what genes are functionally related. The answer to this question also leads us to deduce the functions of unknown genes from their correlation with genes of known functions. Equally important is the problem of organizing samples based on their gene expression profiles so that distinct phenotypes or disease processes may be recognized or discovered.

The solutions to both problems are based on so-called cluster analysis, which is meant to group objects into clusters according to their similarity. For example, genes are clustered by their expression values across multiple conditions; samples are clustered by their expression values across genes. At issue is how to measure the similarity between objects. Two popular measures are the Euclidean distance and Pearson's correlation coefficient. Clustering algorithms can be divided into hierarchical and non-hierarchical (partitional). Hierarchical clustering is either agglomerative (starting with singletons and progressively merging) or divisive (starting with a single cluster and progressively breaking). Hierarchical agglomerative clustering is most commonly used in cluster analysis of microarray data. In this method, two most similar clusters are merged at each stage until all objects are included in a single cluster. The result is a dendrogram (a hierarchical tree) that encodes the relationships among objects by showing how clusters merge at each stage. Partitional clustering algorithms are best exemplified by *k*-means and self-organization maps (SOM). The fact that different clustering algorithms often yield dissimilar results has motivated an approach that seeks a consensus among them (Laderas & McWeeney, 2007).

Discriminant Analysis

Taking an action based on the category of the pattern recognized in microarray gene-expression data is an increasingly important approach to medical diagnosis and management (Furey et al., 2000; Golub et al., 1999; Khan et al., 2001). A class predictor derived on this basis can automatically discover the distinction between different classes of samples, independent of previous biological knowledge (Golub et al., 1999). Gene expression information appears to be a more reliable indicator than phenotypic information for categorizing the underlying causes of diseases. The microarray approach has offered hope for clinicians to arrive at more objective and accurate cancer diagnosis and hence choose more appropriate forms of treatment (Tibshirani, Hastie, Narasimhan, & Chu, 2002).

The central question is how to construct a reliable classifier that predicts the class of a sample on the basis of its gene expression profile. This is a pattern recognition problem and the type of analysis involved is referred to as discriminant analysis. In practice, given a limited number of samples, correct discriminant analysis must rely on the use of an effective gene selection technique to reduce the gene number and hence the data dimensionality. In general, genes that contribute most to classification as well as provide biological insight are selected. Approaches to discriminant analysis range from statistical analysis (Golub et al., 1999) and a Bayesian model (Lee, Sha, Dougherty, Vannucci, & Mallick, 2003) to Fisher's linear discriminant analysis (Xiong, Li, Zhao, Jin, & Boerwinkle, 2001) and support vector machines (SVMs) (Guyon, Weston, Barnhill, & Vapnik, 2002).

Gene Annotation and Pathway Analysis

Differential and coordinated gene expression analyses result in genes or gene clusters critical to the issue under investigation. These results can be further annotated using existing knowledge concerning gene functional classes and gene networks. To this end, an important bioinformatics source is the Gene Ontology (GO) database (at http://www.geneontology.org). This database provides information in the aspects of biological processes, cellular components, and molecular functions for genes under query. Such information can enhance microarray analysis and may also provide cognitive advantages (Lee, Katari, & Sachidanandam, 2005; Liu, Hughes-Oliver, & Menius, 2007).

To reconstruct biological pathways from gene expression data represents a great challenge for microarray data mining. This problem can be tackled more efficiently by capitalizing on existing knowledge. KEGG (the Kyoto Encyclopedia of Genes and Genomics) records networks of molecular interactions on any organism and is instrumental to analysis of the functions of genes and their interactions (Kanehisa & Goto, 2000). Engineering and statistical approaches to

the problem have been developed, notably, the Bayesian network approach. Bayesian networks are graph-based models of joint multivariate probability distributions capturing conditional dependency and independency among variables. The Bayesian approach has been applied to construct gene regulatory networks from gene expression data with success (Friedman, Linial, Nachman, & Pe'er, 2000; Polanski, Polanska, Jarzab, Wiench, & Jarzab, 2007).

Microarray Data Mining Applications

The microarray technology permits a large-scale analysis of gene functions in a genomic perspective and has brought about important changes in how we conduct basic research in science and practice in clinical medicine. There have existed an increasing number of applications with this technology. Table 1 summarizes some of most important microarray data mining problems and their solutions.

Only the minority of all the yeast (Saccharomyces cerevisiae) open reading frames in the genome sequence could be functionally annotated on the basis of sequence information alone (Zweiger, 1999), while microarray results showed that nearly 90% of all yeast mRNAs (messenger RNAs) are observed to be present (Wodicka, Dong, Mittmann, Ho, & Lockhart, 1997). Functional annotation of a newly discovered gene based on sequence comparison with other known gene sequences is sometimes misleading. Microarray-based genome-wide gene expression analysis has made it possible to deduce the functions of novel or poorly characterized genes from co-expression with already known genes (Eisen, Spellman, Brown, & Botstein, 1998). The microarray technology is a valuable tool for measuring whole-genome mRNA and enables system-level exploration of transcriptional regulatory networks (Cho et al., 1998; DeRisi, Iyer, & Brown, 1997; Laub, McAdams, Feldblyum, Fraser, & Shapiro, 2000; Tavazoie, Hughes, Campbell, Cho, & Church, 1999). Hierarchical clustering can help us recognize genes whose cis-regulatory elements are bound by the same proteins (transcription factors) in vivo. Such a set of co-regulated genes is known as a "regulon". Statistical characterization of known regulons is used to derive criteria for inferring new regulatory elements. To identify regulatory elements and associated transcription factors is fundamental to building a global gene regulatory network essential for understanding the genetic control and biology in living cells.

The limitation of the morphology-based approach to cancer classification has led to molecular classifica-

Table 1. Three common computational problems in microarray data mining

Problem I: To identify differentially expressed genes, given microarray gene expression data collected in two conditions, types, or states.

[Solutions:]
- Fold change
- t-test or Wilcoxon rank sum test (with Bonferroni's correction)
- Significance analysis of microarrays

Problem II: To identify genes expressed in a coordinated manner, given microarray gene expression data collected across a set of conditions or time points.

[Solutions:]
- Hierarchical clustering
- Self-organization
- *k*-means clustering

Problem III: To select genes for discriminant analysis, given microarray gene expression data of two or more classes.

[Solutions:]
- Neighborhood analysis
- Support vector machines
- Principal component analysis
- Bayesian analysis
- Fisher's linear discriminant analysis

tion. Techniques such as immunohistochemistry and RT-PCR are used to detect cancer-specific molecular markers, but pathognomonic molecular markers are unfortunately not available for most of solid tumors (Ramaswamy et al., 2001). Furthermore, molecular markers do not guarantee a definitive diagnosis owing to possible failure of detection or presence of marker variants. The approach of constructing a classifier based on gene expression profiles has gained increasing interest, following the success in demonstrating that microarray data differentiated between two types of leukemia (Golub et al., 1999). In this application, the two data-mining problems are to identify gene expression patterns or signatures associated with each type of leukemia and to discover subtypes within each. The first problem is dealt with by gene selection, and the second one by cluster analysis. Table 2 lists some application examples of microarray data mining.

FUTURE TRENDS

The future challenge is to realize biological networks that provide qualitative and quantitative understanding of molecular logic and dynamics. To meet this challenge, recent research has begun to focus on leveraging prior biological knowledge and integration with biological analysis in quest of biological truth. The integration of bioinformatics and system biology has carried microarray data mining to the next level.

CONCLUSION

Microarray technology has rapidly emerged as a powerful tool for biological research and clinical investigation. However, the large quantity and complex nature of data produced in microarray experiments often plague researchers who are interested in using this technology. Microarray data mining uses specific data processing and normalization strategies and has its own objectives, and it requires effective computational algorithms and statistical techniques to arrive at valid results. The microarray technology has been perceived as a revolutionary technology in biomedicine, but the hardware device does not pay off unless backed up with sound data mining software.

Table 2. Examples of microarray data mining applications

Classical Work:

- Identified functional related genes and their genetic control upon metabolic shift from fermentation to respiration (DeRisi et al., 1997).
- Explored co-expressed or co-regulated gene families by cluster analysis (Eisen et al., 1998).
- Determined genetic network architecture based on coordinated gene expression analysis and promoter motif analysis (Tavazoie et al., 1999).
- Differentiated acute myeloid leukemia from acute lymphoblastic leukemia by selecting genes and constructing a classifier for discriminant analysis (Golub et al., 1999).
- Selected genes differentially expressed in response to ionizing radiation based on significance analysis (Tusher et al., 2001).

Recent Work:

- Analyzed gene expression in the Arabidopsis genome (Yamada et al., 2003).
- Discovered conserved genetic modules (Stuart, Segal, Koller, & Kim, 2003).
- Elucidated functional properties of genetic networks and identified regulatory genes and their target genes (Gardner, di Bernardo, Lorenz, & Collins, 2003).
- Identified genes associated with Alzheimer's disease (Roy Walker et al., 2004).
- Detected viruses in human tumors (Li et al., 2006).
- Identified chemosensitivity-related genes of breast cancer (Ikeda, Jinno, & Shirane, 2007).

KEY TERMS

Bioinformatics: All aspects of information processing on biological data, in particular, genomic data. The rise of bioinformatics is driven by the genomic projects.

cis-Regulatory Element: The genetic region that affects the activity of a gene on the same DNA molecule.

Clustering: The process of grouping objects according to their similarity. This is an important approach to microarray data mining.

Functional Genomics: The study of gene functions on a genomic scale, especially, based on microarrays.

Gene Expression: Production of mRNA from DNA (a process known as transcription) and production of protein from mRNA (a process known as translation). Microarrays are used to measure the level of gene expression in a tissue or cell.

Gene Ontology: A controlled vocabulary used to describe the biology of genes and gene products in any organism.

Genomic Medicine: Integration of genomic and clinical data for medical decision.

Microarray: A chip on which numerous probes are placed for hybridization with a tissue sample to analyze its gene expression.

Post-Genome Era: The time after the complete human genome sequence is decoded.

Transcription Factor: A protein that binds to the cis-element of a gene and affects its expression.

Minimum Description Length Adaptive Bayesian Mining

Diego Liberati
Italian National Research Council, Italy

INTRODUCTION

In everyday life, it often turns out that one has to face a huge amount of data, often not completely homogeneous, often without an immediate grasp of an underlying simple structure. Many records, each instantiating many variables are usually collected with the help of several tools.

Given the opportunity to have so many records on several possible variables, one of the typical goals one has in mind is to classify subjects on the basis of a hopefully reduced meaningful subset of the measured variables.

The complexity of the problem makes it natural to resort to automatic classification procedures (Duda and Hart, 1973) (Hand et al., 2001). Then, a further questions could arise, like trying to infer a synthetic mathematical and/or logical model, able to capture the most important relations between the most influencing variables, while pruning (O'Connel 1974) the not relevant ones. Such interrelated aspects will be the focus of the present contribution.

In the First Edition of this encyclopedia we already introduced three techniques dealing with such problems in a pair of articles (Liberati, 2005) (Liberati et al., 2005). Their rationale is briefly recalled in the following background section in order to introduce the kind of problems also faced by the different approach described in the present article, which will instead resort to the Adaptive Bayesian Networks implemented by Yarmus (2003) on a commercial wide spread data base tool like Oracle.

Focus of the present article will thus be the use of Adaptive Bayesian Networks are in order to unsupervisedly learn a classifier direcly form data, whose minimal set of features is derived through the classical Minimun Description Lenght (Barron and Rissanen, 1998) popular in information theory.

Reference will be again made to the same popular micro-arrays data set also used in (Liberati et al., 2005), not just to have a common benchmark useful to compare results and discuss complementary advantages of the various procedures, but also because of the increasing relevance of the bioinformatics field itself.

BACKGROUND

The introduced tasks of selecting salient variables, identifying their relationships from data and infer a logical and/or dynamical model of interaction may be sequentially accomplished with various degrees of success in a variety of ways.

In order to reduce the dimensionality of the problem, thus simplifying both the computation and the subsequent understanding of the solution, the critical problem of selecting the most relevant variables must be solved.

The very simple approach to resort to cascading a Divisive Partitioning of data orthogonal to the Principal Directions – PDDP - (Boley 1998) and *k-means*, already proven to be a good way to initialize k-means (Savaresi and Booley, 2004) and to be successful in the context of analyzing the logs of an important telecom provider (Garatti et al., 2004), was presented in (Liberati et al., 2005) with reference to a paradigmatic case of micro-arrays data in bioinformatics

A more sophisticated possible approach is to resort to a rule induction method, like the one described as Hamming Clustering in Muselli and Liberati (2000). Such a strategy also offers the advantage to extract underlying rules, implying conjunctions and/or disjunctions between the identified salient variables. Thus, a first idea of their even non-linear relations is provided as a first step to design a representative model, whose variables will be the selected ones. Such an approach has been shown (Muselli and Liberati, 2002) to be not less powerful over several benchmarks than the popular decision tree developed by Quinlan (1994). Then, a possible approach to blindly build a simple linear approximating model is to resort to piece-wise affine (PWA) identification of hybrid systems (Ferrari-Trecate

et al., 2003). The cascading of such two last approaches has been proposed in (Liberati, 2005).

Here just a few more approaches are recalled among the most popular ones, to whom the ones used either here or in either (Liberati, 2005) or (Liberati et al., 2005) are in some way comparable. For a widest bibliography, one could refer to both edition of this Encyclopedia, and in particular to the bibliography cited in the referenced papers. Among the simplest approaches, principal components (MacQueen, 1967) (Golub and van Loan, 1996) help to order the variables from the most relevant to the least one, but only under a linear possibly homogeneous framework. Partial least squares do allow to extend to non-linear models, provided that one has prior information on the structure of the involved non-linearity; in fact, the regression equation needs to be written before identifying its parameters. Clustering (Kaufman and Rousseeuw, 1990) (Jain and Dubes, 1998) (Jain at al., 1999) is instead able to operate even in an unsupervised way, without the a priori correct classification of a training set, but even fuzzy (Karayiannis and Bezdek 1997) and supervised (Setnes, 2000) approaches have been explored. Neural networks are known to learn the embedded rules, but their possibility to make rules explicit (Taha & Ghosh, 1999) or to underline the salient variables is only indirect. Support Vector Machines (Vapnik, 1998) are a very simple and popular general purpose approach whose theoretic foundation makes it worth in many applications.

MAIN THRUST OF THE CHAPTER

Adaptive Bayesian Networks

A learning strategy searching for a trade-off between a high predictive accuracy of the classifier and a low cardinality of the selected feature subset may be derived according to the central hypothesis that a good feature subset should contain features that are highly correlated with the class to be predicted, yet uncorrelated with each other.

Based on information theory, the Minimum Description Length (MDL) principle (Barron and Rissanen, 1998) provides the statement that the best theory to infer from training data is the one that minimizes both the length (i.e. the complexity) of the theory itself and the length of the data encoded with respect to it. In particular, MDL can thus be employed as a criteria to judge the quality of a classification model.

The motivation underlying the MDL method is to find a compact encoding of the training data. To this end, the MDL measure introduced in Friedman et al. (1997) can be adopted, weighting how many bits one do need to encode the specific model (i.e. its length), and how many bits are needed to describe the data based on the probability distribution associated to the model.

This approach can be applied to address the problem of feature selection, by considering each feature alone as a simple predictive model of the target class. As described in (Kononenko1995), each feature can be ranked according to its description length, that reflects the strength of its correlation with the target. In this context, the MDL measure is given by Yarmus (2003), again weighting the encoding length, where one have one sub-model for each value of the feature, with the number of bits needed to describe the data, based on the probability distribution of the target value associated to each sub-model.

However, once all features have been ordered by rank, no a priori criterion is available to choose the cut-off point beyond which features can be discarded. To circumvent this drawback, one can start with building a classifier on the set of the n-top ranked features. Then, a new feature is sequentially added to this set, and a new classifier is built, until no improvement in accuracy is achieved.

Our approach takes into account two different classifiers derived from Bayesian Networks, i.e. the Naïve Bayes (NB) and the Adaptive Bayesian Network (ABN).

NB is a very simple Bayesian network consisting of a special node (i.e. the target class) that is parent of all other nodes (i.e. the features or attributes) that are assumed to be conditionally independent, given the value of the class. The NB network can be "quantified" against a training dataset of pre-classified instances, i.e. we can compute the probability associated to a specific value of each attribute, given the value of the class label. Then, any new instance can be easily classified making use of the Bayes rule. Despite its strong independence assumption is clearly unrealistic in several application domains, NB has been shown to be competitive with more complex state-of-the-art classifiers (Friedman et al., 1997) (Keogh and Pazzani., 2002) (Cheng and Greiner,1999).

In the last years, a lot of research has focused on improving NB classifiers by relaxing their full independence assumption. One of the most interesting approaches is based on the idea of adding correlation arcs between the attributes of a NB classifier.

Specific structural constraints are imposed on these "augmenting arcs" (Friedman et al., 1997) (Keogh and Pazzani., 2002), in order to maintain computational simplicity on learning. The algorithm here proposed, the Adaptive Bayesian Network (ABN) (Yarmus, 2003), is a greedy variant, based on MDL, of the approach proposed in (Keogh and Pazzani., 2002).

In brief, the steps needed to build an ABN classifier are the following. First, the attributes (predictors) are ranked according to their MDL importance. Then, the network is initialized to NB on the top k ranked predictors, that are treated as conditionally independent. Next, the algorithm attempts to extend NB by constructing a set of tree-like multi-dimensional features.

Feature construction proceeds as follows. The top ranked predictor is stated as a seed feature, and the predictor that most improves feature predictive accuracy, if any, is added to the seed. Further predictors are added in such a way to form a tree structure, until the accuracy does not improve.

Using the next available top ranked predictor as a seed, the algorithm attempts to construct additional features in the same manner. The process is interrupted when the overall predictive accuracy cannot be further improved or after some pre-selected number of steps.

The resulting network structure consists of a set of conditionally independent multi-attribute features, and the target class probabilities are estimated by the product of feature probabilities. Interestingly, each multi-dimensional feature can be expressed in terms of a set of if-then rules enabling users to easily understand the basis of model predictions.

A Paradigmatic Example: *The Leukemia Classification*

Data are taken from a public repository often adopted as a reference benchmark (Golub et al., 1999) in order to test new classification techniques and compare and complement it with the other available methodologies. Such database is constituted by gene expression data over 72 subjects, relying on 7,129 genes. Of the 72 subjects, 47 are cases of acute lymphoblastic leukaemia (ALL), while the remaining 25 are cases of acute myeloid leukaemia (AML).

An experimental bottleneck in this kind of experiment, like often in several applications, is the difficulty in collecting a high number of homogeneous subjects in each class of interest, making the classification problem even harder: not only a big matrix is involved, but such matrix has a huge number of variables (7,129 genes) with only a very poor number of samples (72 subjects).

On such data set, two series of experiments for learning both NB and ABN classifiers have been supervisedly performed on the 38 samples of the training set already defined in (Golub et al., 1999) in order to be able to compare results. We started with the set of the first 10 predictors found by MDL, and added the following attributes, one by one, feeding them to both NB and ABN classifiers, until no further improvement in accuracy was achieved.

Their predictive accuracy has been evaluated by the rate of correct predictions on the 34 samples of the test set also defined in (Golub et al., 1999). It is worth noticing that the classifiers built with 15 and 20 predictors result in the same accuracy. Interestingly, the only errors of both classifiers consist again in the misclassification of AML samples (i.e. 3 samples for NB and 2 of them, same as in (Golub et al 1999), for ABN).

Interestingly, 12 of the 15 more salient genes found are among the 25 genes most highly correlated with AML in (Golub et al., 1999). None of them is instead among the 25 most highly correlated with ALL in (Golubet al., 1999).

Not surprinsingly, the 2 more salient genes identified via the PDDP + *k-means* approach described in (Liberati et al., 2005) are among the top 15 of the BN approach: even more, the more salient there is the 15th here, after which no improvement is obtained by adding new genes. Finally, the only error performed among the subjects in the test set used here and in (Golub at., 1999) by the unsupervised approach proposed in (Liberati et al., 2005) is one of the 2 errors of ABN

FUTURE TRENDS

Further work is under evaluation in order to infer rules and identify models from this same example with various approaches, as well as approaching different prob-

lems with several recalled approaches, most of whom originally developed each one for different purposes and tested over different benchmarks.

The joint use of the approaches briefly described in the present contribution, together with (some of) those recalled, starting from data without known priors about their relationships, will hopefully allows to reduce dimensionality without significant loss in information, then to infer logical relationships, and, finally, to identify a simple input-output model of the involved process that also could be used for controlling purposes in the systems biology approach to investigate cell dynamics.

The definition (Bosin et al., 2006) of a collaborative framework for e-Science sharing across physical locations could also become a powerful distributed ICT tool for sharing delocalized expertise and data also in data mining approaches to complex problems

CONCLUSION

The proposed approach seems to be consistent at least with the simple clustering (Liberati et al., 2005) also proposed in the first edition of this same Encyclopedia and with the more articulated procedure originally proposed by (Golub et al. 1999), at least on the particular application described, which is anyway representative of quite a general class of not so easy problems even beyond bioinformatics: it can thus represent one more powerful tool for quite a wide spectrum of applications in, and beyond, data mining, providing an up-to-date answer to the quest of formally extracting knowledge from data and helping to sketch a model of the underlying process.

The fact that a combination of different approaches, taken from partially complementary disciplines, proves to be effective may indicate a fruitful direction in combining in different ways classical and new approaches to improve classification even in critical fields.

KEY TERMS

Hamming Clustering: A fast binary rule generator and variable selector able to build understandable logical expressions by analyzing the Hamming distance between samples.

Hybrid Systems: Their evolution in time suddenly switches from a smooth dynamics to a different one.

***k-means*:** Iterative clustering technique subdividing the data in such a way to maximize the distance among centroids of different clusters, while minimizing the distance among data within each cluster. It is sensitive to initialization.

Identification: Definition of the structure and computation of its parameters best suited to mathematically describe the process underlying the data.

PDDP (Principal Direction Divisive Partitioning): One-shot clustering technique based on principal component analysis and singular value decomposition of the data, thus partitioning the dataset according to the direction of maximum variance of the data. It is used here in order to initialize K-means.

Principal Component Analysis: Rearrangement of the data matrix in new orthogonal transformed variables ordered in decreasing order of variance.

Rule Inference: The extraction from the data of the embedded synthetic logical description of their relationships.

Relevant (Salient) Variable*s:* The real important ones among the many apparently involved in a process.

Unsupervised Clustering: Automatic classification of a dataset in two of more subsets on the basis of the intrinsic properties of the data without taking into account further contextual information.

Mining 3D Shape Data for Morphometric Pattern Discovery

Li Shen
University of Massachusetts Dartmouth, USA

University of Texas at Arlington, USA

INTRODUCTION

Recent technological advances in 3D digitizing, non-invasive scanning, and interactive authoring have resulted in an explosive growth of 3D models in the digital world. There is a critical need to develop new 3D data mining techniques for facilitating the indexing, retrieval, clustering, comparison, and analysis of large collections of 3D models. These approaches will have important impacts in numerous applications including multimedia databases and mining, industrial design, biomedical imaging, bioinformatics, computer vision, and graphics.

For example, in similarity search, new shape indexing schemes (e.g. (Funkhouser et al., 2003)) are studied for retrieving similar objects from databases of 3D models. These shape indices are designed to be quick to compute, concise to store, and easy to index, and so they are often relatively compact. In computer vision and medical imaging, more powerful shape descriptors are developed for morphometric pattern discovery (e.g., (Bookstein, 1997; Cootes, Taylor, Cooper, & Graham, 1995; Gerig, Styner, Jones, Weinberger, & Lieberman, 2001; Styner, Gerig, Lieberman, Jones, & Weinberger, 2003)) that aims to detect or localize shape changes between groups of 3D objects. This chapter describes a general shape-based 3D data mining framework for morphometric pattern discovery.

BACKGROUND

The challenges of morphometric pattern discovery are twofold: (1) How to describe a 3D shape and extract shape features; and (2) how to use shape features for pattern analysis to find discriminative regions. Several shape descriptors have been proposed for extracting shape features, including landmark-based descriptors (Bookstein, 1997; Cootes, Taylor, Cooper, & Graham, 1995), deformation fields (Csernansky et al., 1998), distance transforms (Golland, Grimson, Shenton, & Kikinis, 2001), medial axes (Styner, Gerig, Lieberman, Jones, & Weinberger, 2003), and parametric surfaces (Gerig, Styner, Jones, Weinberger, & Lieberman, 2001). Using these features, researchers have developed different pattern analysis techniques for discovering morphometric patterns, including linear discriminant analysis (Csernansky et al., 1998), support vector machines (Golland, Grimson, Shenton, & Kikinis, 2001), principal component analysis (Saykin et al., 2003), and random field theory (Chung et al., 2005).

This chapter describes a general surface-based computational framework for mining 3D objects to localize shape changes between groups. The spherical harmonic (SPHARM) method is employed for surface modeling, where several important shape analysis issues are addressed, including spherical parameterization, surface registration, and multi-object alignment. Two types of techniques are employed for statistical shape analysis: (1) linear classifiers based on a point distribution model, and (2) random field theory combined with heat kernel smoothing.

MAIN FOCUS

Given a set of labeled 3D objects from two distinct shape classes, our task is to identify morphometric patterns that can distinguish these two classes. An important real-life application is to detect anatomical changes due to pathology in biomedical imaging. A surface-based computational framework is presented to solve this problem in three steps: data collection and preprocessing, surface modeling for feature extraction, and pattern analysis and visualization.

Data Collection and Preprocessing

3D models can be collected using different methods including 3D digitizing, non-invasive scanning and interactive authoring. This chapter focuses on the analysis of 3D models whose surface topology is spherical. For example, in medical domain, many human organs and structures belong to this category. After performing segmentation on 3D medical scans (e.g., CT, MRI), the boundary of a structure of interest can be extracted. Since such a 3D boundary model may contain unwanted holes, a preprocessing step sometimes is required to close these 3D holes (Aktouf, Bertrand, & Perroton, 2002). An alternative approach is to perform automatic segmentation with appropriate constraints and create topologically correct results directly from images. After removing unwanted 3D holes, the surface of the 3D model has a spherical topology, which meets the requirement of our surface modeling approach.

Surface Modeling

Spherical harmonics were first used as a type of parametric surface representation for radial surfaces $r(\theta,\varphi)$ in (Ballard & Brown, 1982), where the harmonics were used as basis functions to expand $r(\theta,\varphi)$. Recently, an extended method, called SPHARM, was proposed in (Brechbuhler, Gerig, & Kubler, 1995) to model arbitrarily shaped but simply connected 3D objects, where three functions of θ and φ were used to represent a surface. SPHARM is suitable for surface comparison and can deal with protrusions and intrusions. Due to its numerous advantages such as inherent interpolation, implicit correspondence, and accurate scaling, SPHARM is employed here, requiring three processing steps: (1) spherical parameterization, (2) SPHARM expansion, and (3) SPHARM normalization.

(1) *Spherical parameterization* creates a continuous and uniform mapping from the object surface on to the unit sphere, and its result is a bijective mapping between each point v on the object surface and spherical coordinates θ and φ:

$$v(\theta,\phi) = (x(\theta,\phi), y(\theta,\phi), z(\theta,\phi))^T$$

The classical approach exploits the uniform quadrilateral structure of a voxel surface and solves a constrained optimization problem to minimize area and angle distortions of the parameterization. The approach can be applied only to voxel surfaces and not to general triangle meshes. A new algorithm CALD (Shen & Makedon, 2006) has been proposed to control both area and length distortions and make SPHARM applicable to general triangle meshes.

(2) The *SPHARM expansion* requires a spherical parameterization performed in advance. The parameterization has the form of:

$$v(\theta,\phi) = (x(\theta,\phi), y(\theta,\phi), z(\theta,\phi))^T,$$

Where $x(\theta,\varphi)$, $y(\theta,\varphi)$ and $z(\theta,\varphi)$ are three spherical functions. Spherical harmonics are a natural choice of basis functions for representing any twice-differentiable spherical function. To describe the object surface, we can expand these three spherical functions using spherical harmonics $Y_l^m(\theta,\phi)$, where $Y_l^m(\theta,\phi)$ denotes the spherical harmonic of degree l and order m. The expansion takes the form:

$$v(\theta,\phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} c_l^m Y_l^m(\theta,\phi),$$

Where

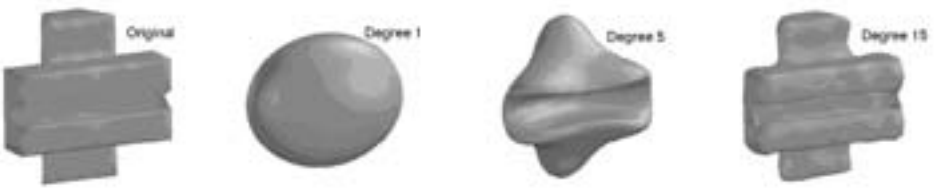
$$c_l^m = (c_{lx}^m, c_{ly}^m, c_{lz}^m)^T.$$

The coefficients c_l^m up to a user-desired degree can be estimated by solving a linear system. The object surface can be reconstructed using these coefficients, and using more coefficients leads to a more detailed reconstruction (Figure 1).

(3) *SPHARM normalization* creates a shape descriptor (*i.e.*, excluding translation, rotation, and scaling) from a normalized set of SPHARM coefficients, which are comparable across objects. A typical approach is as follows: (1) Rotation invariance is achieved by aligning the degree one ellipsoid; (2) scaling invariance is achieved by dividing all the coefficients by a scaling factor; (3) ignoring the degree zero coefficient results in translation invariance.

Using the degree one ellipsoid for establishing surface correspondence and aligning objects may not be sufficient in many cases (e.g., the ellipsoid becomes a sphere). A more general method for establishing surface correspondence is to minimize the mean squared distance between two corresponding surfaces (Huang et al., 2005).

Figure 1. The first picture shows an object surface. The second, third and fourth pictures show its SPHARM reconstructions using coefficients up to degrees 1, 5 and 15, respectively.



The SPHARM technique described above examines shape configurations containing only a single object. In some cases, it is useful to consider multi-object shape configurations so that spatial relation among objects can be extracted as additional features for structural analysis. To create a shape descriptor for a multi-object configuration, one can use the degree one ellipsoid for establishing surface correspondence and then use a quaternion-based algorithm to align surfaces in the object space (Shen, Makedon, & Saykin, 2004).

In both single-object and multi-object cases, the SPHARM coefficients are converted to a dual landmark representation for the convenience of processing. Landmarks are the points of the sampled surface: equal processing of each part of the surface can be ensured by choosing a homogeneous distribution of sampling points; and the sampling resolution can be decided by the size of the object. The landmark representation is an intuitive descriptor that can capture local shape characteristics and has the potential to support the identification of local discriminative patterns implied by a linear classifier. Thus, as a result of the SPHARM surface modeling, in both single-object and multi-object cases, each of the shape configurations is described by a set of normalized landmarks, which are comparable across individuals. These landmark descriptors serve as inputs to the next stage of pattern analysis and visualization.

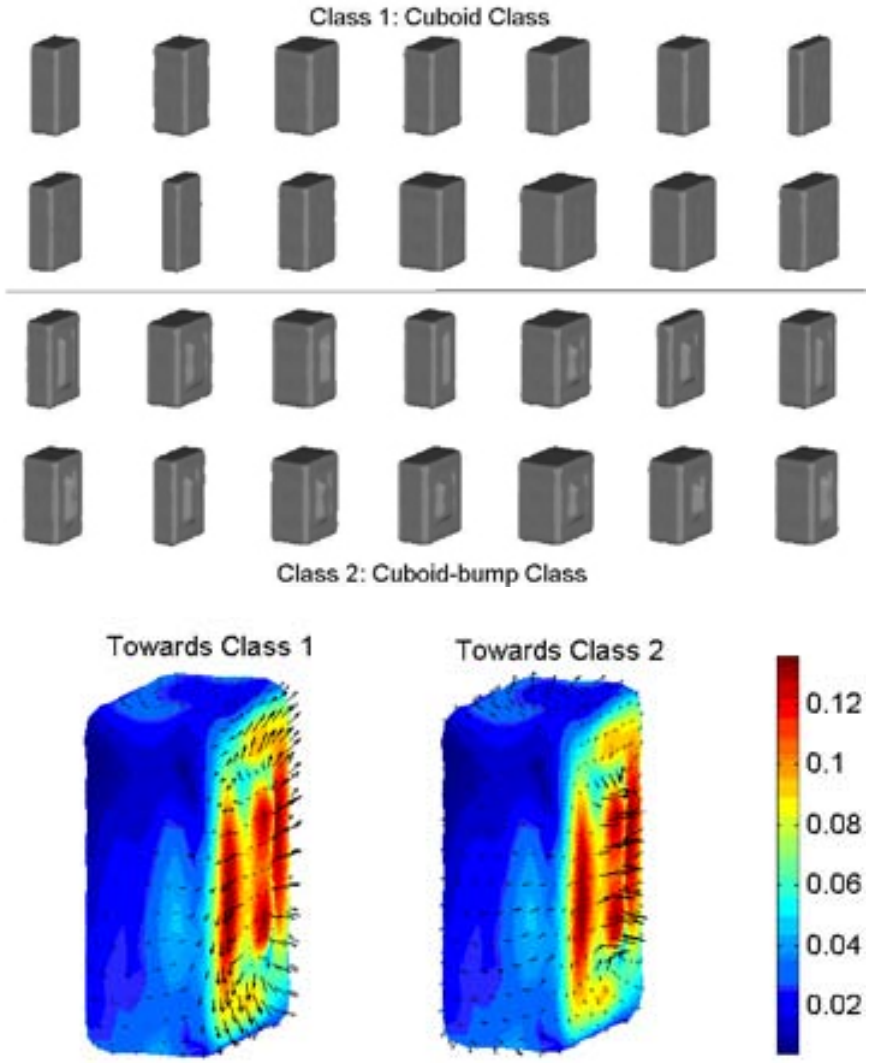
Pattern Analysis and Visualization

To use the derived landmark representation for statistical shape analysis and identification of discriminative patterns, two types of techniques are employed: (1) linear classifiers based on a point distribution model, and (2) random field theory combined with heat kernel smoothing.

Without loss of generality, a single-object case is used to describe the linear classifier approach. Assume that the icosahedron subdivision level 3 is used for surface sampling. Thus, each surface contains n = 642 landmarks and 3n = 1926 feature elements (each landmark is described by its x, y, z coordinates). Principal component analysis (PCA) is applied for dimensionality reduction. This involves eigenanalysis of the covariance matrix Σ of the data: $\Sigma P = PD$; where the columns of P hold eigenvectors, and the diagonal matrix D holds eigenvalues of Σ. The eigenvectors in P can be ordered decreasingly according to respective eigenvalues, which are proportional to the variance explained by each eigenvector. Now any shape $\mathbf{x}$ in the data can be obtained using $\mathbf{x} = \mathbf{x} + P\mathbf{b}$; where $\mathbf{b}$ is a vector containing the components of $\mathbf{x}$ in basis P, which are called *principal components* (PCs). Since eigenvectors are orthogonal, $\mathbf{b}$ can be obtained using $\mathbf{b} = P^T(\mathbf{x} - \mathbf{x})$. Given a dataset of m objects, the first m-1 PCs are enough to capture all the data variance. Thus, $\mathbf{b}$ becomes an m-1 element vector, which can be thought of a more compact representation of the shape $\mathbf{x}$. This model is a point distribution model (PDM) (Cootes, Taylor, Cooper, & Graham, 1995). PDM is applied to the data set to obtain a $\mathbf{b}$ (referred to as a feature vector hereafter) for each shape.

Feature selection may improve classification accuracy by reducing the number of parameters that need to be estimated. In this study, features are PCs, and some PCs are more useful than others for classification, but not necessarily matching the ordering of the variance amounts they explain. Our feature selection scheme selects the first n features according to a certain ordering of PCs, where varying values of n are considered. A typical ordering scheme can be that PCs are ordered by p-value associated with t-test applied to the training set, increasingly.

Figure 2. The left plot shows two classes of rectangular surfaces: the top two rows show 14 surfaces in Class 1, while the bottom two rows show 14 surfaces in Class 2. Note that surfaces in Class 2 have a centered bump on one face. The right plot shows the discriminative patterns mapped onto the mean surface. Red colors indicate the surface location has more discriminative power while blue colors indicate less. The vectors show the deformation directions towards Class 1 (top) and Class 2 (bottom).



Linear classifiers are employed on selected features for classification. Linear techniques are simple and well-understood. Once they succeed in real applications, the results can then be interpreted more easily than those derived from complicated techniques. Typical linear classifiers include Fisher's linear discriminant (FLD) and linear support vector machines (SVMs). FLD projects a training set (consisting of *c* classes) onto *c-1* dimensions such that the ratio of between-class and within-class variability is maximized, which occurs when the FLD projection places different classes into distinct and tight clumps. A linear classifier corresponds to a decision hyperplane separating different classes. The margin is defined as the distance from the decision hyperplane to the closest training set exemplar. The aim in training a linear SVM is to find the separating hyperplane with the largest margin; the expectation is that the larger the margin, the better the generalization of the classifier. The FLD and SVM classifiers have been integrated with SPHARM to form a new frame-

work for 3D surface object classification (Shen, Ford, Makedon, & Saykin, 2004). Applying it to hippocampal data in schizophrenia achieved best cross-validation accuracies of 93% (n=56), competitive with the best prior results.

The discriminative pattern captured by this classifier can be visualized as follows. Let us apply PCA and FLD (possibly with feature selection) to a landmark-based shape set, we get a discriminative value v for each shape $\mathbf{x}$: $v = \mathbf{x}_\delta^T * B_{pca} * B_{fld} = \mathbf{x} * \mathbf{w}$; where $\mathbf{x}_\delta = \mathbf{x} - \mathbf{x}$ is the deformation of $\mathbf{x}$ from the mean shape $\mathbf{x}$, B_{pca} consists of a subset of eigenvectors, depending on which PCs are selected, and B_{fld} is the corresponding FLD basis. Thus $\mathbf{w}$ is a column vector that weights the contribution of each deformation element in $\mathbf{x}_\delta$ to v. We can map these weights onto the mean surface to show significant discriminative regions (Figure 2).

Besides using linear classifiers for pattern analysis and visualization, an alternative approach performs statistical inference directly on the surface signals. For each landmark, the local shape change of an individual is defined as the distance from the mean along its normal direction. In order to increase the signal-to-noise ratio (SNR), Gaussian kernel smoothing is desirable in many statistical analyses. Since the geometry of an object surface is non-Euclidean, we employ heat kernel smoothing, which generalizes Gaussian kernel smoothing to arbitrary Riemannian manifolds (Chung et al., 2005). The heat kernel smoothing is implemented by constructing the kernel of a heat equation on manifolds that is isotropic in the local conformal coordinates. By smoothing the data on the hippocampal surface, the SNR will increase and it will be easier to localize the shape changes.

To perform statistical inference directly on the surface, surface signals are modeled as Gaussian random fields. This theoretical model assumption can be checked using either Lilliefors test or quantile-quantile plots for the shape data. Detecting the region of statistically significant shape changes can be done via thresholding the maximum of the *t* random field defined on the surface. The *p* value of the local maxima of the *t* field will give a conservative threshold. See (Chung et al., 2005) for more details on how to create a corrected *p* value map using a *t* value map and other related information. This technique has been successfully applied to identifying hippocampal shape changes in mild cognitive impairment (Shen et al., 2005).

FUTURE TRENDS

In the near future, we expect that shape-based retrieval, analysis, mining of 3D models will become a very important research area in both data mining and related application domains including computer vision, graphics, biomedical imaging and bioinformatics. There are many interesting and open problems that need to be further explored. For example, automatic segmentation of objects from 3D images remains as a very difficult task and a time consuming process; and further technological advances can help collect useful 3D models more efficiently. The scalability of the existing SPHARM method is limited. To facilitate the mining of large 3D models, there is a need to develop more scalable spherical parameterization and SPHARM expansion algorithms to model large surfaces (e.g., brain cortex) accurately and efficiently. Previous studies on morphometric pattern discovery involve relatively small data sets. With the fast growth of 3D model collections, more efficient and scalable shape-based pattern analysis techniques need to be developed to facilitate mining large-scale collections of 3D models. Morphometric pattern discovery mostly has impact in biomedical imaging and biotechnology. However the shape analysis techniques developed in this domain can be extended to solve other problems such as shape-based retrieval. Shape-based retrieval is in fact a very important research topic which has a wide range of applications in different areas such as bioinformatics (find similar proteins), graphics (find similar models from the web repository), and industrial engineering (find similar CAD/CAM models from engineering databases).

CONCLUSION

We has described a computational framework for data mining of 3D objects using shape features, and the goal is to localize shape changes between groups of 3D objects. The spherical harmonic (SPHARM) method is employed for surface modeling. We discuss a classical spherical parameterization method designed for voxel surfaces as well as a new approach that works for general triangle meshes. Besides using the first order ellipsoid for establishing surface correspondence and aligning objects, we discuss a new and more general method for establishing surface correspondence that

aims to minimize the mean squared distance between two corresponding surfaces. Surface registration issues are addressed for both single-object cases and multi-object cases. Two types of techniques are employed for mining morphometric patterns: (1) linear classifiers based on a point distribution model, and (2) random field theory combined with heat kernel smoothing. Future trends on the topic are also discussed.

KEY TERMS

3D Data Mining: The process of automatically searching large volumes of 3D data for hidden morphometric patterns.

Discriminative Patterns: Patterns that can distinguish two or more sets of objects.

Morphometric Patterns: Patterns that are related to or contain shape information, such as a description of the mean and variability of a shape population.

Morphometrics: The branch of mathematics studying the metrical and statistical properties of shapes and shape changes of geometric objects.

Parametric Surfaces: Surfaces that are defined by functions based on an underlying parameterization.

Shape: All the geometrical information that is invariant to location, scale and rotation.

Shape Alignment: The adjustment of a set of geometric configurations in relation to one another so that their shapes can be compared under a common coordinate system.

Shape Description: A set of variables that describe the shape of a geometric configuration.

Spherical Harmonics: An orthogonal set of solutions to Laplace's equation represented in a system of spherical coordinates.

Surface Parameterization: The process of creating a one-to-one mapping from some parameter domain to a surface.

INTRODUCTION

According to Nonaka & Takeuchi (1995), the majority of the organizational knowledge comes from interactions between people. People tend to reuse solutions from other persons in order to gain productivity.

When people communicate to exchange information or acquire knowledge, the process is named *Collaboration*. Collaboration is one of the most important tasks for innovation and competitive advantage within *learning organizations* (Senge, 2001). It is important to record knowledge to later reuse and analysis. If knowledge is not adequately recorded, organized and retrieved, the consequence is re-work, low productivity and lost of opportunities.

Collaboration may be realized through synchronous interactions (e.g., exchange of messages in a chat), asynchronous interactions (e.g., electronic mailing lists or forums), direct contact (e.g., two persons talking) or indirect contact (when someone stores knowledge and others can retrieve this knowledge in a remote place or time).

In special, chat rooms are becoming important tools for collaboration among people and knowledge exchange. Intelligent software systems may be integrated into chat rooms in order to help people in this collaboration task. For example, systems can identify the theme being discussed and then offer new information or can remember people of existing information sources. This kind of systems is named recommender systems.

Furthermore, chat sessions have implicit knowledge about what the participants know and how they are viewing the world. Analyzing chat discussions allows understanding what people are looking for and how people collaborates one with each other. Intelligent software systems can analyze discussions in chats to extract knowledge about the group or about the subject being discussed.

Mining tools can analyze chat discussions to understand what is being discussed and help people. For example, a recommender system can analyze textual messages posted in a web chat, identify the subject of the discussion and then look for items stored in a Digital Library to recommend individually to each participant of the discussion. Items can be electronic documents, web pages and bibliographic references stored in a digital library, past discussions and authorities (people with expertise in the subject being discussed). Besides that, mining tools can analyze the whole discussion to map the knowledge exchanged among the chat participants.

The benefits of such technology include supporting learning environments, knowledge management efforts within organizations, advertisement and support to decisions.

BACKGROUND

Some works has investigated the analysis of online discussions. Brutlag and Meek (2000) have studied the identification of themes in e-mails. The work compares the identification by analyzing only the subject of the e-mails against analyzing the message bodies. One conclusion is that e-mail headers perform so well

as message bodies, with the additional advantage of reducing the number of features to be analyzed.

Busemann et al. (2000) investigated the special case of messages registered in call centers. The work proved possible to identify themes in this kind of message, although the informality of the language used in the messages. This informality causes mistakes due to jargons, misspellings and grammatical inaccuracy.

The work of Durbin et al. (2003) has shown possible to identify affective opinions about products and services in e-mails sent by customers, in order to alert responsible people or to evaluate the organization and customers' satisfaction. Furthermore, the work identifies the intensity of the rating, allowing the separation of moderate or intensive opinions.

Tong (2001) investigated the analysis of online discussions about movies. Messages represent comments about movies. This work proved to be feasible to find positive and negative opinions, by analyzing key or cue words. Furthermore, the work also extracts information about the movies, like directors and actors, and then examines opinions about these particular characteristics.

The only work found in the scientific literature that analyzes chat messages is the one from Kahn et al. (2002). They apply mining techniques over chat messages in order to find social interactions among people. The goal is to find who is related to whom inside a specific area, by analyzing the exchange of messages in a chat and the subject of the discussion.

MAIN THRUST

Following, the chapter explains how messages can be mined, how recommendations can be made and how the whole discussion (an entire chat session) can be analyzed.

Identifying Themes in Chat Messages

To provide people with useful information during a collaboration session, the system has to identify what is being discussed. Textual messages sent by the users in the chat can be analyzed for this purpose. Texts can lead to the identification of the subject discussed because the words and the grammar present in the texts represent knowledge from people, expressed in written formats (Sowa, 2000).

An ontology or thesaurus can be used to help to identify cue words for each subject. The ontology or thesaurus has concepts of a domain or knowledge area, including relations between concepts and the terms used in written languages to express these concepts (Gilchrist, 2003). The ontology can be created by machine learning methods (supervised learning), where human experts select training cases for each subject (for example, texts of positive and negative examples) and an intelligent software system identifies the keywords that define each subject. The TFIDF method from Salton & McGill (1983) is the most used in this kind of task.

If considering that the terms that compose the messages compose a bag of words (have no difference in importance), probabilistic techniques can be used to identify the subject. By other side, natural language processing techniques can identify syntactic elements and relations, then supporting more precise subject identification.

The identification of themes should consider the context of the messages to determine if the concept identified is really present in the discussion. A group of messages is better to infer the subject than a single message. That avoids misunderstandings due to words ambiguity and use of synonyms.

Making Recommendations in a Chat Discussion

A recommender system is a software whose main goal is to aid in the social collaborative process of indicating or receiving indications (Resnick & Varian, 1997). Recommender systems are broadly used in electronic commerce for suggesting products or providing information about products and services, helping people to decide in the shopping process (Lawrence et al., 2001) (Schafer et al., 2001). The offered gain is that people do not need to request recommendation or to perform a query over an information base, but the system decides what and when to suggest. The recommendation is usually based on user profiles and reuse of solutions.

When a subject is identified in a message, the recommender searches for items classified in this subject. Items can come from different databases. For example, a Digital Library may provide electronic documents, links to Web pages and bibliographic references.

A profile database may contain information about people, including the interest areas of each person, as well an associated degree, informing the user's

knowledge level on the subject or how much is his/her competence in the area (his/her expertise). This can be used to indicate who is the most active user in the area or who is the authority in the subject.

A database of past discussions records everything that occurs in the chat, during every discussion session. Discussions may be stored by sessions, identified by data and themes discusses and can include who participated in the session, all the messages exchanged (with a label indicating who sent it), the concept identified in each message, the recommendations made during the session for each user and documents downloaded or read during the session. Past discussions may be recommended during a chat session, remembering the participants that other similar discussions have already happened. This database also allows users to review the whole discussion later after the session. The great benefit is that users do not re-discuss the same question.

Mining a Chat Session

Analyzing the themes discussed in a chat session can bring an important overview of the discussion and also of the subject. Statistical tools applied over the messages sent and the subjects identified in each message can help users to understand which were the themes more discussed. Counting the messages associated with each subject, it is possible to infer the central point of the discussion and the peripheral themes.

The list of subjects identified during the chat session compose an interesting order, allowing users to analyze the path followed the participants during the discussion. For example, it is possible to observe which was the central point of the discussion, whether the discussion deviated from the main subject and whether the subjects present in the beginning of the discussion were also present at the end. The coverage of the discussion may be identified by the number of different themes discussed.

Furthermore, this analysis allows identifying the depth of the discussion, that is, whether more specific themes were discussed or whether the discussion occurred superficially at a higher conceptual level. The analysis can also map the coverage of the discussion: how many different subjects were discussed.

Analyzing the messages sent by every participant allows determining the degree of participation of each person in the discussion: who participated more and who did less. Furthermore, it is possible to observe which are the interesting areas for each person and in someway to determine the expertise of the group and of the participants (which are the areas where the group is more competent).

Association techniques can be used to identify correlations between themes or between themes and persons. For example, it is possible to find that some theme is present always when other theme is also present or to find that every discussion where some person participated had a certain theme as the principal.

FUTURE TRENDS

Recommender systems are still an emerging area. There are some doubts and open issues. For example, whether is good or bad to recommend items already suggested in past discussions (re-recommend, as if remembering the person). Besides that it is important to analyze the level of the participants in order to recommend only basic or advanced items.

Collaborative filtering techniques can be used to recommend items already seen by other users (Resnick et al., 1994; Terveen and Hill, 2001). Grouping people with similar characteristics allows to cross recommended items, for example, offer documents read by one person to others.

In the same way, software systems can capture relevance feedback from users to narrow the list of recommendations. Users should read some items of the list and rate them, so that the system can use this information to eliminate items from the list or to reorder the items in a new ranking.

The context of the messages needs to be more studied. To infer the subject being discussed, the system can analyze a group of messages, but it is necessary to determine how many (a fixed number or all messages sent in the past N minutes ?).

An orthographic corrector is necessary to clean the messages posted to the chat. Lots of linguistic mistakes are expected since people are using chats in a hurry, with little attention to the language, without revisions and in an informal way. Furthermore, the text mining tools must analyze special signs like novel abbreviations, emoticons and slang expressions. Special words may be added to the domain ontology in order to hold the differences in the language.

CONCLUSION

An example of such a system discussed in this chapter is available in http://gpsi.ucpel.tche.br/sisrec. Currently, the system uses a domain ontology for Computer Science, but others can be used. Similarly, the current digital library only has items related to Computer Science.

The recommendation system facilitates the organizational learning because people receive suggestions of information sources during online discussions. The main advantage of the system is to free the user of the burden to search information sources during the online discussion. Users do not have to choose attributes or requirements from a menu of options, in order to retrieve items of a database; the system decides when and what information to recommend to the user. This proactive approach is useful for non-experienced users that receive hits about what to read in a specific subject. User's information needs are discovered naturally during the conversation.

Furthermore, when the system indicates people who are authorities in each subject, naïve users can meet these authorities for getting more knowledge.

Other advantage of the system is that part of the knowledge shared in the discussion can be made explicit through the record of the discussion for future retrieval. Besides that, the system allows the posterior analysis of each discussion, presenting the subjects discussed, the messages exchanged, the items recommended and the order in which the subjects were discussed.

An important feature is the statistical analysis of the discussion, allowing understanding the central point, the peripheral themes, the order of the discussion, its coverage and depth.

The benefit of mining chat sessions is of special interest for Knowledge Management efforts. Organizations can store tacit knowledge formatted as discussions. The discussions can be retrieved, so that knowledge can be reused. In the same way, the contents of a Digital Library (or Organizational Memory) can be better used through recommendations. People do not have to search for contents neither to remember items in order to suggest to others. Recommendations play this role in a proactive way, examining what people are discussing and users' profiles and selecting interesting new contents.

In special, such systems (that mine chat sessions) can be used in e-learning environments, supporting the construction of knowledge by individuals or groups. Recommendations help the learning process, suggesting complementary contents (documents and sites stored in the Digital Library). Recommendations also include authorities in topics being discussed, that is, people with high degree of knowledge.

KEY TERMS

Chat: A software system that enables real-time communication among users through the exchange of textual messages.

Collaboration: The process of communication among people with the goal of sharing information and knowledge.

Digital Library: A set of electronic resources (usually documents) combined with a software system which allows storing, organizing and retrieving the resources.

Knowledge Management: Systems and methods for storing, organizing and retrieving explicit knowledge.

Mining: The application of statistical techniques to infer implicit patterns or rules in a collection of data, in order to discover new and useful knowledge.

Ontology: A formal and explicit definition of concepts (classes or categories) and their attributes and relations.

Recommender System: A software system that makes recommendations to a user, usually analyzing the user's interest or need.

Recommendations: Results of the process of providing useful resources to a user, like products, services or information.

Text Mining: The process of discovering new information analyzing textual collections.

Mining Data Streams

Tamraparni Dasu
AT&T Labs, USA

Gary Weiss
Fordham University, USA

INTRODUCTION

When a space shuttle takes off, tiny sensors measure thousands of data points every fraction of a second, pertaining to a variety of attributes like temperature, acceleration, pressure and velocity. A data gathering server at a networking company receives terabytes of data a day from various network elements like routers, reporting on traffic throughput, CPU usage, machine loads and performance. Each of these is an example of a data stream. Many applications of data streams arise naturally in industry (networking, e-commerce) and scientific fields (meteorology, rocketry).

Data streams pose three unique challenges that make them interesting from a data mining perspective.

1. **Size:** The number of measurements as well as the number of attributes (variables) is very large. For instance, an IP network has thousands of elements each of which collects data every few seconds on multiple attributes like traffic, load, resource availability, topography, configuration and connections.
2. **Rate of accumulation:** The data arrives very rapidly, like "water from a fire hydrant". Data storage and analysis techniques need to keep up with the data to avoid insurmountable backlogs.
3. **Data transience:** We get to see the raw data points at most once since the volumes of the raw data are too high to store or access.

BACKGROUND

Data streams are a predominant form of information today, arising in areas and applications ranging from telecommunications, meteorology and sensor networks, to the monitoring and support of e-commerce sites. Data streams pose unique analytical, statistical and computing challenges that are just beginning to be addressed. In this chapter we give an overview of the analysis and monitoring of data streams and discuss the analytical and computing challenges posed by the unique constraints associated with data streams.

There are a wide variety of analytical problems associated with mining and monitoring data streams, such as:

1. Data reduction,
2. Characterizing constantly changing distributions and detecting changes in these distributions,
3. Identifying outliers, tracking rare events and anomalies,
4. "Correlating" multiple data streams,
5. Building predictive models,
6. Clustering and classifying data streams, and
7. Visualization.

As innovative applications in on-demand entertainment, gaming and other areas evolve, new forms of data streams emerge, each posing new and complex challenges.

MAIN FOCUS

The data mining community has been active in developing a framework for the analysis of data streams. Research is focused primarily in the field of computer science, with an emphasis on computational and database issues. Henzinger, Raghavan & Rajagopalan (1998) discuss the computing framework for maintaining aggregates from data using a limited number of passes. Domingos & Hulten (2001) formalize the challenges, desiderata and research issues for mining data streams. Collection of rudimentary statistics for data streams is addressed in Zhu & Sasha (2002) and Babcock, Datar, Matwani & O'Callaghan (2003). Clustering (Aggarwal, Han, Wang & Yu, 2003), classification, association rules (Charikar, Chen & Farach-

Colton, 2002) and other data mining algorithms have been considered and adapted for data streams.

Correlating multiple data streams is an important aspect of mining data streams. Guha, Gunopulous & Koudas (2003) have proposed the use of singular value decomposition (SVD) approaches (suitably modified to scale to the data) for computing correlations between multiple data streams.

A good overview and introduction to data stream algorithms and applications from a database perspective is found in Muthukrishnan (2003). Aggarwal (2007) has a comprehensive collection of work in the computer science field on data streams. In a similar vein, Gaber (2006) maintains a frequently updated website of research literature and researchers in data streams.

However, there is not much work in the statistical analysis of data streams. Statistical comparison of signatures of telecommunication users was used by Cortes & Pregibon (2001) to mine large streams of call detail data for fraud detection and identifying social communities in a telephone network. Papers on change detection in data streams (Ben-David, Gehrke & Kifer, 2004; Dasu, Krishnan, Venkatasubramanian & Yi, 2006) use statistical approaches of varying sophistication. An important underpinning of statistical approaches to data mining is density estimation, particularly histogram based approaches. Scott (1992) provides a comprehensive statistical approach to density estimation, with recent updates included in Scott & Sain (2004). A tutorial by Urbanek & Dasu (2007) sets down a statistical framework for the rigorous analysis of data streams with emphasis on case studies and applications. Dasu, Koutsofios & Wright (2007) discuss application of statistical analysis to an e-commerce data stream. Gao, Fan, Han & Yu (2007) address the issue of estimating posterior probabilities in data streams with skewed distributions.

Visualization of data streams is particularly challenging, from the three perspectives dimensionality, scale and time. Wong, Foote, Adams, Cowley & Thomas (2003) present methods based on multi dimensional scaling. Urbanek & Dasu (2007) present a discussion of viable visualization techniques for data streams in their tutorial.

Data Quality and Data Streams

Data streams tend to be dynamic and inherently noisy due to the fast changing conditions.

An important but little discussed concern with data streams is the quality of the data. Problems could and do arise at every stage of the process.

Data Gathering: Most data streams are generated automatically. For instance, a router sends information about packets at varying levels of detail. Similarly an intrusion detection system (IDS) automatically generates an alarm on a network when a predefined rule or condition is met. The data streams change when the rule settings are changed either intentionally by an operator or due to some software glitch. In either case, there is no documentation of the change to alert the analyst that the data stream is no longer *consistent* and *can not be interpreted* using the existing data definitions. Software and hardware components fail on occasion leading to gaps in the data streams (*missing or incomplete data*).

Data Summarization: Due to the huge size and rapid accumulation, data streams are usually summarized for storage -- for instance using 5-minute aggregates of number of packets, average CPU usage, and number of events of a certain type in the system logs. However, the average CPU usage might not reflect abnormal spikes. Or, a rare but catastrophic event might be unnoticed among all the other types of alarms. The trade-off between data granularity and aggregation is an important one. There has been much interest in representing data streams using histograms and other distributional summaries (Guha, Koudas & Shim, 2001) but largely for univariate data streams. Options for multivariate data streams and the use of sufficient statistics (Moore, 2006) for building regression type models for data streams are explored in Dasu, Koutsofios & Wright (2007).

Data Integration: Creating a comprehensive data set from multiple data sources always poses challenges. Sometimes there are no well defined join keys – only soft keys like names and addresses that can be represented in many different ways. For example, "J. Smith", "John Smith" and "John F. Smith" might be different variations of the same entity. Disambiguation is not easy. One data source might contain only a fraction of the entities contained in the other data sources, leading to gaps in the data matrix. Data streams pose additional complexities such as synchronization of multiple streams. There are two ways the temporal aspect could be a problem. First, if the clocks that timestamp the data streams are out of step and second, if the aggregation granularity does not allow the two data streams to be synchronized in any meaningful fashion.

Data quality is of particular concern in data streams. We do not have the luxury of referring back to the raw data to validate or correct mistakes. Furthermore, data quality mistakes could get compounded rapidly due to the high rate of accumulation, resulting in a significant divergence from reality and accuracy.

A Framework

A data stream is typically a sequential set of measurements in time. In most extant literature, a data stream is univariate i.e. measures just one attribute. It is represented in a reduced, more manageable form by maintaining statistical summaries for a given slice of the data stream, called a window, where every chunk of *N* points constitutes a window.

In Figure 1, the gray dots are data points that have been processed and summarized into aggregates *{A(t-1)}*, the black dots represent the data in the current time window that will be stored as aggregates *{A(t)}* and the white dots are data points yet to be processed. Another approach to maintaining summaries is to compute cumulative summaries based on the entire history of the data stream and updating these as the data comes in.

Aggregates are typically counts, sums and higher order moments like sums of squares; extreme values like minimum and maximum; and other percentiles. It is important to select these summaries carefully since there is no further opportunity to access the raw data to either update the existing summaries or compute additional aggregates. The amount of type and kind of statistics to be maintained can be customized depending on the application and may include:

1. Characterizing the distribution of a data stream by building histograms – see Guha, Koudas & Shim (2001) and Muthukrishnan (2003).
2. Detecting changes in the distribution and updating the distribution to reflect the changes – change detection has received much attention since it plays a critical role in network monitoring, security applications and maintaining robust and reliable aggregates for data stream modeling. We will discuss this in a little greater detail later on in the context of the application.
3. Comparing two or more data streams (Cormode, Datar, Indyk & Muthukrishnan (2002)) or the same data stream at different points in time (Dasu, Krishnan, Venkatasubramanian & Yi (2006)).
4. Detecting anomalies and outliers in a data stream.
5. Discovering patterns and sequences in data stream anomalies. See Aggarwal (2006).
6. Building predictive models.

Figure 1

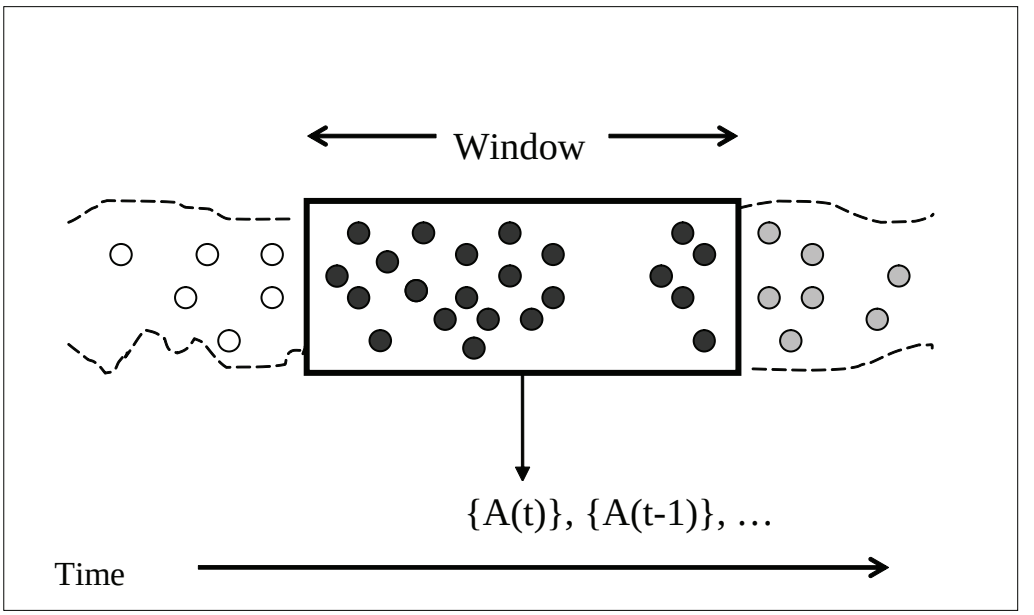

Figure 2.

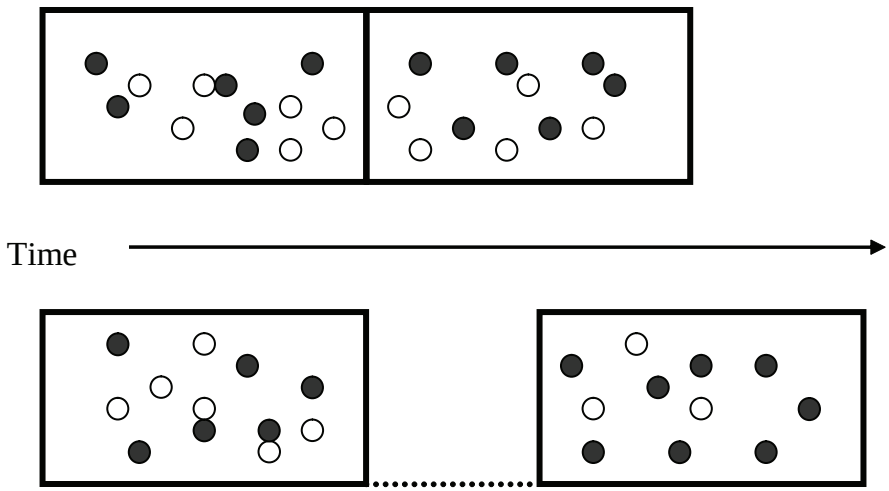


An important example of the use of data stream summaries is change detection in data streams. Changes are detected by comparing data in two or more windows.

Short term changes are detected using adjacent windows that move in lock-step across time. Long term changes are detected using fixed-slide windows where one window is kept fixed while the second window moves forward in time. When a change is detected, the fixed window is moved to the most recent position and the process starts all over again. Ben-David, Gehrke & Kifer (2004) use a rank based method (Lehmann, 1974) to detect changes in the two windows. However, this can not be extended to higher dimensional data streams since there is no ordering of data in higher dimensions. Nor can it be used for categorical attributes. The method proposed by Dasu, Krishnan, Venkatasubramanian & Yi (2006) based on the Kullback-Leibler information theoretic distance measure addresses these shortcomings. We give a brief description of the basic methodology since our case study relies on this technique.

1. First, use any data partitioning scheme to "bin" the data in the two windows being compared. The partition can be predefined, based on the values of categorical attributes (e.g. gender) or intervals of continuous attributes (e.g., income), or a simple data-driven grid, based on the quantiles of individual attributes. A partition can also be induced by a model such as a clustering or classification algorithm. In our application, we use a DataSphere partition (Johnson & Dasu, 1998) that has the property that the number of bins increases linearly with the number of dimensions or attributes. It is characterized by *distance layers* that divide the data into groups of data points that are within a distance range of a given reference point such as the mean; and *directional pyramids* characterized by the direction of greatest deviation. A detailed discussion is beyond the scope of this chapter.
2. Next, we compute two histograms *H1* and *H2*, one for each of the two windows being compared. The histograms are represented by the frequency vectors

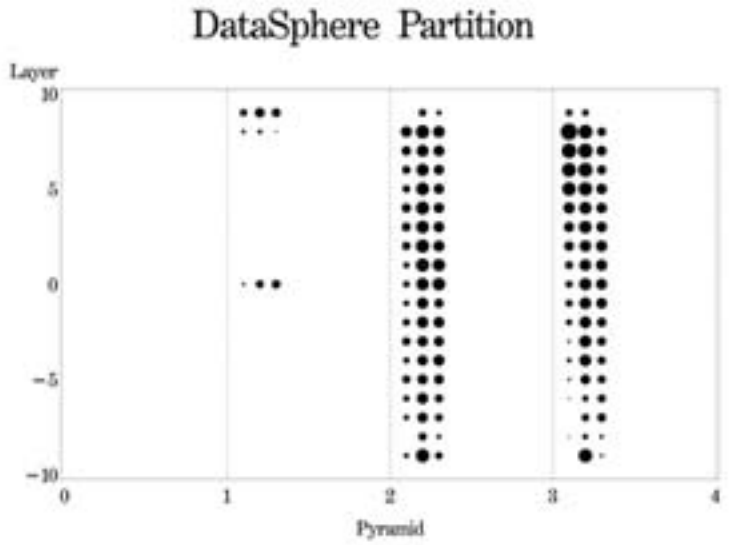
   (p1, p2, …, pB)

   and

   (q1, q2, …, qB),

   where *B* is the number of bins and *pi, qi* are the frequency counts.
3. We compare the distance between the two histograms using a range of statistical tests, like the naïve multinomial Chi-square or a similar test based on the Kullback-Leibler divergence. We use bootstrapping to simulate a sampling distribution when an exact test is not known.

Figure 3



4. Finally, we choose a desired level of confidence (e.g., 95%) and use the sampling distribution to see if the difference is significant.

The methodology is derived from the classical hypothesis testing framework of statistics. A brief discussion of statistical hypothesis testing along with the bootstrap methodology in the context of change detection is found in Dasu, Krishnan, Venkatasubramanian & Yi (2006). We use additional tests to identify regions of greatest difference. We present below an application that uses this approach.

An Application: Monitoring IP Networks

IP networks carry terabytes of data a day to enable the smooth functioning of almost every aspect of life, be it running corporations, industrial plants, newspapers, educational institutions or simpler residential tasks like exchanging e-mail or pictures. The networks are made of thousands of hardware and software components, and governed by rules called protocols that direct and regulate the data traffic. The traffic, its movement, and the functioning of the components are recorded in daunting detail in various forms. Traffic flows are recorded by netflows that specify the amount and type of data, its origin and destination, and intermediate stops if any. The topology of the network is like a dynamic road map for the data traffic and maintained in configuration tables. The functioning of the components like routers that direct the traffic is recorded in terms of resource usage. Alarms and unusual events are logged by software installed at critical points of the network. We brought together several such data sources to give us a timely and accurate picture of the state of the network.

We present below a brief analysis of a major network observed over a six week period. We are deliberately vague about the details to preserve proprietary information and some of the data distributions have been modified in a manner that does not affect the illustrative purpose of this application. For narrative convenience, we focus on three attributes of the data: the proportion of errors, the total traffic in bytes of type A, and the total traffic of type B. We use a specified week to create a baseline DataSphere partition based on the three attributes and compare the data from other weeks to the baseline. In Figure 3, we focus on a particular network device, D1. The *Y*-axis represents the distance layers, where a "negative" layer corresponds to values of deviations that are below average. The *X*-axis represents the directional pyramids. For example, a data point that has an above average proportion of errors and is

Figure 4.

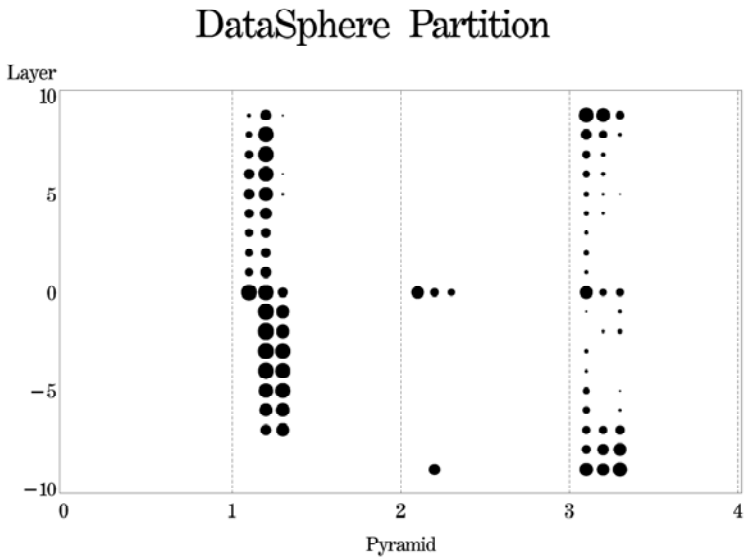


Figure 5.

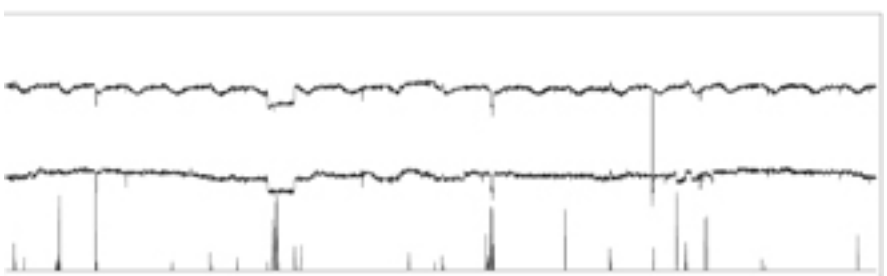

Figure 6.

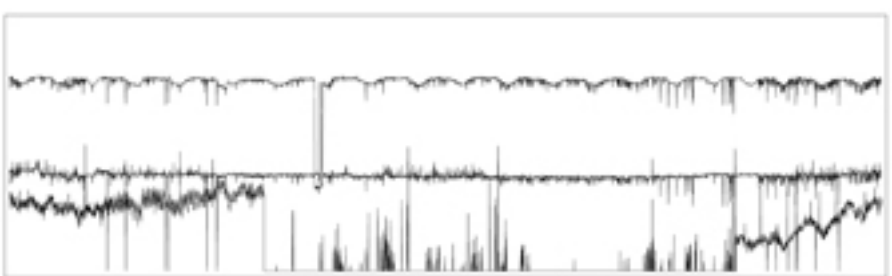

most deviant with respect to that attribute will fall in pyramid 1. The more extreme the values, the greater the distance from the reference point and therefore higher the value of the distance layer. The dots are proportional to the amount of data in that bin. And the three columns within a specific pyramid range correspond to three consecutive weeks, where the middle column is the baseline week. In Figure 3, the distribution has shifted slightly in the three weeks, most notably in pyramid 3 (traffic type B) where the mass has shifted from higher values to more average values. Figure 4, describes the same information but for a different but comparable network device D2. Over the three weeks, we notice major shifts in the data mass in pyramid 1. The patterns for the error proportion are completely reversed from the first week to the third week. There is an unusually high proportion of errors which is fixed during weeks 2 and 3. This pattern is accompanied by an unusually large volume of type B traffic which returns to normal by the third week.

On examining the three individual attributes represented by the three lines in Figure 5, we see that for device D1, the individual attributes are well behaved with slight deviations from the ordinary patterns.

Figure 5 shows the same information for device D2. The erratic patterns in error proportions (bottom line in the plot) are evident, as well as the single big drop in type A traffic (top line in the plot) which corresponds to the big dot in pyramid 2, layer -8, week 2 in Figure 4.

The two dimensional "distance layer-directional pyramid" plots are a convenient and comprehensive way of displaying the distribution of the mass in the bins of the DataSphere partition, irrespective of the number of attributes. Note that line plots like the ones in Figures 5 and 6 become too numerous and overwhelming as the number of attributes increases.

In the case of the data streams above, the differences were clearly significant. In situations where the differences are more subtle, statistical tests of significance are used. See Dasu, Koutsofios & Wright (2007) for a case study that further illustrates the use of these tests.

FUTURE TRENDS

An interesting problem arises while comparing two data streams using multivariate histograms. Given the generally noisy nature of data streams, we can expect standard statistical tests to routinely declare differences. However, can we adapt the test to ignore differences in specified cells which we know a priori to be noisy and which might vary over time?

Research opportunities abound in the warehousing and querying of data streams. Aggarwal (2007) has a comprehensive collection of research articles that provide insights into the current research in the database community as well as open problems that require interdisciplinary solutions.

CONCLUSION

We have provided a brief overview of mining and monitoring data streams. Data streams are an inevitable and challenging form of information in many industrial and scientific applications, particularly the telecommunications industry. The research in this area is in its infancy and provides challenging research opportunities in managing, storing, querying and mining of data streams.

KEY TERMS

Bootstrap: A technique by which multiple samples are created from a single sample to compute error bounds for statistics computed from the original sample. Efron & Tibshirani (1993).

Chi-Square Test: A statistical test based on the Chi-square distribution to determine the statistical significance of a sample statistic.

Histogram: A histogram is a mapping that counts the number of observations that fall into various disjoint categories (known as bins).

Hypothesis Testing: A statistical framework for making decisions using relatively small samples of data. Bickel & Doksum (2001).

IDS: Intrusion detection system is software installed at critical points in a network to monitor the data packets that pass through for suspicious patterns.

Join Key (Match Key): An attribute or field in a database used to join or combine different database tables.

Kullback-Leibler Distance: A measure of the divergence between two probability distributions. Cover & Thomas (1991).

Partition: A method of dividing an attribute space into mutually exclusive classes that completely cover the space.

Quantiles: Values of a random variable that mark off certain probability cut-offs of the distribution. For example, the median is the 50% quantile of a distribution.

Sampling Distribution: The empirical distribution of a statistic computed from multiple samples drawn from the same populations under the same conditions.

Mining Data with Group Theoretical Means

Gabriele Kern-Isberner
University of Dortmund, Germany

INTRODUCTION

Knowledge discovery refers to the process of extracting new, interesting, and useful knowledge from data and presenting it in an intelligible way to the user. Roughly, knowledge discovery can be considered a three-step process: preprocessing data; data mining, in which the actual exploratory work is done; and interpreting the results to the user. Here, I focus on the data-mining step, assuming that a suitable set of data has been chosen properly.

The patterns that we search for in the data are plausible relationships, which agents may use to establish cognitive links for reasoning. Such plausible relationships can be expressed via association rules. Usually, the criteria to judge the relevance of such rules are either frequency based (Bayardo & Agrawal, 1999) or causality based (for Bayesian networks, see Spirtes, Glymour, & Scheines, 1993). Here, I will pursue a different approach that aims at extracting what can be regarded as structures of knowledge — relationships that may support the inductive reasoning of agents and whose relevance is founded on information theory. The method that I will sketch in this article takes numerical relationships found in data and interprets these relationships as structural ones, using mostly algebraic techniques to elaborate structural information.

BACKGROUND

Common sense and expert knowledge is most generally expressed by rules, connecting a precondition and a conclusion by an if-then construction. For example, you avoid puddles on sidewalks because you are aware of the fact that if you step into a puddle, then your feet might get wet; similarly, a physician would likely expect a patient showing the symptoms of fever, headache, and a sore throat to suffer from a flu, basing his diagnosis on the rule that if a patient has a fever, headache, and sore throat, then the ailment is a flu, equipped with a sufficiently high probability.

If-then rules are more formally denoted as conditionals. The crucial point with conditionals is that they carry generic knowledge that is applicable to different situations. This fact makes them most interesting objects in artificial intelligence, in a theoretical as well as in a practical respect. For instance, a sales assistant who has a general knowledge about the preferences of his or her customers can use this knowledge when consulting any new customer.

Typically, two central problems have to be solved in practical applications: First, where do the rules come from? How can they be extracted from statistical data? And second, how should rules be represented? How should conditional knowledge be propagated and combined for further inferences? Both of these problems can be dealt with separately, but it is most rewarding to combine them, that is, to discover rules that are most relevant with respect to some inductive inference formalism and to build up the best model from the discovered rules that can be used for queries.

MAIN THRUST

This article presents an approach to discover association rules that are most relevant with respect to the maximum entropy methods. Because entropy is related to information, this approach can be considered as aiming to find the most informative rules in data. The basic idea is to exploit numerical relationships that are observed by comparing (relative) frequencies, or ratios of frequencies, and so forth, as manifestations of interactions of underlying conditional knowledge.

My approach differs from usual knowledge discovery and data-mining methods in various respects:

- It explicitly takes the instrument of inductive inference into consideration.

- It is based on statistical information but not on probabilities close to 1; actually, it mostly uses only structural information obtained from the data.
- It is not based on observing conditional independencies (as for learning causal structures), but aims at learning relevant conditional dependencies in a nonheuristic way.
- As a further novelty, it does not compute single, isolated rules, but yields a set of rules by taking into account highly complex interactions of rules.
- Zero probabilities computed from data are interpreted as missing information, not as certain knowledge.

The resulting set of rules may serve as a basis for maximum entropy inference. Therefore, the method described in this article addresses minimality aspects, as in Padmanabhan and Tuzhilin (2000), and makes use of inference mechanisms, as in Cristofor and Simovici (2002). Different from most approaches, however, it exploits the inferential power of the maximum entropy methods in full consequence and in a structural, nonheuristic way.

Modelling Conditional Knowledge by Maximum Entropy (ME)

Suppose a set $R^* = \{(B1|A1)[x1], \ldots, (Bn|An)[xn]\}$ of probabilistic conditionals is given. For instance, R^* may describe the knowledge available to a physician when he has to make a diagnosis. Or R^* may express common sense knowledge, such as "Students are young with a probability of (about) 80%" and "Singles (i.e., unmarried people) are young with a probability of (about) 70%", the latter knowledge being formally expressed by $R^* = \{ (young|student)[0.8], (young|single)[0.7] \}$.

Usually, these rule bases represent incomplete knowledge, in that a lot of probability distributions are apt to represent them. So learning or inductively representing the rules, respectively, means to take them as a set of conditional constraints and to select a unique probability distribution as the best model that can be used for queries and further inferences. Paris (1994) investigates several inductive representation techniques in a probabilistic framework and proves that the principle of maximum entropy (ME-principle) yields the only method to represent incomplete knowledge in an unbiased way, satisfying a set of postulates describing sound common sense reasoning. The entropy H(P) of a probability distribution P is defined as

$$H(P) = - \Sigma_w P(w) \log P(w),$$

where the sum is taken over all possible worlds, w, and measures the amount of indeterminateness inherent to P. Applying the principle of maximum entropy, then, means to select the unique distribution $P^* = ME(R^*)$ that maximizes H(P) among all distributions P that satisfy the rules in R^*. In this way, the ME-method ensures that no further information is added, so the knowledge R^* is represented most faithfully.

Indeed, the ME-principle provides a most convenient and founded method to represent incomplete probabilistic knowledge (efficient implementations of ME-systems are described in Roedder & Kern-Isberner, 2003). In an ME-environment, the expert has to list only whatever relevant conditional probabilities he or she is aware of. Furthermore, ME-modelling preserves the generic nature of conditionals by minimizing the amount of information being added, as shown in Kern-Isberner (2001).

Nevertheless, modelling ME-rule bases has to be done carefully so as to ensure that *all* relevant dependencies are taken into account. This task can be difficult and troublesome. Usually, the modelling rules are based somehow on statistical data. So, a method to compute rule sets appropriate for ME-modelling from statistical data is urgently needed.

Structures of Knowledge

The most typical approach to discover interesting rules from data is to look for rules with a significantly high (conditional) probability and a concise antecedent (Bayardo & Agrawal, 1999; Agarwal, Aggarwal, & Prasad, 2000; Fayyad & Uthurusamy, 2002; Coenen, Goulbourne, & Leng, 2001). Basing relevance on frequencies, however, is sometimes unsatisfactory and inadequate, particularly in complex domains such as medicine. Further criteria to measure the interestingness of the rules or to exclude redundant rules have also been brought forth (Jaroszewicz & Simovici, 2001; Bastide, Pasquier, Taouil, Stumme, & Lakhal, 2000; Zaki, 2000). Some of these algorithms also make use of optimization criteria, which are based on entropy (Jaroszewicz & Simovici, 2002).

Mostly, the rules are considered as isolated pieces of knowledge; no interaction between rules can be taken into account. In order to obtain more structured information, one often searches for causal relationships by investigating conditional independencies and thus noninteractivity between sets of variables (Spirtes et al., 1993).

Although causality is undoubtedly most important for human understanding, the concept seems to be too rigid to represent human knowledge in an exhaustive way. For instance, a person suffering from a flu is certainly sick (P(sick | flu) = 1), and he or she often will complain about headaches (P(headache | flu) = 0.9). Then you have P(headache | flu) = P(headache | flu & sick), but you would surely expect that P(headache | not flu) is different from P(headache | not flu & sick)! Although the first equality suggests a conditional independence between sick and headache, due to the causal dependency between headache and flu, the second inequality shows this to be (of course) false. Furthermore, a physician might also state some conditional probability involving sickness and headache, so you obtain a complex network of rules. Each of these rules will be considered relevant by the expert, but none will be found when searching for conditional independencies! So what, exactly, are the *structures of knowledge* by which conditional dependencies (not independencies! See also Simovici, Cristofor, D., & Cristofor, L., 2000) manifest themselves in data?

To answer this question, the *theory of conditional structures* has been presented in Kern-Isberner (2000). Conditional structures are an algebraic means to make the effects of conditionals on possible worlds (i.e., possible combinations or situations) transparent, in that they reflect whether the corresponding world verifies the conditional or falsifies it, or whether the conditional cannot be applied to the world because the *if*-condition is not satisfied. Consider, for instance, the conditional "If you step in a puddle, then your feet might get wet." In a particular situation, the conditional is applicable (you actually step into a puddle) or not (you simply walk around it), and it can be found verified (you step in a puddle and indeed, your feet get wet) or falsified (you step in a puddle, but your feet remain dry because you are wearing rain boots).

This intuitive idea of considering a conditional as a three-valued event is generalized in Kern-Isberner (2000) to handle the simultaneous impacts of a set of conditionals by using algebraic symbols for positive and negative impact, respectively. Then for each world, a word of these symbols can be computed, which shows immediately how the conditionals interact on this world. The proper mathematical structure for building words are (semi)groups, and indeed, group theory provides the basis for connecting numerical to structural information in an elegant way. In short, a probability (or frequency) distribution is called *(conditionally) indifferent with respect to a set of conditionals R** iff its numerical information matches the structural information provided by conditional structures. In particular, each ME-distribution turns out to be indifferent with respect to a generating set of conditionals.

Data Mining and Group Theory — A Strange Connection?

The concept of conditional structures, however, is not only an algebraic means to judge well-behavedness with respect to conditional information. The link between numerical and structural information, which is provided by the concept of conditional indifference, can also be used in the other direction, that is, to derive structural information about the underlying conditional relationships from numerical information. More precisely, finding a set of rules with the ability to represent a given probability distribution *P* via ME-methods can be done by elaborating numerical relationships in *P*, interpreting them as manifestations of underlying conditional dependencies. The procedure to discover appropriate sets of rules is sketched in the following steps:

- Start with a set *B* of simple rules, the length of which is considered to be large enough to capture all relevant dependencies.
- Search for numerical relationships in *P* by investigating which products of probabilities match.
- Compute the corresponding conditional structures with respect to *B*, yielding equations of group elements.
- Solve these equations by forming appropriate factor groups.
- Building these factor groups corresponds to eliminating and joining the basic conditionals in *B* to make their information more concise, in accordance with the numerical structure of *P*. Actually, the antecedents of the conditionals in *B* are shortened so as to comply with the numerical relationships in *P*.

So the basic idea of this algorithm is to start with long rules and to shorten them in accordance with the probabilistic information provided by *P* without losing information.

Group theory actually provides an elegant framework, on the one hand, to disentangle highly complex conditional interactions in a systematic way, and on the other hand, to make operations on the conditionals computable, which is necessary to make information more concise.

How to Handle Sparse Knowledge

The frequency distributions calculated from data are mostly not positive — just to the contrary, they would be sparse, full of zeros, with only scattered clusters of nonzero probabilities. This overload of zeros is also a problem with respect to knowledge representation, because a zero in such a frequency distribution often merely means that such a combination has not been recorded. The strict probabilistic interpretation of zero probabilities, however, is that such a combination does not exist, which does not seem to be adequate.

The method sketched in the preceding section is also able to deal with that problem in a particularly adequate way: The zero values in frequency distributions are taken to be unknown but equal probabilities, and this fact can be exploited by the algorithm. So they actually help to start with a tractable set B of rules right from the beginning (see also Kern-Isberner & Fisseler, 2004).

In summary, zeros occurring in the frequency distribution computed from data are considered as missing information, and in my algorithm, they are treated as non-knowledge without structure.

FUTURE TRENDS

Although by and large, the domain of knowledge discovery and data mining is dominated by statistical techniques and the problem of how to manage vast amounts of data, the increasing need for and popularity of human-machine interactions will make it necessary to search for more structural knowledge in data that can be used to support (humanlike) reasoning processes. The method described in this article offers an approach to realize this aim. The conditional relationships that my algorithm reveals can be considered as kind of cognitive links of an ideal agent, and the ME-technology takes the task of inductive reasoning to make use of this knowledge. Combined with clustering techniques in large databases, for example, it may turn out a useful method to discover relationships that go far beyond the results provided by other, more standard data-mining techniques.

CONCLUSION

In this article, I have developed a new method for discovering conditional dependencies from data. This method is based on information-theoretical concepts and group-theoretical techniques, considering knowledge discovery as an operation inverse to inductive knowledge representation. By investigating relationships between the numerical values of a probability distribution *P,* the effects of conditionals are analyzed and isolated, and conditionals are joined suitably so as to fit the knowledge structures inherent to *P.*

KEY TERMS

Conditional: The formal algebraic term for a rule that need not be strict, but also can be based on plausibility, probability, and so forth.

Conditional Independence: A generalization of plain statistical independence that allows you to take a context into account. Conditional independence is often associated with causal effects.

Conditional Structure: An algebraic expression that makes the effects of conditionals on possible worlds transparent and computable.

Entropy: Measures the indeterminateness inherent to a probability distribution and is dual to information.

Possible World: Corresponds to the statistical notion of an elementary event. Probabilities over possible worlds, however, have a more epistemic, subjective meaning, in that they are assumed to reflect an agent's knowledge.

Principle of Maximum Entropy: A method to complete incomplete probabilistic knowledge by minimizing the amount of information added.

Probabilistic Conditional: A conditional that is assigned a probability. To match the notation of conditional probabilities, a probabilistic conditional is written as (B|A)[x] with the meaning "If A holds, then B holds with probability x."

Mining Email Data

Steffen Bickel
Humboldt-Universität zu Berlin, Germany

Tobias Scheffer
Humboldt-Universität zu Berlin, Germany

INTRODUCTION

E-mail has become one of the most important communication media for business and private purposes. Large amounts of past e-mail records reside on corporate servers and desktop clients. There is a huge potential for mining this data. E-mail filing and spam filtering are well-established e-mail mining tasks. E-mail filing addresses the assignment of incoming e-mails to predefined categories to support selective reading and organize large e-mail collections. First research on e-mail filing was conducted by Green and Edwards (1996) and Cohen (1996). Pantel and Lin (1998) and Sahami, Dumais, Heckerman, and Horvitz (1998) first published work on spam filtering. Here, the goal is to filter unsolicited messages. Recent research on e-mail mining addresses automatic e-mail answering (Bickel & Scheffer, 2004) and mining social networks from e-mail logs (Tyler, Wilkinson, & Huberman, 2004).

In Section *Background* we will categorize common e-mail mining tasks according to their objective, and give an overview of the research literature. Our *Main Thrust* Section addresses e-mail mining with the objective of supporting the message creation process. Finally, we discuss *Future Trends* and conclude.

BACKGROUND

There are two objectives for mining e-mail data: supporting communication and discovering hidden properties of communication networks.

Support of Communication

The problems of filing e-mails and filtering spam are text classification problems. Text classification is a well studied research area; a wide range of different methods is available. Most of the common text classification algorithms have been applied to the problem of e-mail classification and their performance has been compared in several studies. Because publishing an e-mail data set involves disclosure of private e-mails, there are only a small number of standard e-mail classification data sets. Since there is no study that compares large numbers of data sets, different classifiers and different types of extracted features, it is difficult to judge which text classifier performs best specifically for e-mail classification.

Against this background we try to draw some conclusions on the question which is the best text classifier for e-mail. Cohen (1996) applies rule induction to the e-mail classification problem and Provost (1999) finds that Naïve Bayes outperforms rule induction for e-mail filing. Naïve Bayes classifiers are widely used for e-mail classification because of their simple implementation and low computation time (Pantel & Lin, 1998; Rennie, 2000; Sahami, Dumais, Heckerman, & Horvitz, 1998). Joachims (1997, 1998) shows that Support Vector Machines (SVMs) are superior to the Rocchio classifier and Naïve Bayes for many text classification problems. Drucker, Wu, and Vapnik (1999) compares SVM with boosting on decision trees. SVM and boosting show similar performance but SVM proves to be much faster and has a preferable distribution of errors.

The performance of an e-mail classifier is dependent on the extraction of appropriate features. Joachims (1998) shows that applying feature selection for text classification with SVM does not improve performance. Hence, using SVM one can bypass the expensive feature selection process and simply include all available features. Features that are typically used for e-mail classification include all tokens in the e-mail body and header in bag-of-words representation using TF- or TFIDF-weighting. HTML tags and single URL elements also provide useful information (Graham, 2003).

Boykin and Roychowdhury (2004) propose a spam filtering method that is not based on text classification

but on graph properties of message sub-graphs. All addresses that appear in the headers of the inbound mails are graph nodes; an edge is added between all pairs of addresses that jointly appear in at least one header. The resulting sub-graphs exhibit graph properties that differ significantly for spam and non-spam sub-graphs. Based on this finding "black-" and "whitelists" can be constructed for spam and non-spam addresses. While this idea is appealing, it should be noted that the approach is not immediately practical since most headers of spam e-mails do not contain other spam recipients' addresses, and most senders' addresses are used only once.

Additionally, the "*semantic e-mail"* approach (McDowell, Etzioni, Halevy, & Levy, 2004) aims at supporting communication by allowing automatic e-mail processing and facilitating e-mail mining; it is the equivalent of *semantic web* for e-mail. The goal is to make e-mails human- and machine-understandable with a standardized set of e-mail processes. Each e-mail has to follow a standardized process definition that includes specific process relevant information. An example for a *semantic e-mail* process is meeting coordination. Here, the individual process tasks (corresponding to single e-mails) are issuing invitations and collecting responses. In order to work, *semantic e-mail* would require a global agreement on standardized semantic processes, special e-mail clients and training for all users. Additional mining tasks for support of communication are automatic e-mail answering and sentence completion. They are described in Section *Main Thrust*.

Discovering Hidden Properties of Communication Networks

E-mail communication patterns reveal much information about hidden social relationships within organizations. Conclusions about informal communities and informal leadership can be drawn from e-mail graphs. Differences between informal and formal structures in business organizations can provide clues for improvement of formal structures which may lead to enhanced productivity. In the case of terrorist networks, the identification of communities and potential leaders is obviously helpful as well. Additional potential applications lie in marketing, where companies – especially communication providers – can target communities as a whole.

In social science, it is common practice for studies on electronic communication within organizations to derive the network structure by means of personal interviews or surveys (Garton Garton, Haythornthwaite, & Wellman, 1997; Hinds & Kiesler, 1995). For large organizations, this is not feasible. Building communication graphs from e-mail logs is a very simple and accurate alternative provided that the data is available. Tyler, Wilkinson, and Huberman (2004) derive a network structure from e-mail logs and apply a divisive clustering algorithm that decomposes the graph into communities. Tyler, Wilkinson, and Huberman verify the resulting communities by interviewing the communication participants; they find that the derived communities correspond to informal communities.

Tyler et al. also apply a force-directed spring algorithm (Fruchterman & Rheingold, 1991) to identify leadership hierarchies. They find that with increasing distance of vertices from the "spring" (center) there is a tendency of decreasing real hierarchy depth.

E-mail graphs can also be used for controlling virus attacks. Ebel, Mielsch, and Bornholdt (2002) show that vertex degrees of e-mail graphs are governed by power laws. By equipping the small number of highly connected nodes with anti-virus software the spreading of viruses can be prevented easily.

MAIN THRUST

In the last section we categorized e-mail mining tasks regarding their objective and gave a short explanation on the single tasks. We will now focus on the ones that we consider to be most interesting and potentially most beneficial for users and describe them in greater detail. These tasks aim at supporting the message creation process. Many e-mail management systems allow the definition of message templates that simplify the message creation for recurring topics. This is a first step towards supporting the message creation process, but past e-mails that are available for mining are disregarded. We describe two approaches for supporting the message creation process by mining historic data: mining question-answer pairs and mining sentences.

Mining Question-Answer Pairs

We consider the problem of learning to answer incoming e-mails from records of past communication.

We focus on environments in which large amounts of similar answers to frequently asked questions are sent – such as call centers or customer support departments. In these environments, it is possible to *manually* identify equivalence classes of answers in the records of *outbound* communication. Each class then corresponds to a set of semantically equivalent answers sent in the past; it depends strongly on the application context which fraction of the outbound communication falls into such classes. Mapping *inbound* messages to one of the equivalence classes of answers is now a multi-class text classification problem that can be solved with text classifiers.

This procedure requires a user to manually group previously sent answers into equivalence classes which can then serve as class labels for training a classifier. This substantial manual labeling effort reduces the benefit of the approach. Even though it can be reduced by employing semi-supervised learning (Nigam, McCallum, Thrun, & Mitchell, 2000; Scheffer, 2004), it would still be much preferable to learn from only the available data: stored inbound and outbound messages. Bickel and Scheffer (2004) discuss an algorithm that learns to answer questions from only the available data and does not require additional manual labeling. The key idea is to replace the manual assignment of outbound messages to equivalence classes by a clustering step.

The algorithms for training (learning from message pairs) and answering a new question are shown in Table 1. In the training phase, a clustering algorithm identifies groups of similar outbound messages. Each cluster then serves as class label; the corresponding questions which have been answered by a member of the cluster are used as training examples for a multi-class text classifier. The medoid of each cluster (the outbound message closest to the center) is used as an answer template. The classifier maps a newly incoming question to one of the clusters; this cluster's medoid is then proposed as answer to the question. Depending on the user interface, high confidence messages might be answered automatically, or an answer is proposed which the user may then accept, modify, or reject (Scheffer, 2004).

The approach can be extended in many ways. Multiple topics in a question can be identified to mix different corresponding answer templates and generate

Table 1. Algorithms for learning from message pairs and answering new questions.

Learning from message pairs.

Input: Message pairs, variance threshold σ^2, pruning parameter π.

1. Recursively cluster answers of message pairs with bisecting partitioning cluster algorithm, end recursion when cluster variance lies below σ^2.
2. Prune all clusters with less than π elements. Combine all pruned clusters into one "miscellaneous" cluster. Let n be the number of resulting clusters.
3. For all n clusters
    a. Construct an answer template by choosing the answer that is most similar to the centroid of this cluster in vector space representation and remove salutation line.
    b. Let the inbound mails that have been answered by a mail in the current cluster be the positive training examples for this answer class.
2. Train SVM classifier that classifies an inbound message into one of the n answer classes or the "miscellaneous" class from these training examples. Return this classifier.

Answering new questions.

Input: New question message, message answering hypothesis, confidence threshold θ.

1. Classify new message into one of the n answer classes and remember SVM decision function value.
2. If confidence exceeds the confidence threshold, propose the answer template that corresponds to the classification result. Perform instantiation operations that typically include formulating a salutation line.

a multi-topic answer. Question specific information can be extracted in an additional information extraction step and automatically inserted into answer templates. In this extraction step also customer identifications can be extracted and used for a database lookup that provides customer and order specific information for generating more customized answers.

Bickel and Scheffer (2004) analyze the relationship of answer classes regarding the separability of the corresponding questions using e-mails sent by the service department of an online shop. By analyzing this relationship one can draw conclusions about the amount of additional information that is needed for answering specific types of questions. This information can be visualized in an *inseparability graph*, where each class of equivalent answers is represented by a vertex, and an edge is drawn when a classifier that discriminates between these classes achieves only a low AUC performance (the AUC performance is the probability that, when a positive and a negative example are drawn at random, a discriminator assigns a higher value to the positive than to the negative one). Typical examples of inseparable answers are "your order has been shipped this morning" and "your order will be shipped tomorrow". Intuitively, it is not possible to predict which of these answers a service employee will send, based on only the question "when will I receive my shipment?"

Mining Sentences

The message creation process can also be supported on a sentence level. Given an incomplete sentence, the task of *sentence completion* is to propose parts or the total rest of the current sentence, based on an application specific document collection. A sentence completion user interface can, for instance, display a proposed completion in a "micro window" and insert the proposed text when the user presses the "tab" key.

The sentence completion problem poses new challenges for data mining and information retrieval, including the problem of finding sentences whose initial fragment is similar to a given fragment in a very large text corpus. To this end, Grabski and Scheffer (2004) provide a retrieval algorithm that uses a special inverted indexing structure to find the sentence whose initial fragment is most similar to a given fragment, where similarity is defined in terms of the greatest cosine similarity of the TFIDF vectors. In addition, they study an approach that compresses the data further by identifying clusters of the most frequently used similar sets of sentences. In order to evaluate the accuracy of sentence completion algorithms, Grabski and Scheffer (2004) measure how frequently the algorithm, when given a sentence fragment drawn from a corpus, provides a prediction with confidence above θ, and how frequently this prediction is semantically equivalent to the actual sentence in the corpus. They find that for the sentence mining problem higher precision and recall values can be obtained than for the problem of mining question answer pairs; depending on the threshold θ and the fragment length, precision values of between 80% and 100% and recall values of about 40% can be observed.

FUTURE TRENDS

Spam filtering and e-mail filing based on message text can be reduced to the well studied problem of text classification. The challenges that e-mail classification faces today concern technical aspects, the extraction of spam-specific features from e-mails, and an arms race between spam filters and spam senders adapting to known filters. By comparison, research in the area of automatic e-mail answering and sentence completion is in an earlier stage; we see a substantial potential for algorithmic improvements to the existing methods. The technical integration of these approaches into existing e-mail clients or call-center automation software provides an additional challenge. Some of these technical challenges have to be addressed before mining algorithms that aim at supporting communication can be evaluated under realistic conditions.

Construction of social network graphs from e-mail logs is much easier than by surveys and there is a huge interest in mining social networks – see, for instance, the DARPA program on Evidence Extraction and Link Discovery (EELD). While social networks have been studied intensely in the social sciences and in physics, we see a considerable potential for new and better mining algorithms for social networks that computer scientists can contribute.

CONCLUSION

Some methods that can form the basis for effective spam filtering have reached maturity (text classification),

additional foundations are being worked on (social network analysis). Today, technical challenges dominate the development of spam filters. The development of methods that support and automate communication processes is a research topic and first solutions to some of the problems involved have been studied. Mining social networks from e-mail logs is a new challenge; research on this topic in computer science is in an early stage.

KEY TERMS

Community: A group of people having mutual relationships among themselves or having common interests. Clusters in social network graphs are interpreted as communities.

Mining E-Mails: The application of analytical methods and tools to e-mail data for a) support of communication by filing e-mails into folders, filtering spam, answering e-mails automatically, or proposing completions to sentence fragments, b) discovery of hidden properties of communication networks by e-mail graph analysis.

Mining Question-Answer Pairs: Analytical method for automatically answering question e-mails using knowledge that is discovered in question-answer pairs of past e-mail communication.

Mining Sentences: Analytical method for interactively completing incomplete sentences using knowledge that is discovered in a document collection.

Semantic E-Mail: E-mail framework in which the semantics of e-mails is understandable by both, human and machine. A standardized definition of semantic e-mail processes is required.

Spam E-Mail: Unsolicited and unwanted bulk e-mail. Identifying spam e-mail is a text classification task.

Text Classification: The task of assigning documents expressed in natural language to one or more categories (classes) of a predefined set.

TFIDF: Weighting scheme for document and query representation in the vector space model. Each dimension represents a term, its value is the product the frequency of the term in a document (TF) and the inverse document frequency (IDF) of the term. The inverse document frequency of a term is the logarithmic proportion of documents in which the term occurs. The TFIDF scheme assigns a high weight to terms which occur frequently in the focused document, but are infrequent in average documents.

Mining Generalized Association Rules in an Evolving Environment

Wen-Yang Lin
National University of Kaohsiung, Taiwan

Ming-Cheng Tseng
Institute of Information Engineering, Taiwan

INTRODUCTION

The mining of Generalized Association Rules (GARs) from a large transactional database in the presence of item taxonomy has been recognized as an important model for data mining. Most previous studies on mining generalized association rules, however, were conducted on the assumption of a static environment, i.e., static data source and static item taxonomy, disregarding the fact that the taxonomy might be updated as new transactions are added into the database over time, and as such, the analysts may have to continuously change the support and confidence constraints, or to adjust the taxonomies from different viewpoints to discover more informative rules. In this chapter, we consider the problem of mining generalized association rules in such a dynamic environment. We survey different strategies incorporating state-of-the-art techniques for dealing with this problem and investigate how to efficiently update the discovered association rules when there are transaction updates to the database along with item taxonomy evolution and refinement of support constraint.

BACKGROUND

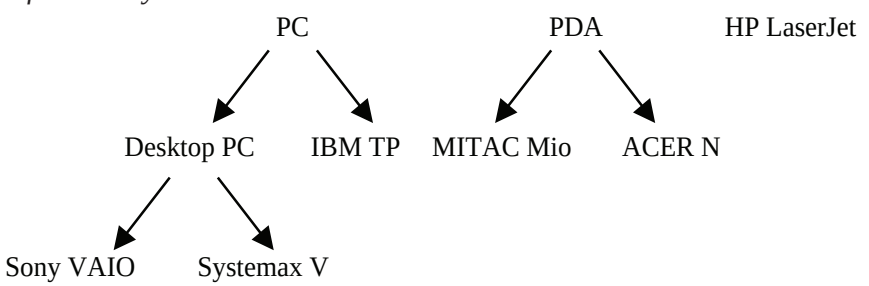
An association rule is an expression of the form $X \Rightarrow Y$, where X and Y are sets of items. Such a rule reveals that transactions in the database containing items in X tend to also contain items in Y, and the probability, measured as the fraction of transactions containing X that also contain Y, is called the *confidence* of the rule. The *support* of the rule is the fraction of the transactions that contain all items in both X and Y. The problem of mining association rules is to discover all association rules that satisfy support and confidence constraints.

In many applications, there are explicit or implicit taxonomies over the items, so it may be more useful to find associations at different taxonomic levels than only at the primitive concept level. For example, consider the taxonomy of items in Figure 1. It is likely that the association rule,

Systemax V $\Rightarrow$ HP LaserJet ($sup \geq 20\%$, $conf = 100\%$) does not hold when the minimum support is set to 25%, but the following association rule may be valid,

Desktop PC $\Rightarrow$ HP LaserJet

Figure 1. Example of taxonomy



This kind of association rule with taxonomy is also called the *generalized association rule* (Srikant & Agrawal, 1995) or the *multi-level association rule* (Han & Fu, 1995). The work in Srikant and Agrawal (1995) aimed at finding associations among items at any level of the taxonomy, whereas the objective in Han and Fu (1995) was to discover associations level-by-level in a fixed hierarchy, i.e., only associations among items on the same level were examined progressively from the top level to the bottom.

Mining GARs with Transaction Update

In the real world, however, data mining practitioners are usually confronted with a dynamic environment. The first challenge comes from the fact that the source database is not static. New transactions are continually added into the database over time, outdated transactions are occasionally or periodically purged from the repository, and some transactions might be modified, thus leading to the essence of updating discovered association rules when transaction updates occur in the database over time. Cheung et al. (1996a) first addressed this problem and proposed an algorithm called FUP (Fast UPdate). They further extended the model to incorporate the situations of deletion and modification (Cheung et al., 1997). Subsequently, a number of techniques have been proposed to improve the efficiency of incremental mining algorithms, such as *negative border* (Sarda & Srinivas, 1998; Thomas et al., 1997), *dynamic counting* (Ng & Lam, 2000), *pre-large itemsets* (Hong et al., 2001), *sliding window filter* (Lee et al., 2005), *support prediction* (Guirguis et al., 2006), and *FP-like tree structure* (Ezeife & Su, 2002; Leung et al., 2007), although all of these were confined to mining associations among primitive items.

The maintenance issue for generalized association rules was also first studied by Cheung et al. (1996b), who proposed an extension of their FUP algorithm, called MLUp, to accomplish the task. Hong et al. (2004) then extended Han and Fu's approach (Han & Fu, 1995) by introducing the concept of pre-large itemsets (Hong et al., 2000) to postpone the original database rescanning until a number of records have been modified. In (Tseng & Lin, 2004), Tseng and Lin extended the problem to incorporate non-uniform minimum support.

Mining GARs with Interestingness Refinement

The second challenge arises from users' perception of information needs. Faced with an unknown and large volume of data collected under a highly competitive environment, analysts generally lack of knowledge about the application domains and so have to change their viewpoints continuously, in an interactive way to find informative rules. In the context of association mining, the user's viewpoint, in its simplest form, is specified through the rule's thresholds, e.g., minimum support and minimum confidence. In the past decade, various strategies have been proposed to realize the interactive (or online) association mining, including *precomputation* (Han, 1998; Aggarwal & Yu, 2001; Czejdo et al., 2002; Duan et al., 2006; Liu et al., 2007), *caching* (Nag et al., 1999), and *incremental update* (Hidber, 1999; Liu & Yin, 2001; Ma et al., 2002; Deng et al., 2005).

The general idea for precomputation strategy is to precompute all frequent itemsets relative to a presetting support threshold, and once the specified support threshold is larger than the presetting value, the qualified association rules can be immediately generated without the burden of an expensive phase for itemset generation. With a similar philosophy, the caching strategy tries to eliminate the cost spent on frequent itemsets computation by temporarily storing previously discovered frequent itemsets (may be accompanied with some infrequent itemsets) that are beneficial to subsequent association queries. The effectiveness of this strategy relies primarily on a successful design of the cache replacement algorithm. The third strategy can be regarded as a compensation for the first two strategies. During the course of a sequence of remining trials with varied support thresholds, the incremental update strategy endeavors to utilize the discovered frequent itemsets in previous trial to reduce the cost for subsequent re-execution.

Mining GARs with Taxonomy Evolution

The third challenge comes to the evolution of item taxonomy. As a representation of the classification relationship imposed on items, a taxonomy must evolve to reflect what has occurred to the domain applications. For example, items corresponding to new products must be added into the taxonomy, and their insertion

would further introduce new classifications if they are of new types. On the other hand, outdated items along with their classifications will also be abandoned if they are no longer produced. All of these changes would reshape the taxonomy and in turn invalidate previously discovered generalized association rules and/or introduce new rules.

In addition to the evolution of taxonomies due to application background change, analysts might also like to adjust the taxonomies from different viewpoints to discover more informative rules (Han & Fu, 1994). Consider Figure 1 for example. The analysts would like to add an additional level, say "Product Vendor", into the taxonomy to discover rules that exploit associations involving such a concept.

Compared with the substantial amount of research on the first two challenges there is a lack of effort devoted to the problem of mining GARs with taxonomy evolution. Lin and Tseng (Lin & Tseng, 2004; Tseng et al., 2005b; Tseng et al., 2006) have considered this problem and some of its extensions, and proposed efficient Apriori-like algorithms.

MAIN FOCUS

System Framework for Mining Evolving GARs

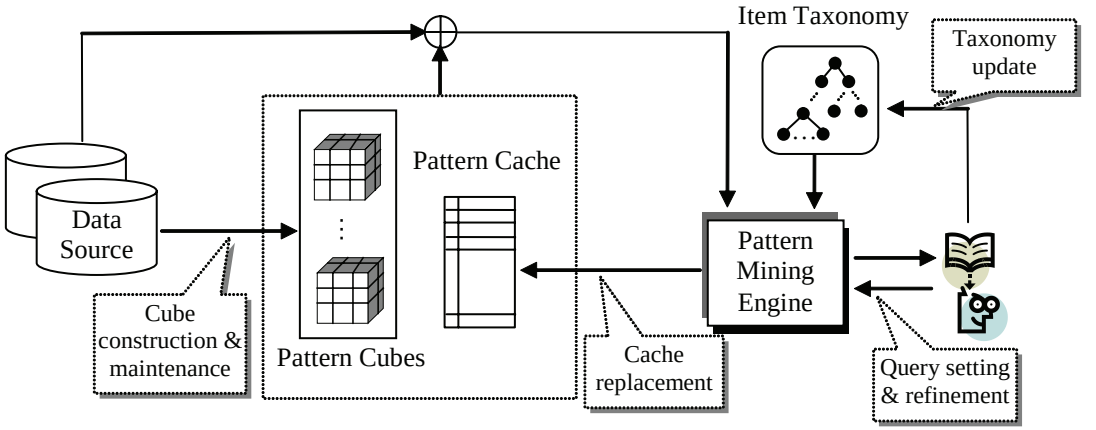
In light of the various considerations addressed in the previous section for mining GARs in an evolving environment, we conjecture that the best way is to integrate various techniques developed so far for dealing with only one or two aspects of the problem. Towards this goal, we propose a general framework, as depicted in Figure 2, which can accommodate all the state-of-the-art techniques to accomplish interactive mining of GARs in an evolving environment.

Essential to this framework is an efficient frequent pattern mining engine that can handle the most complicated situation when new transactions are added to the source data, along with the taxonomy being updated by the system administrator or the user, and as such the user should refine the mining query with a new support threshold. In what follows, we describe our proposed Apriori-based incremental mining algorithm.

Incremental Algorithm for Mining Generalized Frequent Itemsets

Consider the situation when new transactions, denoted as *db*, are added to a database *DB* and the taxonomy *T* is changed into a new one *T**. Let *ED** and *ed** denote the extended version of the original database *DB* and incremental database *db*, respectively, by adding the generalized items in *T** to each transaction. Further, let *UE** be the updated extended database containing *ED** and *ed**, i.e., *UE** = *ED** + *ed**. To update the set of frequent itemsets in *ED*, L^{ED}, when new transactions *db* are added to *DB*, *T* is changed into *T**, and the old minimum support (ms_{old}) is changed into the new one (ms_{new}), this problem is equivalent to finding the set of frequent itemsets in *UE** with respect to ms_{new}, denoted as L^{UE*}. Based on an Apriori-like framework, our algorithm employs a bottom-up search strategy, first discovering the set of all frequent 1-itemsets, and

Figure 2. General framework for GAR mining



proceeding towards the set of frequent itemsets with maximal cardinality *m*. Each pass for mining the frequent *k*-itemsets, for $1 \leq k \leq m$, involves the following main steps:

1. Generate candidate *k*-itemsets C_k.
2. Differentiate in C_k the affected itemsets (C_k^+) from the unaffected ones (C_k^-). Here the term affected itemsets refer to those itemsets whose support would be changed with respect to the taxonomy evolution.
3. Scan the incremental database *db* with the new taxonomy *T** to find frequent itemsets L_k^{ed*} with respect to the new support threshold ms_{new}.
4. Incorporate L_k^{ED}, L_k^{ed*}, C_k^+, C_k^-, ms_{old} and ms_{new} to determine whether a candidate itemset is frequent or not in the resulting database *UE**. Cases for the inference of frequent itemsets are shown in Table 1. Take case 5 for example: If *A* is an unaffected infrequent itemset in *ED* but is frequent in *ed**, then no matter whether $ms_{new} \leq ms_{old}$ or $ms_{new} > ms_{old}$, it is an undetermined itemset in *UE**.
5. Scan *DB* with *T**, i.e., *ED**, to count the supports of itemsets that are undetermined in Step 4.

Empirical Evaluation

To examine the performance of our algorithm, we conduct experiments to compare its performance with that of applying two leading generalized association mining algorithms, Cumulate and Stratify (Srikant & Agrawal, 1995), to the whole updated database with a new taxonomy under new support threshold. All experiments were performed on an Intel Pentium-IV 2.80GHz with 2GB RAM, running on Windows 2000. A synthetic dataset, generated by the IBM data generator (Agrawal & Srikant, 1994), with artifact taxonomy consisting of 5 groups of hierarchies with depth of 3 and average fanout of 5 is used in the experiments. The evaluations were examined from three aspects: the effect of varying minimum supports, that of varying incremental size and that of the degree of taxonomy evolution. All results showed that our algorithm is significantly faster than running Cumulate or Stratify from scratch.

FUTURE TRENDS

Since many current applications generate large volumes of data in a continuous and automated way, the problem of data stream mining has become an emerging issue (Babcock et al., 2002; Golab & Ozsu, 2003; Jin & Agrawal, 2007). The fast-changing and potentially infinite characteristics of stream data, however, make the problem of mining stream data very different from that of mining traditional transaction data. The most important difference is that "you can only look once", which implies that mining algorithms requiring more than a single pass of dataset scan are not applicable. In addition, memory limitation is always a significant concern. To the best of our knowledge, the taxonomy information and the effect of taxonomy evolution mining association rules over data streams has not yet been addressed in the literature.

Another promising avenue for future studies is the incorporation of domain knowledge other than tax-

Table 1. Cases for frequent candidate inference under incremental database update, minimum support refinement and taxonomy evolution

Conditions				Result	
$T \rightarrow T^*$	L^{ED} (ms_{old})	L^{ed*} (ms_{new})	ms_{new} vs ms_{old}	UE^* (ms_{new})	Case

			$\geq$	infreq.	2
affected	$\in, \notin$	$\in, \notin$	$\leq, >$	undetd.	7

onomy into the processing of association discovery. According to Storey (1993), the semantic relationships imposed on items in the real world can be classified into several categories, including possession, inclusion, attachment, attribution, antonyms, synonyms and case. Mining association rules incorporating such complex item relationships would be an interesting but very challenging issue.

CONCLUSION

In this chapter, we have investigated the problem of mining generalized association rules in an evolving environment and have surveyed state-of-the-art techniques for solving various aspects, including transaction update, threshold refinement, and taxonomy evolution of this problem. A general framework that can incorporate all of these techniques towards the interactive discovery of generalized association rules has been proposed. Of particular importance to the success of this system is an efficient algorithm that can incrementally update discovered frequent itemsets with respect to any kind of evolving aspects. Empirical studies have shown that the proposed algorithm is significantly faster than the simple strategy of re-mining frequent itemsets from scratch with the fastest algorithms.

KEY TERMS

Apriori-like Algorithm: A class of efficient association rule discovery algorithms that are characterized by candidate generation and pruning derived from the apriori property—an itemset can be frequent only if all of its subsets are frequent.

Association Rule: An implication rule that presents the co-occurrence of two set of items in a database. Two criteria, called support and confidence, are usually adopted to measure the quality of the rule.

Frequent Candidate Inference: A general approach aiming to determine in advance whether or not a candidate pattern is frequent according to some collected information. The purpose is to reduce unnecessary computation as well as database scanning.

Generalized Association Rule: An extension of plain association rule that presents the co-occurrence of two sets of items not only corresponding to primitive concepts in a taxonomy but also to those at higher abstraction levels.

Incremental Maintenance: A general data or knowledge maintenance strategy that refers to the process for updating previously discovered or computed knowledge without having to rebuild them as some database change occurs.

Interactive Data Mining: A human-computer collaboration knowledge discovery process that allows the user to interact with the mining system to view and discovered pattern from different perspectives by refining mining requests according to returned results.

Taxonomy: The process of naming and classifying things into groups within a larger system according to their similarities and differences.

Mining Generalized Web Data for Discovering Usage Patterns

INTRODUCTION

Web Usage Mining (WUM) includes all the Data Mining techniques used to analyze the behavior of a Web site's users (Cooley, Mobasher & Srivastava, 1999, Spiliopoulou, Faulstich & Winkler, 1999, Mobasher, Dai, Luo & Nakagawa, 2002). Based mainly on the data stored into the access log files, these methods allow the discovery of frequent behaviors. In particular, the extraction of sequential patterns (Agrawal, & Srikant, 1995) is well suited to the context of Web logs analysis, given the chronological nature of their records. On a Web portal, one could discover for example that "25% of the users navigated on the site in a particular order, by consulting first the homepage then the page with an article about the bird flu, then the Dow Jones index evolution to finally return on the homepage before consulting their personal e-mail as a subscriber". In theory, this analysis allows us to find frequent behaviors rather easily. However, reality shows that the diversity of the Web pages and behaviors makes this approach delicate. Indeed, it is often necessary to set minimum thresholds of frequency (i.e. minimum support) of about 1% or 2% before revealing these behaviors. Such low supports combined with significant characteristics of access log files (e.g. huge number of records) are generally the cause of failures or limitations for the existent techniques employed in Web usage analysis.

A solution for this problem consists in clustering the pages by topic, in the form of a taxonomy for example, in order to obtain a more general behavior. Considering again the previous example, one could have obtained: "70% of the users navigate on the Web site in a particular order, while consulting the home page then a page of news, then a page on financial indexes, then return on the homepage before consulting a service of communication offered by the Web portal". A page on the financial indexes can relate to the Dow Jones as well as the FTSE 100 or the NIKKEI (and in a similar way: the e-mail or the chat are services of communication, the bird flu belongs to the news section, etc.). Moreover, the fact of grouping these pages under the "financial indexes" term has a direct impact by increasing the support of such behaviors and thus their readability, their relevance and significance.

The drawback of using a taxonomy comes from the time and energy necessary to its definition and maintenance. In this chapter, we propose solutions to facilitate (or guide as much as possible) the automatic creation of this taxonomy allowing a WUM process to return more effective and relevant results. These solutions include a prior clustering of the pages depending on the way they are reached by the users. We will show the relevance of our approach in terms of efficiency and effectiveness when extracting the results.

BACKGROUND

The structure of a log file is formally described in Definition 7 (at the end of this chapter). This data structure can be easily transformed to the one used by sequential pattern mining algorithms. A record in a log file contains, among other data, the client IP, the date and time of the request, and the Web resource requested. To extract frequent behaviors from such a log file, for each user session in the log file, we first have to: transform the ID-Session into a client number (ID), the date and time into a time number, and the URL into an item number. Table 1 gives a file example obtained after that pre-

Table 1. File obtained after a pre-processing step

Client \ Date	d1	d2	d3	d4	d5
1	a	c	d	b	c
2	a	c	b	f	c
3	a	g	c	b	c

processing. To each client corresponds a series of times and the URL requested by the client at each time. For instance, the client 2 requested the URL "f" at time *d4*. The goal is thus, according to definition 2 and by means of a data mining step, to find the sequential patterns in the file that can be considered as frequent. The result may be, for instance, *<(a)(c)(b)(c)>* (with the file illustrated in table 1 and a minimum support given by the user: 100%). Such a result, once mapped back into URLs, strengthens the discovery of a frequent behavior, common to *n* users (with *n* the threshold given for the data mining process) and also gives the sequence of events composing that behavior.

The main interest in employing sequential patterns for Web usage mining aims at taking into account the time-dimension of the data as in the papers described thereafter.

The WUM tool (Web Utilisation Miner) proposed in (Spiliopoulou, Faulstich & Winkler, 1999) allows the discovery of navigation patterns which are interesting either from the statistical point of view or through their structure. The extraction of sequential patterns proposed by WUM is based on the frequency of the patterns considered.

Unfortunately, the amount of data (in terms of different items—pages—as well as sequences) is an issue for the techniques of sequential pattern mining. The solution would consist in lowering the minimum support used, but in this case the algorithms are not able to succeed. A proposal for solving this issue was made by the authors of (Masseglia, Tanasa & Trousse, 2004), who were interested in extracting sequential patterns with low support on the basis that high values for the minimum support often generate obvious patterns. The authors proposed to divide the problem in a recursive way in order to proceed to a phase of data mining on each sub-problem.

Another solution is to reduce the number of items by using a generalization of URLs. In (Fu, Sandhu & Shih, 2000) the authors use a syntactic generalization of URLs with a different type of analysis (clustering). Before applying a clustering, the syntactic topics of a level greater than two are replaced by their syntactic topics of a lower level.

Finally, there are other methods (Srikant & Agrawal, 1996) that can be used to extract sequential patterns by taking into account a generalization, but in other domain than the Web. Nevertheless, the automatic construction of generalizations (in the form of classes) of Web pages and for the purposes of a Web usage analysis was not studied yet. We propose in the following section such a method which is based on characteristics of Web usage data.

GWUM: MOTIVATIONS AND GENERAL PRINCIPLE

We present here our main motivations and the way we perform an usage-driven generalization of Web pages. As we mentioned in the introduction, the generalization of the items is a key factor during the extraction of sequential patterns. To understand the advantage of our work compared to a classical technique of sequential pattern mining, we propose the following example.

Let us consider the recordings from INRIA Sophia-Antipolis' Web access log (in the preprocessed form) as illustrated in Table 2. We can see there that the user C1 at date D1 made a request for the URL "homepage_DT" which is Doru Tanasa's homepage, then at date D2 he made a request for the publications page of Doru Tanasa and, finally, a request for INRIA's homepage. Similarly, user C2 made a request for Sergiu Chelcea's homepage at Date D1, and so on.

When extracting sequential patterns with a minimum support of 100%, no patterns will be found in this log (there is no item supported by 100% of the sequences). To find a frequent pattern, it will be necessary to lower the minimum support down to 50%, which allows the extraction of the following behaviors:

Table 2. Accesses to the Web site grouped by client (User)

Date / Client	D1	D2	D3
C1	homepage_DT	publications_DT	homepage_Inria
C2	homepage_SC	publications_SC	logiciels_AxIS
C3	homepage_DT	publications_AxIS	publications_DT
C4	homepage_AxIS	homepage_SC	publications_SC

1. < (homepage_DT) (publications_DT) > (supported by C1 and C3)
2. <(homepage_SC)(publications_SC)>(supported by C2 and C4)

On the other hand lowering the support:

1. Slows or even does not allow the mining algorithm to finish.
2. Discovers more general results, difficult to interpret because of their significant number and similarities (or redundancy).

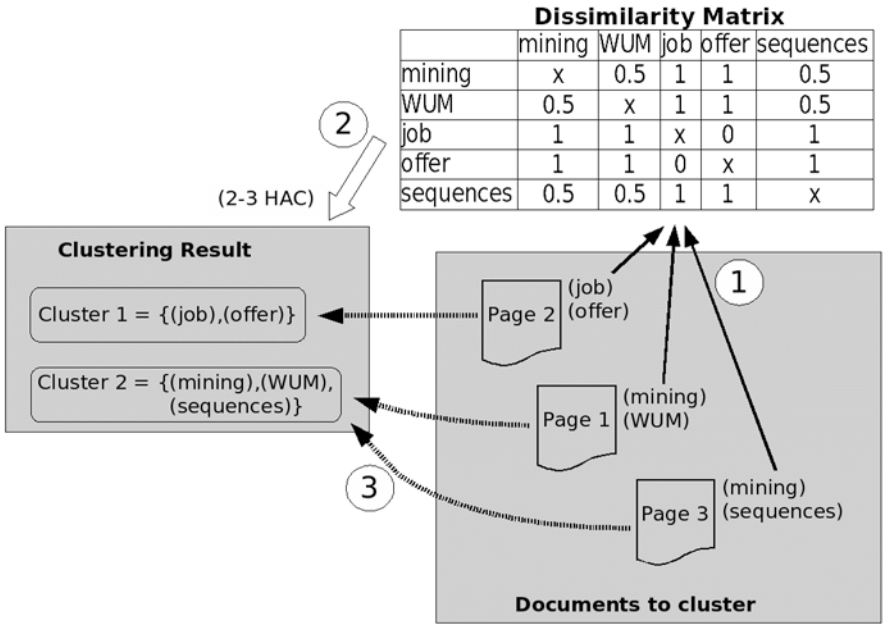
Suppose now that we are able to classify the URLs of this log in various categories. For example the category "*Pub*" would contain the pages with the researchers' publications (in our case: "publications_DT" and "publications_SC"). The category "*Mining*" would contain the pages relative to data mining (in our case, the homepages of Doru Tanasa and Sergiu Chelcea who are working on this topic). With such a classification, we would be able to extract a pattern with a support from 100% which would be: < (Mining) (Pub) >. The interpretation of this pattern is that 100% of the users consult a page about data mining and then a page of publications. We can indeed verify this behavior on the records from Table 2.

To perform a Web page generalization, we first propose to extract the information about the users' access to these pages (from the referer field). We are interested by the keywords that the user employed to search for the page. Therefore, we employ the referer of an HTTP request only when this one contains a request made to a search engine and then, we extract the keywords from the referer.

The objective is to obtain a clustering of the pages guided by their usages. Indeed, we consider that keywords which are frequently employed in a search engine to reach a page, can be used to characterize this page. For example, if the Web page of Doru Tanasa is frequently accessed with the keywords "Data Mining" and "WUM", and the Web page of Florent Masseglia with the keywords "Data Mining" and "Sequential Patterns", then it would be logical to create a category of pages "Data Mining" which would contain these two Web pages. Consequently, this means that, according to users' who reached these pages following a request on a search engine, these pages relate to "Data Mining".

The procedure that we set up for clustering the Web pages is described in Figure 1. Ideally, we should have built a matrix of dissimilarities for URLs and carry out directly a classification on it. Unfortunately, in our experiments, the high dimensionality of the data did not allow us to proceed this way. In fact, we obtained 62 721 distinct URLs, described by a total of 35 367 keywords and the matrix would have reached the size of 62 721 x 35 367 (2.2×10^9).

Figure 1. Web pages clustering based on their usage



Therefore, we chose to first classify the keywords (stage 2 in Figure 1). For that, we propose to build the matrix of distances between the keywords (stage 1 of Figure 1). The distance between two keywords *a* and *b* (i.e. *Dist(a, b)*) is given by the following formula (Jaccard's index of dissimilarity):

$$Dist(a,b) = \frac{P_{ab}}{P_a + P_b - P_{ab}}$$

where P_x is the distinct number of URLs having been reached using the keyword *x* and P_{xy} is the distinct number of URLs having been reached using the keywords *x* and *y*. The distance varies from 0 (no common page for the keywords) to 1 (same accesses for the two keywords). Once this matrix is built, we carry out the classification of the keywords, using an hierarchical clustering algorithm, the 2-3HAC (Chelcea, Bertrand & Trousse, 2003) (stage 2, in Figure 1).

Let *C* be the set of clusters for the keywords and *U* the set of URLs. The last stage consists in assigning each URL from *U* in one cluster from *C* by applying the following heuristic (stage 3 in Figure 1):

$$\forall u \in U, \forall c \in C, \forall d \in C, \ \text{if} \ \frac{words(u,c)}{|c|} \geq \frac{words(u,d)}{|d|} \ \text{then} \ c \leftarrow u$$

where *words(u, c)* is the number of keywords shared by *u* and *c*. This procedure allows assigning the pages to the clusters containing the words that describe them best. The keywords assigned to this cluster are used for its description. During our experiments, we obtained, for example, the following clusters:

- Cluster (*log,mining*), which includes for instance:
  - http://www-sop.inria.fr/axis/personnel/Florent.Masseglia/
  - http://www-sop.inria.fr/axis/personnel/Doru.Tanasa/papers/
- Cluster (*Internet,audio*), which includes for instance:
  - http://www-sop.inria.fr/rodeo/fphone/
  - http://www-sop.inria.fr/interne/accueil/audioconference.shtml

The first cluster contains pages about the following topic: data mining applied to Web access logs. The second one contains pages about the audio communications via Internet. The final step of our method now consists in replacing the URLs with their categories (when available) in the log file that will be analyzed.

EXPERIMENTS

GWUM (Generalized Web Usage Mining) is implemented in Java and is based on the PSP algorithm (Masseglia, Cathala & Poncelet, 1998). The experiments were carried out with the Web access logs of INRIA Sophia Antipolis Web site (www-sop.inria.fr) gathered in one month (October 2005). The data file has been preprocessed with the techniques described in (Tanasa & Trousse, 2004). It contains 258 061 navigations (i.e. user visits to the Web site) and 845 208 requests. The average length of navigations is 3.3 pages and there are 114 238 navigations with a length greater than 1.

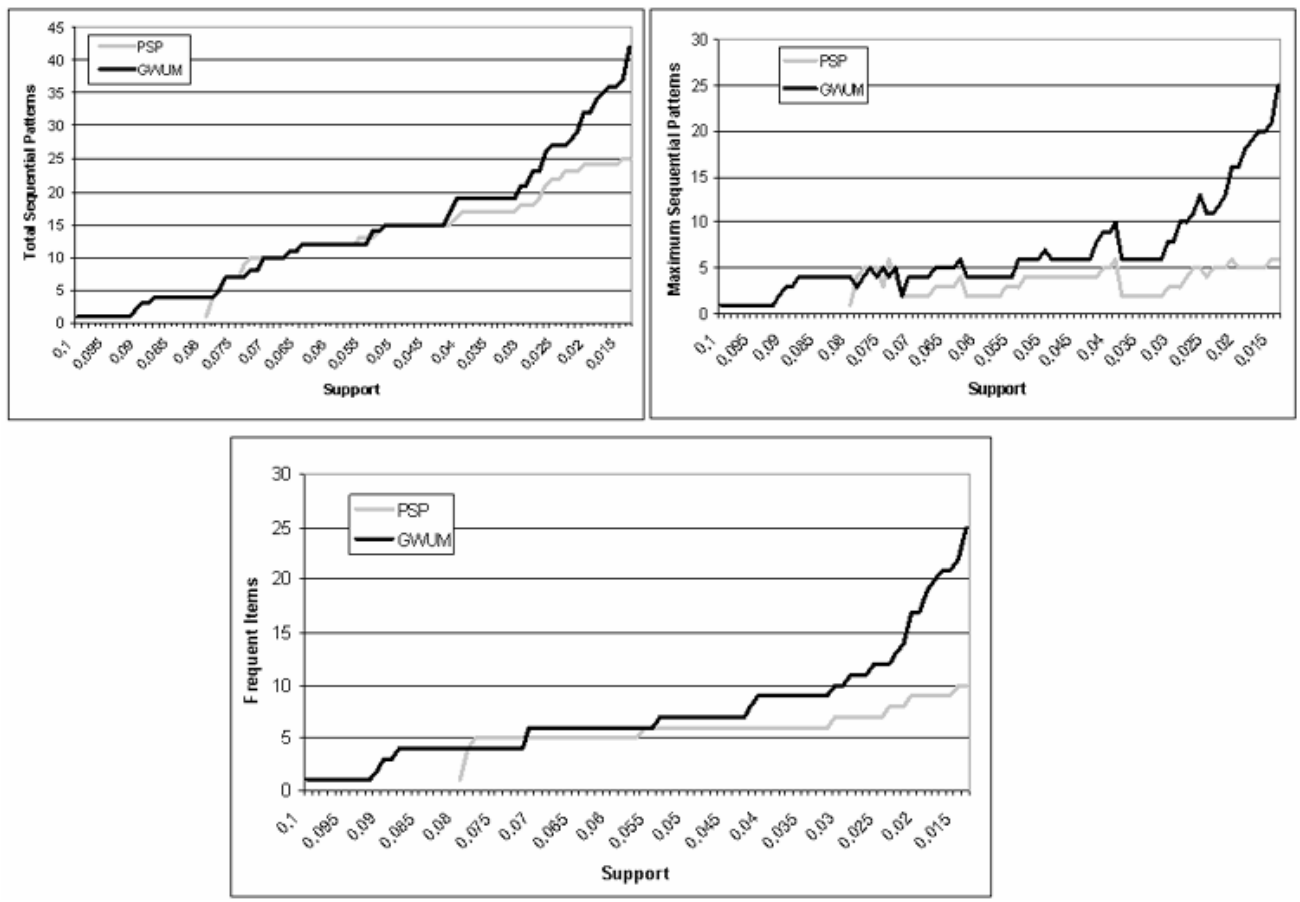
Data Preprocessing

We noticed that 164 685 requests (19.5% out of the total 845 208) were reached following a query in a search engine. From these requests we extracted 35 367 different keywords. We selected only the keywords having served for reaching at least 8 different pages. Thus, we reduced the vocabulary to 2 800 different roots of words (keywords) having been used in search engines to reach 14 264 different Web pages. We clustered the 2 800 keywords in 1 517 classes which were then utilized to classify the 14 264 URLs. For our experiments we selected only the navigations of a length higher than 1 (i.e. 114 238 navigations) together with a second dataset of generalized navigations (where the generalized URLs were replaced by their classes).

GWUM Effects on the Number of Sequential Patterns

The objective of this section is to show the benefit of our Web page generalization approach for a WUM process in terms of minimum support and number of sequential patterns extracted. Our goal is to prove that the minimum support can be increased through a generalization of URLs. Figure 2 gives the number of patterns extracted with (GWUM) and without (PSP) URLs Generalization.

Figure 2. Impact of the Generalization on the Minimum Support



The upper left part includes maximal and non-maximal patterns (without pruning). We can observe there, for example, that for the initial value of a minimum support fixed at 10%, the number of generalized patterns found was 2 whereas no patterns based on URLs only were found. In order to find the first two patterns in the URLs only dataset, it was necessary to decrease the minimum support to 7.5%. For the same minimum support, we found 4 generalized patterns using GWUM. The upper right part of Figure 2 gives the same comparison in terms of maximal patterns. From the chart, one can see that starting from a minimum support of approximately 3% the number of maximal patterns obtained is significantly higher for the generalized sequential patterns. For example, with a minimum support of 1%, the number of sequential patterns found by GWUM is 25 while PSP found only 6. Finally, in the down chart of Figure 2 we report the number of items extracted with and without URL generalization.

Example of Discovered Sequential Patterns

Throughout our experiments, we learned that most of the patterns discovered with GWUM contained classes of URLs. To illustrate the potential of our method in terms of results interpretation, but also to illustrate its impact on the minimum support, we give, in this section, one of the numerous results obtained. It arises in the following form:

< (c,code,programme,source) (software,free) >. This pattern represents the behavior of users that consulted a page about to the source code of programs written with the ***C*** language. Its support is of 0.2%. We found several possible variations for this behavior in the initial log file (without URL generalization):

1. <(www-sop.inria.fr/mimosa/fp/Bigloo/) (www-sop.inria.fr/mimosa/fp/Bigloo/doc/bigloo.

html)>. Indeed, the first page of this pattern belongs to the class (*C,code,program,source*) and the second page belongs to the class (*software,free*). Moreover, by examining these pages on the Web site, we saw that this membership was justified by the content of the pages. The support of this behavior is 0.13%.

2. <(www-sop.inria.fr/oasis/ProActive/home.html) (www-sop.inria.fr/oasis/proactive/(...)/C3DRenderingEngine.java.html})> with a support of 0.0026%.
3. And 84 patterns similar to the previous ones with a support close to zero, but whose accumulation in the classes (*C,code,program,source*) and (*software,free*) increases the support of the generalized pattern. However, none of these variations would have been found directly by using as minimum support the value of their generalized pattern's support, which emphasizes the benefit of our approach.

CONCLUSION

In this chapter, we describe an original method for Web usage analysis based on a user-driven generalization of Web pages. The information extracted for these pages, for the clustering purpose, regards the users' access to the pages. The information is obtained from the referer field of the Web access logs when the user employed a search engine to find the page. The experiment that we carried out illustrates our methodology and shows some of the benefits obtained with such an approach in the discovery of frequent sequential patterns. These benefits consist in obtaining generalized patterns with a higher support and easier to interpret. Our next objective is to explore other criteria allowing a better and more precise generalization of the Web pages. We also envisage to integrate multiple categories within the same process used for extracting sequential patterns. This will allow us to obtain patterns presenting simultaneously several categories.

ACKNOWLEDGMENT

The authors would like to thank Sergiu Chelcea and Sofiane Sellah for their support.

DEFINITIONS

Definitions 1-3: Sequence, Data-Sequence and Subsequence.

Let $I=\{i_1, i_2, ...,i_m\}$, be a set of m literals (*items*). I is a *k-itemset* where k is the number of items in I. A **sequence** is an ordered list of itemsets denoted by $<s_1 s_2 \dots s_n>$ where s_j is an itemset. The **data-sequence** of a customer c is the sequence in D corresponding to customer c. A sequence $<a_1 a_2 \dots a_n>$ is a **subsequence** of another sequence $<b_1 b_2 \dots b_m>$ if there exist integers $i_1 < i_2 < \dots < i_n$ such that $a_1 \subseteq b_{i1}$, $a_2 \subseteq b_{i2}$, …, $a_n \subseteq b_{in}$.

Example 1. Let C be a client and $S=<(c) (d e) (h)>$, be that client's purchases. S means that "C bought item c, then he bought d and e at the same moment (i.e. in the same transaction) and finally bought item h".

Definitions 4-5: Support and Frequent Sequential Pattern.

The **support** of a sequence s, also called *supp(s)*, is defined as the fraction of total data-sequences that contain s. If $supp(s) \geq minsupp$, with a minimum support value *minsupp* given by the user, s is considered as a **frequent sequential pattern**.

Definition 6: Sequential Pattern Mining.

The problem of sequential pattern mining is to find all the frequent sequential patterns as stated in definition 2.

Definition 7: Log Entry.

A log entry describes a request made to the Web server, recorded in a chronological order into a Web server log file. For instance, in the Extended Common Log Format (ECLF), a log entry contains at least the following information:

The client's host name or its IP address,

The date and time of the request,

The operation type (GET, POST, HEAD, etc.),

The requested resource name,

The user agent (a string identifying the browser and the operating system used),

The Web access log line from Figure 3 shows that a user from the IP address 192.168.0.1, successfully requested the page /axis/people.shtml on October 3rd, 2006 at 14:05 PM. The user arrived on this page by selecting a link from the Web page http://www-sop.inria.fr/axis/ and used Microsoft Internet Explorer 6.0 to display the page. Finally the requests are sorted in ascending order of time for each couple (IP, user agent). The couple (IP, user agent) associated to the set of requests is called an user session and is given an ID-Session. For instance an user session

S12 = < (192.168.0.1, "Mozilla/4.0 …."), (['/axis/', Tue Oct 3 14:05:22] ['/axis/people.shtml', Tue Oct 3 14:05:59])> means that an user has requested URL '/axis' followed by URL '/axis/people.shtml' 37 seconds later.

Figure 3. Example of a Log Entry

```
192.168.0.1 - [03/Oct/2006:14:05:59 +0200] ``GET /axis/people.shtml HTTP/1.1'' ``Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.2; .NET CLR 1.1.4322)"
```

Mining Group Differences

INTRODUCTION

Finding differences among two or more groups is an important data-mining task. For example, a retailer might want to know what the different is in customer purchasing behaviors during a sale compared to a normal trading day. With this information, the retailer may gain insight into the effects of holding a sale and may factor that into future campaigns. Another possibility would be to investigate what is different about customers who have a loyalty card compared to those who don't. This could allow the retailer to better understand loyalty cardholders, to increase loyalty revenue, or to attempt to make the loyalty program more appealing to non-cardholders.

This article gives an overview of such group mining techniques. First, we discuss two data-mining methods designed specifically for this purpose—Emerging Patterns and Contrast Sets. We will discuss how these two methods relate and how other methods, such as exploratory rule discovery, can also be applied to this task.

Exploratory data-mining techniques, such as the techniques used to find group differences, potentially can result in a large number of models being presented to the user. As a result, filter mechanisms can be a useful way to automatically remove models that are unlikely to be of interest to the user. In this article, we will examine a number of such filter mechanisms that can be used to reduce the number of models with which the user is confronted.

BACKGROUND

There have been two main approaches to the group discovery problem from two different schools of thought. The first, Emerging Patterns, evolved as a classification method, while the second, Contrast Sets, grew as an exploratory method. The algorithms of both approaches are based on the Max-Miner rule discovery system (Bayardo Jr., 1998). Therefore, we will briefly describe rule discovery.

Rule discovery is the process of finding rules that best describe a dataset. A dataset is a collection of records in which each record contains one or more discrete attribute-value pairs (or items). A rule is simply a combination of conditions that, if true, can be used to predict an outcome. A hypothetical rule about consumer purchasing behaviors, for example, might be *IF buys_milk AND buys_cookies THEN buys_cream*.

Association rule discovery (Agrawal, Imielinski & Swami, 1993; Agrawal & Srikant, 1994) is a popular rule-discovery approach. In association rule mining, rules are sought specifically in the form of where the antecedent group of items (or *itemset*), A, implies the consequent itemset, *C*. An association rule is written $A \rightarrow C$s . Of particular interest are the rules where the probability of *C* is increased when the items in *A* also occur. Often association rule-mining systems restrict the consequent itemset to hold only one item as it reduces the complexity of finding the rules.

In association rule mining, we often are searching for rules that fulfill the requirement of a minimum support criteria, *minsup*, and a minimum confidence criteria, *minconf*. Where support is defined as the frequency with which *A* and *C* co-occur support($A \rightarrow C$) = frequency($A \cup C$) and confidence is defined as the frequency with which *A* and *C* co-occur, divided by the frequency with which *A* occurs throughout all the data

$$\text{confidence}(A \rightarrow C) = \frac{\text{support}(A \rightarrow C)}{\text{frequency}(A)}$$

The association rules discovered through this process then are sorted according to some user-specified interestingness measure before they are displayed to the user.

Another type of rule discovery is *k*-most interesting rule discovery (Webb, 2000). In contrast to the support-confidence framework, there is no minimum support or confidence requirement. Instead, *k*-most interesting rule discovery focuses on the discovery of up to *k* rules that maximize some user-specified interestingness measure.

MAIN THRUST

Emerging Patterns

Emerging Pattern analysis is applied to two or more datasets, where each dataset contains data relating to a different group. An Emerging Pattern is defined as an itemset whose support increases significantly from one group to another (Dong & Li, 1999). This support increase is represented by the growth rate—the ratio of support of an itemset in group 1 over that of group 2. The support of a group G is given y:

$$\text{supp}_G(X) = \frac{\text{count}_G(X)}{|G|}$$

The *GrowthRate*(X) is defined as 0 if $\text{supp}_1(X) = 0$ and $\text{supp}_2(X) = 0$; ∞ if $\text{supp}_1(X) = 0$ and $\text{supp}_2(X) \neq 0$; or else $\text{supp}_2(X)/\text{supp}_1(X)$. The special case where *GrowthRate*(X) = ∞ is called a Jumping Emerging Pattern, as it is said to have jumped from not occurring in one group to occurring in another group. This also can be thought of as an association rule having a confidence equaling 1.0.

Emerging Patterns are not presented to the user, as models are in the exploratory discovery framework. Rather, the Emerging Pattern discovery research has focused on using the mined Emerging Patterns for classification, similar to the goals of Liu et al. (1998, 2001). Emerging Pattern mining-based classification systems include CAEP (Dong, Zhang, Wong & Li, 1999), JEP-C (Li, Dong & Ramamohanarao, 2001), BCEP (Fan & Ramamohanarao, 2003), and DeEP (Li, Dong, Ramamohanarao & Wong, 2004). Since the Emerging Patterns are classification based, the focus is on classification accuracy. This means no filtering method is used, other than the infinite growth rate constraint used during discovery by some the classifiers (e.g., JEP-C and DeEP). This constraint discards any Emerging Pattern X for which *GrowthRate*(X) $\neq \infty$.

Contrast Sets

Contrast Sets (Bay & Pazzani, 1999, 2001) are similar to Emerging Patterns, in that they are also itemsets whose support differs significantly across datasets. However, the focus of Contrast Set research has been to develop an exploratory method for finding differences between one group and another that the user can utilize, rather than as a classification system focusing on prediction accuracy. To this end, they present filtering and pruning methods to ensure only the most interesting and optimal number rules are shown to the user, from what is potentially a large space of possible rules.

Contrast Sets are discovered using STUCCO, an algorithm that is based on the Max-Miner search algorithm (Bayardo Jr., 1998). Initially, only Contrast Sets are sought that have supports that are both significant and the difference large (i.e., the difference is greater than a user-defined parameter, *mindev*). Significant Contrast Sets (*cset*), therefore, are defined as those that meet the criteria:

$$P(cset \mid G_i) \neq P(cset \mid G_j)$$

Large Contrast Sets are those for which:

$$\text{support}(cset, G_i) - \text{support}(cset, G_j) \geq mindev$$

As Bay and Pazzani have noted, the user is likely to be overwhelmed by the number of results. Therefore, a filter method is applied to reduce the number of Contrast Sets presented to the user and to control the risk of type-1 error (i.e., the risk of reporting a Contrast Set when no difference exists). The filter method employed involves a chi-square test of statistical significance between the itemset on one group to that Contrast Set on the other group(s). A correction for multiple comparisons is applied that lowers the value of α as the size of the Contrast Set (number of attribute value pairs) increases.

Further pruning mechanisms also are used to filter Contrast Sets that are purely specializations of other more general Contrast Sets. This is done using another chi-square test of significance to test the difference between the parent Contrast Set and its specialization Contrast Set.

Mining Group Differences Using Rule Discovery

Webb, Butler, and Newlands (2003) studied how Contrast Sets relate to generic rule discovery approaches. They used the OPUS_AR algorithm-based Magnum Opus software to discover rules and to compare them to those discovered by the STUCCO algorithm.

OPUS_AR (Webb, 2000) is a rule-discovery algorithm based on the OPUS (Webb, 1995) efficient search technique, to which the Max-Miner algorithm is closely related. By limiting the consequent to a group variable, this rule discovery framework is able to be adapted for group discovery.

While STUCCO and Magnum Opus specify different support conditions in the discovery phase, their conditions were proven to be equivalent (Webb et al., 2003). Further investigation found that the key difference between the two techniques was the filtering technique. Magnum Opus uses a binomial sign test to filter spurious rules, while STUCCO uses a chi-square test. STUCCO attempts to control the risk of type-1 error by applying a correction for multiple comparisons. However, such a correction, when given a large number of tests, will reᵃ uce the value to an extremely low number, meaning that the risk of type-2 error (i.e., the risk of not accepting a non-spurious rule) is substantially increased. Magnum Opus does not apply such corrections so as not to increase the risk of type-2 error.

While a chi-square approach is likely to be better suited to Contrast Set discovery, the correction for multiple comparisons, combined with STUCCO's minimum difference, is a much stricter filter than that employed by Magnum Opus. As a result of Magnum Opus' much more lenient filter mechanisms, many more rules are being presented to the end user. After finding that the main difference between the systems was their control of type-1 and type-2 errors via differing statistical test methods, Webb, et al. (2003) concluded that Contrast Set mining is, in fact, a special case of the rule discovery task.

Experience has shown that filters are important for removing spurious rules, but it is not obvious which of the filtering methods used by systems like Magnum Opus and STUCCO is better suited to the group discovery task. Given the apparent tradeoff between type-1 and type-2 error in these data-mining systems, recent developments (Webb, 2003) have focused on a new filter method to avoid introducing type-1 and type-2 errors. This approach divides the dataset into exploratory and holdout sets. Like the training and test set method of statistically evaluating a model within the classification framework, one set is used for learning (the exploratory set) and the other is used for evaluating the models (the holdout set). A statistical test then is used for the filtering of spurious rules, and it is statistically sound, since the statistical tests are applied using a different set. A key difference between the traditional training and test set methodology of the classification framework and the new holdout technique is that many models are being evaluated in the exploratory framework rather than only one model in the classification framework. We envisage the holdout technique will be one area of future research, as it is adapted by exploratory data-mining techniques as a statistically sound filter method.

Case Study

In order to evaluate STUCCO and the more lenient Magnum Opus filter mechanisms, Webb, Butler, and Newlands (2003) conducted a study with a retailer to find interesting patterns between transactions from two different days. This data was traditional market-basket transactional data, containing the purchasing behaviors of customers across the many departments. Magnum Opus was used with the group, encoded as a variable and the consequent restricted to that variable only.

In this experiment, Magnum Opus discovered all of the Contrast Sets that STUCCO found, and more. This is indicative of the more lenient filtering method of Magnum Opus. It was also interesting that, while all of the Contrast Sets discovered by STUCCO were only of size 1, Magnum Opus discovered conjunctions of sizes up to three department codes.

This information was presented to the retail marketing manager in the form of a survey. For each rule, the manager was asked if the rule was surprising and if it was potentially useful to the organization. For ease of understanding, the information was transformed into a plain text statement.

The domain expert judged a greater percentage of the Magnum Opus rules of surprise than the STUCCO contrasts; however, the result was not statistically significant. The percentage of rules found that potentially were useful were similar for both systems. In this case, Magnum Opus probably found some rules that were

spurious, and STUCCO probably failed to discover some rules that were potentially interesting.

FUTURE TRENDS

Mining differences among groups will continue to grow as an important research area. One area likely to be of future interest is improving filter mechanisms. Experience has shown that the use of filter is important, as it reduces the number of rules, thus avoiding overwhelming the user. There is a need to develop alternative filters as well as to determine which filters are best suited to different types of problems.

An interestingness measure is a user-generated specification of what makes a rule potentially interesting. Interestingness measures are another important issue, because they attempt to reflect the user's interest in a model during the discovery phase. Therefore, the development of new interestingness measures and determination of their appropriateness for different tasks are both expected to be areas of future study.

Finally, while the methods discussed in this article focus on discrete attribute-value data, it is likely that there will be future research on how group mining can utilize quantitative, structural, and sequence data. For example, group mining of sequence data could be used to investigate what is different about the sequence of events between fraudulent and non-fraudulent credit card transactions.

CONCLUSION

We have presented an overview of techniques for mining differences among groups, discussing Emerging Pattern discovery, Contrast Set discovery, and association rule discovery approaches. Emerging Patterns are useful in a classification system where prediction accuracy is the focus but are not designed for presenting the group differences to the user and thus don't have any filters.

Exploratory data mining can result in a large number of rules. Contrast Set discovery is an exploratory technique that includes mechanisms to filter spurious rules, thus reducing the number of rules presented to the user. By forcing the consequent to be the group variable during rule discovery, generic rule discovery software like Magnum Opus can be used to discover group differences. The number of differences reported to the user by STUCCO and Magnum Opus are related to the different filter mechanisms for controlling the output of potentially spurious rules. Magnum Opus uses a more lenient filter than STUCCO and thus presents more rules to the user. A new method, the holdout technique, will be an improvement over other filter methods, since the technique is statistically sound.

KEY TERMS

Association Rule: A rule relating two itemsets—the antecedent and the consequent. The rule indicates that the presence of the antecedent implies that the consequent is more probable in the data. Written as $A \rightarrow C$.

Contrast Set: Similar to an Emerging Pattern, it is also an itemset whose support differs across groups. The main difference is the method's application as an exploratory technique rather than as a classification one.

Emerging Pattern: An itemset that occurs significantly more frequently in one group than another. Utilized as a classification method by several algorithms.

Filter Technique: Any technique for reducing the number of models with the aim of avoiding overwhelming the user.

Growth Rate: The ratio of the proportion of data covered by the Emerging Pattern in one group over the proportion of the data it covers in another group.

Holdout Technique: A filter technique that splits the data into exploratory and holdout sets. Rules discovered from the exploratory set then can be evaluated against the holdout set using statistical tests.

Itemset: A conjunction of items (attribute-value pairs (e.g., *age = teen* $\wedge$ *hair = brown*).

k-Most Interesting Rule Discovery: The process of finding *k* rules that optimize some interestingness measure. Minimum support and/or confidence constraints are not used.

Market Basket: An itemset; this term is sometimes used in the retail data-mining context, where the itemsets are collections of products that are purchased in a single transaction.

Rule Discovery: The process of finding rules that then can be used to predict some outcome (e.g., *IF 13 <= age <= 19 THEN teenager*).

Mining Repetitive Patterns in Multimedia Data

Junsong Yuan
Northwestern University, USA

Ying Wu
Northwestern University, USA

INTRODUCTION

One of the focused themes in data mining research is to discover frequent and repetitive patterns from the data. The success of frequent pattern mining (Han, Cheng, Xin, & Yan, 2007) in structured data (e.g., transaction data) and semi-structured data (e.g., text) has recently aroused our curiosity in applying them to multimedia data. Given a collection of unlabeled images, videos or audios, the objective of repetitive pattern discovery is to find (if there is any) similar patterns that appear repetitively in the whole dataset. Discovering such repetitive patterns in multimedia data brings in interesting new problems in data mining research. It also provides opportunities in solving traditional tasks in multimedia research, including visual similarity matching (Boiman & Irani, 2006), visual object retrieval (Sivic & Zisserman, 2004; Philbin, Chum, Isard, Sivic & Zisserman, 2007), categorization (Grauman & Darrell, 2006), recognition (Quack, Ferrari, Leibe & Gool, 2007; Amores, Sebe, & Radeva, 2007), as well as audio object search and indexing (Herley, 2006).

- In image mining, frequent or repetitive patterns can be similar image texture regions, a specific visual object, or a category of objects. These repetitive patterns appear in a sub-collection of the images (Hong & Huang, 2004; Tan & Ngo, 2005; Yuan & Wu, 2007, Yuan, Wu & Yang, 2007; Yuan, Li, Fu, Wu & Huang, 2007).
- In video mining, repetitive patterns can be repetitive short video clips (*e.g.* commercials) or temporal visual events that happen frequently in the given videos (Wang, Liu & Yang, 2005; Xie, Kennedy, Chang, Divakaran, Sun, & Lin, 2004; Yang, Xue, & Tian, 2005; Yuan, Wang, Meng, Wu & Li, 2007).
- In audio mining, repetitive patterns can be repeated structures appearing in music (Lartillot, 2005) or broadcast audio (Herley, 2006).

Repetitive pattern discovery is a challenging problem because we do not have any *a prior* knowledge of the possible repetitive patterns. For example, it is generally unknown in advance (i) what the repetitive patterns look like (e.g. shape and appearance of the repetitive object/contents of the repetitive clip); (ii) where (location) and how large (scale of the repetitive object or length of the repetitive clip) they are; (iii) how many repetitive patterns in total and how many instances each repetitive pattern has; or even (iv) whether such repetitive patterns exist at all. An exhaustive solution needs to search through all possible pattern sizes and locations, thus is extremely computationally demanding, if not impossible.

BACKGROUND

As a purely unsupervised task, repetitive pattern discovery is different from traditional pattern detection/retrieval problem, where a pattern template or a query example is provided and the task is to find its re-occurrences (Divakara, Peker, Chang, Radhakrishnan, & Xie, 2004). When mining repetitive patterns, we have no *a prior* knowledge of the pattern. Therefore, it differs from supervised learning problems (*e.g.* classification and retrieval) that have been widely studied in machine learning research.

Repetitive pattern discovery is also different from unsupervised tasks like clustering. The task of clustering is to partition a collection of data samples into several disjoint groups, where data samples belonging to the same group are similar to each other, whereas data samples from different groups are dissimilar. Instead of clustering individual data samples, pattern discovery aims at repetitive patterns that are shared by some data samples. Such a repetitive pattern describes the common characteristics among the data. For example, given an image dataset, a repetitive pattern can be a sub-image region (e.g. a visual object) that appears in

many images. Thus the repetitive pattern corresponds to an image region while not the whole image.

MAIN FOCUS

Multimedia data mining is different from transaction and text data mining mainly in two aspects. Firstly, transaction and text data are discrete data, for example, transactions are composed of items and texts are composed of vocabularies. However, multimedia data are usually characterized by continuous features and these features generally exhibit much larger variabilities and uncertainties than predefined items and vocabularies. Taking the visual pattern in image data for example, the same visual pattern (e.g. a visual object) is likely to exhibit quite different visual appearances under different lighting conditions, views, scales, not to mention partial occlusion. As a result, it is very difficult find invariant visual features that are insensitive to these variations to uniquely characterize visual patterns.

Another characteristic of multimedia data mining, besides the features uncertainties, is that multimedia patterns have more complex structure than transaction and text patterns. For example, the spatial configuration is important in characterizing an image pattern. Therefore, when discovering repetitive patterns from images, the difficulty of representing and discovering spatial patterns prevents straightforward generalization of traditional frequent pattern mining methods that are applicable to transaction data, which are orderless sets of items, or text data, which are represented by strings of words. Although there exist methods for spatial collocation pattern discovery from geo-spatial data (Huang, Shekhar, & Xiong, 2004), they cannot be directly applied to image data which are characterized by high-dimensional continuous features. Similarly, when mining audio and video data, we should take the temporal structure into consideration, as the repetitive patterns are usually temporal sequences.

The main focus of repetitive pattern discovery in multimedia data mining is to develop methods that address the aforementioned two challenges. In the following, we summarize three major components of repetitive pattern discovery in multimedia data: (1) pattern representation, (2) pattern matching and (3) pattern mining. We will discuss the specific challenges and the-state-of-the-art techniques in each component.

Pattern Representation

Pattern representation is important for general machine learning and data mining tasks. In multimedia data mining, it determines how we represent the image/video/audio data, typically in terms of features and data models. Data mining algorithms perform directly on the extracted features instead of the raw multimedia data. Due to the page limit, we do not list all possible features that can be extracted from the multimedia data. Instead, we discuss the requirements of the features for repetitive pattern discovery.

- For repetitive pattern discovery in image data, it is usually desirable that the extracted visual features are robust under different pattern variations like rotation, scale changes and even affine transformations. Recently, it is found that the "bag of features" representation is beneficial for pattern discovery because it can handle pattern variations as well as incomplete patterns. The basic visual features are local visual primitives detected from images (Philbin, Chum, Isard, Sivic & Zisserman, 2007; Quack, Ferrari, Leibe & Gool, 2007; Sivic & Zisserman, 2004; Yuan, Wu, & Yang, 2007). Each visual primitive describes an informative local image region and is expected to be invariant under the following variations. (Mikolajczyk, Tuytelaars, Schmid, Zisserman, Matas, Schaffalitzky, Kadir, & Gool, 2005).

1. **View point changes:** The same image pattern can look different under different view-points, depending on the capture angle of the camera.
2. **Scale changes:** The same image pattern can look smaller or larger, depending on the distance of the camera to the object, as well as the zoom in/out parameters of the camera.
3. **Lighting condition changes:** The appearances of a same image pattern may vary according to different lighting conditions at the capture.
4. **Partial Occlusions:** It is possible that a pattern (e.g. a repetitive object) is occluded in the image. Such an incomplete pattern, however, could still be of interests and want to be discovered.

5. **Intra-class variations:** When the goal of pattern discovery is to find objects of the same category, it is important that the features inherit the ability to handle intra-class variations. That is, the objects of the same category share similar features, while the objects of different categories do not.

- For repetitive pattern discovery in audio and video data, features are extracted based on video/audio frames or temporal windows. Usually features are desirable to be robust under various signal changes.

1. **Speed changes:** It is possible that the same temporal pattern may be played at different speeds due to frame rate changes or pattern variations.
2. **Codec changes:** It is possible the same contents are compressed into different format/quality after coding.
3. **Intra-class variations:** When the goal of pattern discovery is to find similar patterns of the same category, it is important that the feature inherit the ability to handle intra-class variations.

Pattern Matching

Pattern matching plays a critical role in multimedia data mining, as its accuracy and speed largely determine the quality of the data mining results as well as the efficiency of the data mining methods. Given two patterns, pattern matching determines whether they are similar or not. Therefore it can be applied to measure the repetition of a query pattern. In matching multimedia patterns, it is important to consider the spatial/spatial-temporal characteristics of the image/video data (Yuan & Wu, 2007). We discuss pattern matching methods for image and video/audio respectively.

- In image pattern discovery, to avoid handling high-dimensional features, many recent work tend to represent an image as a "bag of words" by quantizing high-dimensional visual features into "visual items" or "visual words" through clustering (*e.g.* k-means clustering). Therefore each image is translated to a visual document or a set of transaction records (Philbin, Chum, Isard, Sivic, & Zisserman, 2007; Quack, Ferrari, Leibe, & Gool, 2007; Sivic J. & Zisserman, 2004; Yuan, Wu, & Yang, 2007), with each transaction corresponding to a local image patch and describing its composition of visual primitive classes (items). Matching images is like matching documents/transactions, and data mining techniques can be applied to such an induced transaction database from images for discovering meaningful visual patterns.
- For the video/audio case, video frames (e.g. key frames) or video/audio temporal windows can be quantized into a discrete symbol and the whole video sequence becomes a symbolic string which is similar to a DNA sequence. Traditional sequence mining algorithm can thus be applied (Wang, Liu, & Yang, 2005). Although the quantization/clustering idea is popular in the literature, some recent work also argue that such representations discard information due to the invertible quantization errors from continuous visual features to discrete visual words. Therefore matching visual primitives in the original continuous domain is still preferred as it gives more accurate matching results (Philbin, Chum, Isard, Sivic & Zisserman, 2007; Yuan & Wu, 2007). Many methods performed directly on original continuous features, unfortunately, are *not* computationally efficient due to the cost of matching two sets of points in the high-dimensional space (Boiman & Irani, 2006; Hong & Huang, 2004; Tan & Ngo, 2005). To overcome the matching cost of image data, approximate matching methods of linear complexity are proposed (Grauman & Darrell, 2006; Yuan & Wu, 2007).

To speed up the pattern matching process, many efficient indexing and searching methods are applied, such as the inverted file index method (Sivic & Zisserman, 2004), locality sensitive hashing for approximate nearest neighbor search (Yuan, Li, Fu, Wu, & Huang, 2007), as well as fast similarity matching in the high-dimensional space (Grauman & Darrell, 2006; Yuan & Wu, 2007).

Pattern Mining

Although a repetitive pattern is easy to be evaluated, for example, we can determine whether a query pattern is repetitive by simply searching it through the whole dataset and counting the re-occurrences, it is

difficult to discover repetitive patterns automatically. Generally, pattern mining is of high computational cost, not only due to the large size of the database, but also because we have no *a prior* knowledge of the possible repetitive patterns. One advantage of the "bag of words" representation is that we can easily transfer the multimedia data into transaction data, thus efficient data mining algorithm like frequent itemset mining can be applied directly (Yuan, Wu & Yang, 2007). However, if continuous features are applied, due to the huge candidate number of repetitive patterns, efficient pruning strategies are required to avoid exhaustive search of repetitive patterns (Yuan, Li, Fu, Wu & Huang, 2007).

FUTURE TRENDS

By mining repetitive patterns in multimedia data, it will bring advantages in many tasks associated with multimedia database, such as content-based retrieval, indexing and visual object detection and categorization. We are looking forward to more applications of repetitive pattern discovery from multimedia data. At the same time, to handle real large database (*e.g.* image database of billions images), more efficient repetitive pattern discovery algorithm is required. Finally, interactive repetitive pattern discovery can be an interesting direction which takes consideration of the feedback from the users in order to improve the pattern mining results.

CONCLUSION

As an emerging research direction, repetitive pattern discovery provides opportunities in solving many existing problems in multimedia research. Compared with traditional data mining in transaction data, we need to handle the feature uncertainty and pattern complexity problems, which are challenges brought by the multimedia data.

There are three major components in mining repetitive patterns from multimedia data: pattern representation, pattern matching and pattern mining. As a cross-discipline research topic, it needs more efforts from multimedia database, data mining, machine learning, information retrieval, and computer vision. As a powerful data mining tool, the ultimate objective of repetitive pattern discovery in multimedia data is to help analyze, organize and retrieve the multimedia database more efficiently and accurately.

KEY TERMS

Frequent Itemset Mining (FIM): Data mining process for discovering itemsets that appear frequent enough from a large collection of transactions.

High-Dimensional Feature Space: An abstract vector space of high-dimension, typically above tens of dimensions. In pattern recognition, each pattern sample is represented as a point in the feature space. The number of dimensions is equal to the number of features.

Invertible Quantization Error: The inaccuracy introduced in the process of quantization, which depends on the resolution of the quantization and cannot be recovered after quantization.

Locality Sensitive Hashing (LSH): A fast approximate nearest neighbor search technique in the high-dimensional space through random projection.

Multimedia Data Mining: The process of discovering novel knowledge from multimedia data, such as images, audios and videos, which can help to analyze, organize and retrieve the multimedia database.

Nearest Neighbor Search: The process of finding nearest neighbors of a given query point in the feature space. Nearest neighbor search is useful in retrieval and classification.

Quantization: The process that approximates a continuous value/vector with a discrete value/symbol.

Scale of a Visual Pattern: The relative size/length of the pattern appearing in images/videos.

Transaction Data: A specific type of data, where each transaction is composed by a collection of discrete items. A typical example of transaction data is the market basket data, where each single transaction is composed by the collection of items purchased by the customer. Transaction data is popularly considered in data mining.

Visual Primitive: The elementary visual pattern. For images, it denotes informative local interesting points or regions. For audios and videos, it can be the basic unit, like a shot or a fixed-length window.

Mining Smart Card Data from an Urban Transit Network

Bruno Agard
École Polytechnique de Montréal, Canada

Catherine Morency
École Polytechnique de Montréal, Canada

Martin Trépanier
École Polytechnique de Montréal, Canada

INTRODUCTION

In large urban areas, smooth running public transit networks are key to viable development. Currently, economic and environmental issues are fueling the need for these networks to adequately serve travel demand, thereby increasing their competitiveness and their market share. Better balance between transit supply and demand will also help reduce and control operating costs.

The fact is, however, that transit operators are finding it extremely difficult to adjust the service to meet the demand, because this demand changes continuously with the time or day of travel (period of the day, day of the week, season or holiday) and other factors like weather and service breakdown. In order to enhance their service, operators need to better understand the travel demand (customer behaviors and the variability of the demand in space and time). This can be achieved only by continuously monitoring the day-to-day activities of users throughout the transit network.

Some large cities around the world take advantage of smart card capabilities to manage their transit networks by using Smart Card Automated Fare Collection Systems (SCAFCS). An SCAFCS gives travelers greater flexibility, since a single card may be used by one user at various times and on different parts of the transit network, and may support various fare possibilities (by travel, line, zone, period, etc.). For transit operators, these systems not only validate and collect fares, but also represent a rich source of continuous data regarding the use of their network. Actually, this continuous dataset (developed for fare collection) has the potential to provide new knowledge about transit use. Following the application of various pretreatments which make it possible to extract real-time activity, data mining techniques can reveal interesting patterns. These techniques are aimed at precisely describing customer behavior, identifying sets of customers with similar behaviors, and measuring the spatial and temporal variability of transit use. Patterns are extracted and analyzed to document various issues, such as identifying transit use cycles or homogeneous days and weeks of travel for various periods of the year. This information is required for a better understanding and modeling of customer behavior, and consequently better adjustment of the service to the demand. These adjustments may, for instance, lead to the restructuring of the transit network, to the adaptation of route scheduling or to the definition of new and different subscription options (fares).

Below, results from various experiments conducted with a real dataset are provided. They show the potential of data mining to provide useful and novel information about user behavior on a transit network. The data processed in the study are extracted from a system operating in a Canadian city (Gatineau, Quebec).

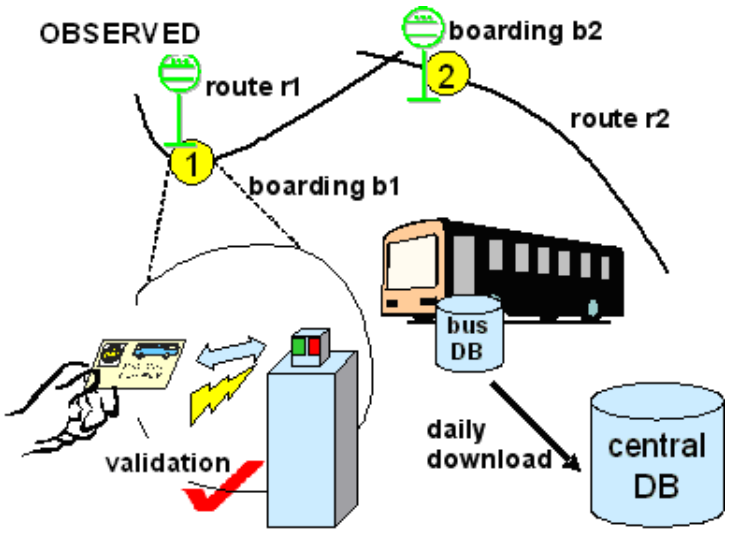
BACKGROUND

Smart Card in Public Transport

Generally, SCAFCS are composed of cards, onboard readers and a centralized information system (see Figure 1).

A smart card is simply an RFID device implanted in a transport card, and is similar to a typical credit card. Smart cards offer various advantages over traditional paper systems:

Figure 1. Smart card automated fare collection system (SCAFCS)



- Validation of the user transaction (boarding/transfer) is instantaneous and does not require any interaction with the driver.
- Complex fare systems (multiple zones, rates), common in large metropolitan areas where networks are integrated, can easily be managed.
- Elementary security procedures can be taken.
- Data are continuously collected, resulting in datasets much larger than those usually available to measure customer traffic; hence, a larger user proportion is observed.

These systems are being used increasingly frequently, since the software and hardware tools necessary to support their implementation are now stable and accessible, with a good quality of data output (Chira-Chavala and Coifman 1996, Meadowcroft 2005). Smart cards in transportation have mainly been implemented to simplify fare collection, but could also be used to advantage to monitor the service itself. In most cases, the adoption of a smart card system by transit authorities is related to their level of funding and the level of sophistication of their other technologies (Iseki et al. 2007, Yoh et al. 2006). Cheung (2006) demonstrated the overall benefits of smart card systems in The Netherlands, but it was Bagchi and White (2004, 2005) who were the first to substantiate this potential for transit planning. Using three case studies (British networks), they illustrate the ability of smart card data to estimate turnover rates, trip rates per card and the impacts of the use of smart cards on the number of linked trips. They also discuss the complementary nature of smart card data and other data collection methods, arguing that smart cards should not replace those methods. Utsunomiya et al. (2006) presented a study based on Chicago Transit Authority data for a one-week period involving about 500,000 boarding transactions. They reported difficulties associated with the data, especially missing transactions and incorrect bus routes.

Travel Behavior Variability

In practice, many transit planners use statistics from synthetic models, onboard travel surveys or regional travel surveys to describe how their networks are used. Average statistics are constructed, describing typical customer behaviors during a typical weekday. The underlying hypothesis that all weekdays are similar is

less well accepted. Actually, many studies validate the fact that travel behaviors vary a great deal in space and time. Some studies show the importance of understanding the variations in daily peak profiles to arriving at a better assessment of demand management schemes (Bonsall et al. 1984). Others illustrate the construction of detailed results by classifying travelers in terms of similar daily activity patterns (Jun and Goulias 1997). Garling and Axhausen (2003) talk about the habitual nature of travel. Metrics are available to evaluate any similarity between days of travel using a six-week travel diary (Schlich and Axhausen 2003), and others for the spatio-temporal variability (time-space prism) of day-to-day behaviors (Kitamura et al. 2006).

Not only is there agreement that variability needs to be assessed, but also that it is hard to measure, because the available data usually rely on a single day's record of each individual's travel. Bagchi and White (2004) have argued that a SCAFCS could improve these results because they provide access to larger sets of individual data. They also offer the possibility of linking user and transit card information. Hence, continuous data are available for long periods of time, which may lead to better knowledge of a large number of transit users.

More recent results have proved the ability of smart card data to measure the demand precisely and to understand its dynamics with a view to making day-to-day predictions (Morency et al. 2007). The methods developed will soon provide automatic survey tools which will help planners perform these tasks. However, trip-end analyses require the estimation of the destination of smart card trips. Trepanier et al. (2007) propose a destination estimation model with a success rate of about 80% at peak hours.

It is important to keep in mind that a transportation smart card belongs to an individual user, and that privacy rules must be respected (Clarke 2001, CNIL 2003).

MAIN FOCUS

The case study data used in our investigation were provided by the Société de transport de l'Outaouais (STO), a transit authority which manages a fleet of 200 buses in the Gatineau (Quebec) region of Canada (240,000 inhabitants). At this time (2007), about 80% of all STO passengers have a smart card, and every STO bus is equipped with a smart card reader and a GPS capturing device.

Data Collection Process

Figure 2 shows the general data flow of the smart card information system. Each time a smart cardholder boards a bus (step A), a transaction is recorded. The reader validates the smart card with the help of basic operational information, like the route number, the direction and the fare policy for this route. The current location is punched in at the same time (GPS reading). Every night, when the bus returns to the depot, all this data on transactions is uploaded to the database server, called the *Système d'Information et de Validation des Titres* (SIVT). At this point, the operational data for the next day are downloaded to the reader on the bus (step B).

The SIVT server collects data on both user and boarding (transactions), but keeps the information separate for privacy purposes. The SIVT server receives its operational data (routes, run assignments, stop list) from the STO's service operation information system (step C).

The SIVT exchanges data with the STO's accounting system on a continuous basis (step D). The accounting system is responsible for issuing and "recharging" individual smart cards.

In an SCAFCS, data are designed for fare collection and revenue management. Basic statistics, such as the number of users per line or per day, are easily extracted. The hypothesis driving the work reported here is that the data hold a great deal of other information about the overall system, and that it may provide interesting and relevant knowledge. That knowledge may be useful for helping planners better understand transit user behavior, leading to improved service.

The volume of data is perpetually growing, and this represents a considerable challenge in terms of knowledge extraction. In the present case, over a 10-month period, January 1st to October 4th, 2005, 27,033 smart cards were being used on the network, and nearly 6.2 millions transactions were validated. Trepanier and Chapleau (2001) developed an object model based on the Transportation Object-Oriented Modeling approach (Figure 3). The model shows strong links between network elements (routes, stops), operational data (drivers, vehicles, work pieces) and user data (cards, transactions, fares). There are up to 36 fare types at the STO, characterized by user status (student, adult, elderly) and network use privileges (regular, express and interzone routes).

Mining the Data

Here, we focus on the automatic extraction of user patterns on the transit network, using data mining tools. Data transformation and analysis are explained in detail. For a description of any of the data mining tools we mention, the reader may refer to the relevant chapters of the present encyclopedia.

Data Preprocessing

Each data refers to a specific spatial location and time. Every time a card is validated, a new line is created in the database. Since one card corresponds to one user, multiple lines can be created for each individual user. Each user may also have a different number of boardings, depending on his or her own activity.

Preprocessing operations have been conducted in such a way that every customer is represented on a fixed-length vector, in order to be able to extract user behavior in terms of temporal behavior. Depending on the accuracy of the analysis, two transformations are presented, both based on the same idea. In one, a day is made up of 24 periods (one hour each), and in the other a week is made up of 28 periods (4 periods per day, 7 days). Also included is a card ID and the day or week concerned (see Figure 4).

Group Behavior

Our analysis focuses on the way the individual users behave on the transit network, in terms of temporal activity. Different "groups" of users are identified. The number of groups depends on the level of granularity of interest in the study. An example, a split in 4 clusters with a k-mean, is presented in Figure 5.

Analysis of each cluster provides interesting information about the way the users who compose it use the transit network (temporal behavior). The following results are observed (see Figure 6, Agard et al. 2006): Cluster 1 represents 45.6% of the user weeks; Cluster 2: 14.8%; Cluster 3: 14.3%; and Cluster 4: 25.2%. Almost 60% of the cards from type "Adult" are in Cluster 1, while almost 80% of "Elderly" cards

Figure 4. Data transformation for the extraction of temporal user behavior

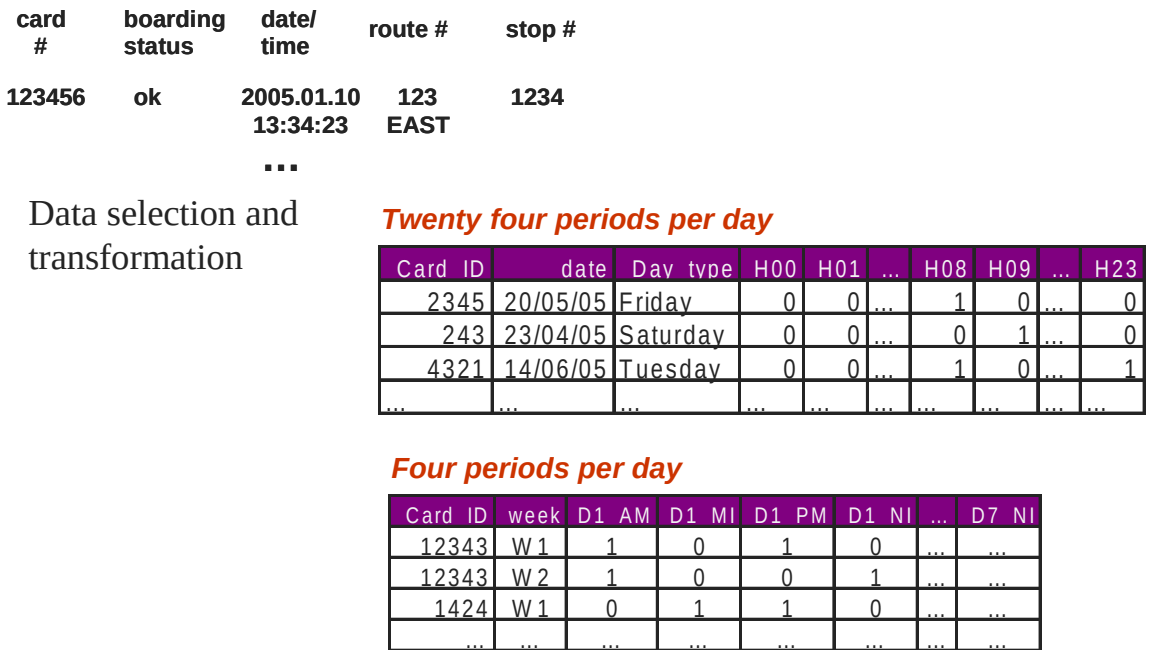

Figure 5. Decomposition into 4 clusters with a k-mean

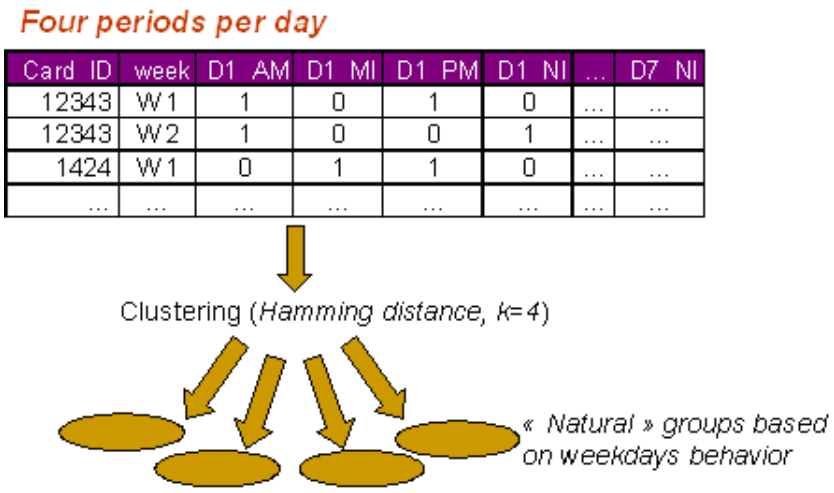

Figure 6. Composition of the clusters

Card type	Cl 1	Cl 2	Cl 3	Cl 4	TOT
Adult	58.8%	13.9%	9.2%	18.1%	100%
Student	21.0%	17.7%	26.4%	34.8%	100%
Elderly	6.2%	6.4%	7.9%	79.5%	100%

Card type	Cl 1	Cl 2	Cl 3	Cl 4
Adult	85.6%	62.4%	42.7%	47.7%
Student	13.9%	36.1%	55.4%	41.7%
Elderly	0.5%	1.4%	1.8%	10.6%
Total	100%	100%	100%	100%

are in Cluster 4. In contrast, Cluster 1 is composed of 85.6% of "Adults", Cluster 3 of 55.4% of "Students" and Cluster 4 of 10% of "Elderly".

Some results for the temporal behavior for each cluster (Agard et al. 2006) are summarized in Figure 7.

The users in Cluster 1 are typical workers, 79.4% of them traveling during the peak AM hours and 71.0% during the peak PM hours on weekdays. The users in Cluster 3 are the earlybirds, 77.6% of them traveling during the peak AM hours and 74.8% during the mid-day period. Clusters 2 and 4 show no clear patterns, but similar behavior may be observed from one weekday to another. However, Cluster 4 users are characterized by light use of the transit network.

Figure 7. Temporal behavior for clusters 1 to 4

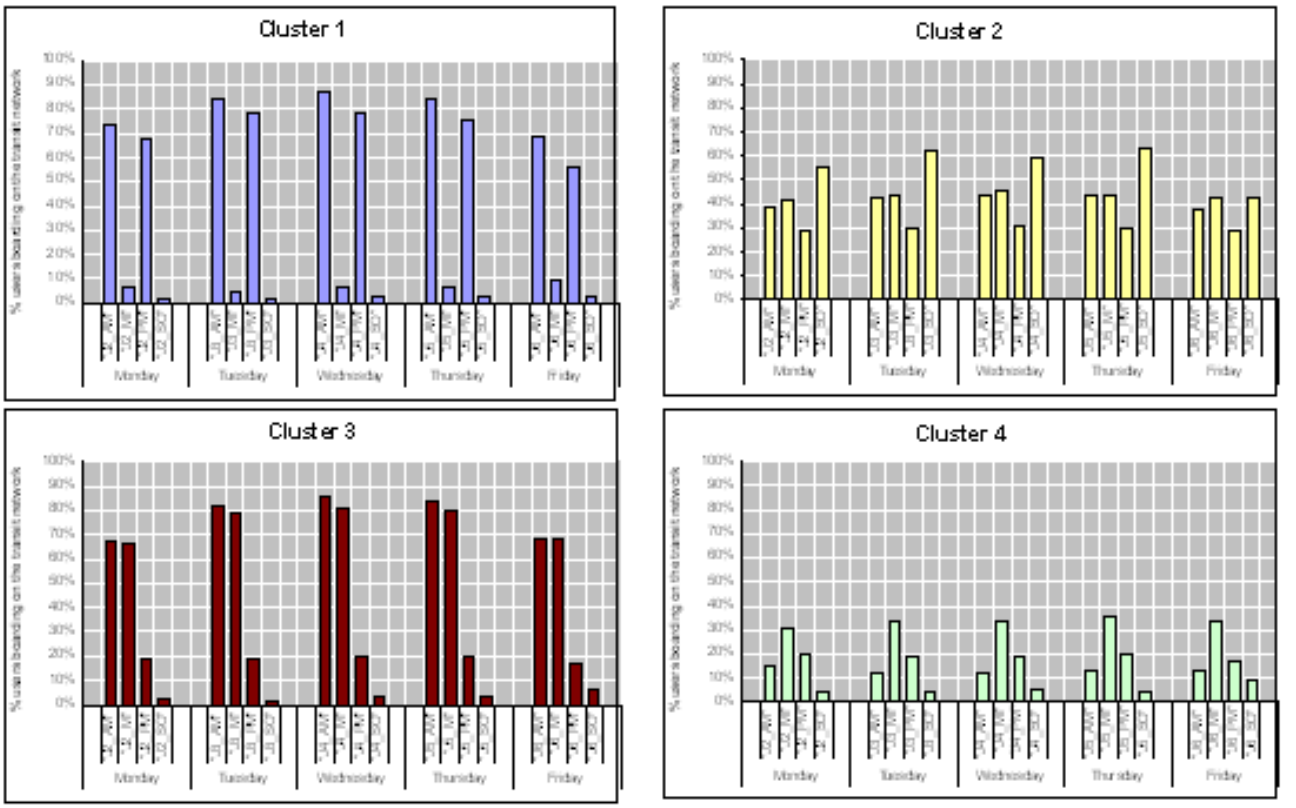

Figure 8. Variability of student behavior

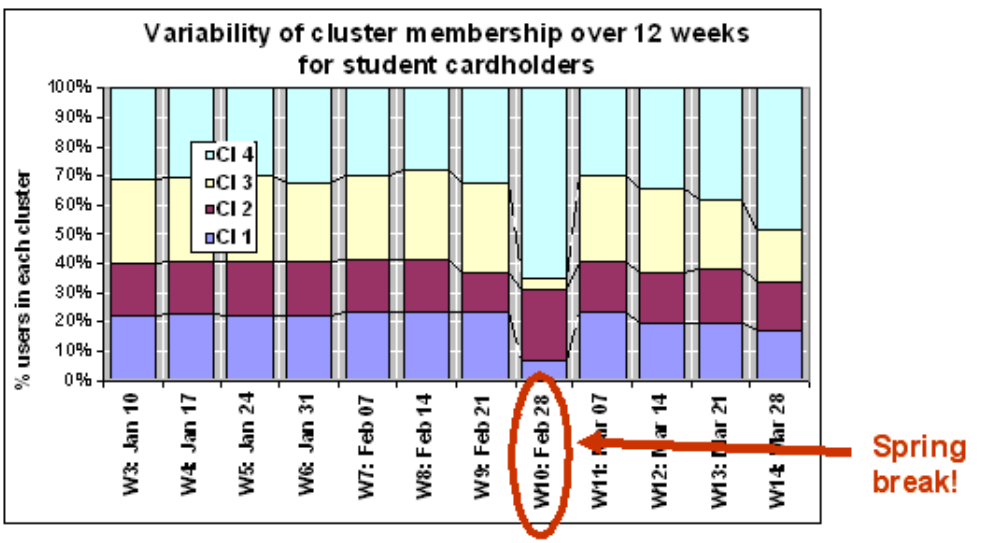

If we focus on the variability (Agard et al. 2006) over 12 weeks (January to April, 2005) of a predefined population (students), we observe that the average proportion of each behavior is relatively stable, except during the spring break where Cluster 4 (light use) predominates (also, Cluster 2, with no clear pattern, becomes important during this period). All this shows a major change in student behaviors (Figure 8).

Individual Behavior

Application of the same technique (clustering on temporal description of user behavior) at various levels of granularity may reveal individual patterns (Figure 9).

Clusters are computed on the overall population in order to extract patterns which may be useful for all the datasets. From these clusters, it is relatively easy to construct one map for each user to represent the variability between clusters for each type of day (Morency et al. 2006) (see Figure 10).

The behavior of the card owner ("Regular ADULT" above) is easy to predict. For example, since 95% of this user's Sunday behavior belongs to the same cluster (no. 9), we can easily predict, from the description of cluster no. 9, which contains an hourly record of boarding times, this user's transit behavior on Sundays. Other users behave less predictably, and, in these instances, each day may be characterized by less representative clusters.

FUTURE TRENDS

Data mining of a SCAFC is a powerful tool for providing information about transit system use. Further studies will make it possible to evaluate travel behaviors in space, and to detect the existence of punctual activities involving new transit paths or established paths which are evolving.

Current and future research concerns include the following:

- Refinement of the alighting location estimation model (to be implemented at the STO)
- Geospatial trip behavior (using geospatial data mining techniques)
- Specific route usage over space and time (to measure user turnover)
- More detailed mining in a specific time period (using the exact time of the first boarding for each day over a one-year period, for example)
- Application of mining techniques to the measurement of the spatial variability of travel behavior (boarding locations) and linking this information with spatial statistics

Figure 9. k-mean clustering on daily activities

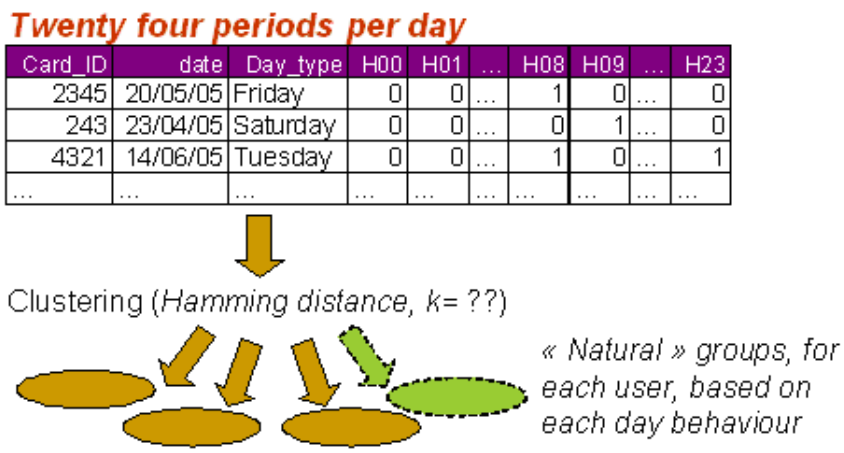

Figure 10. Examples of maps of behavior variability

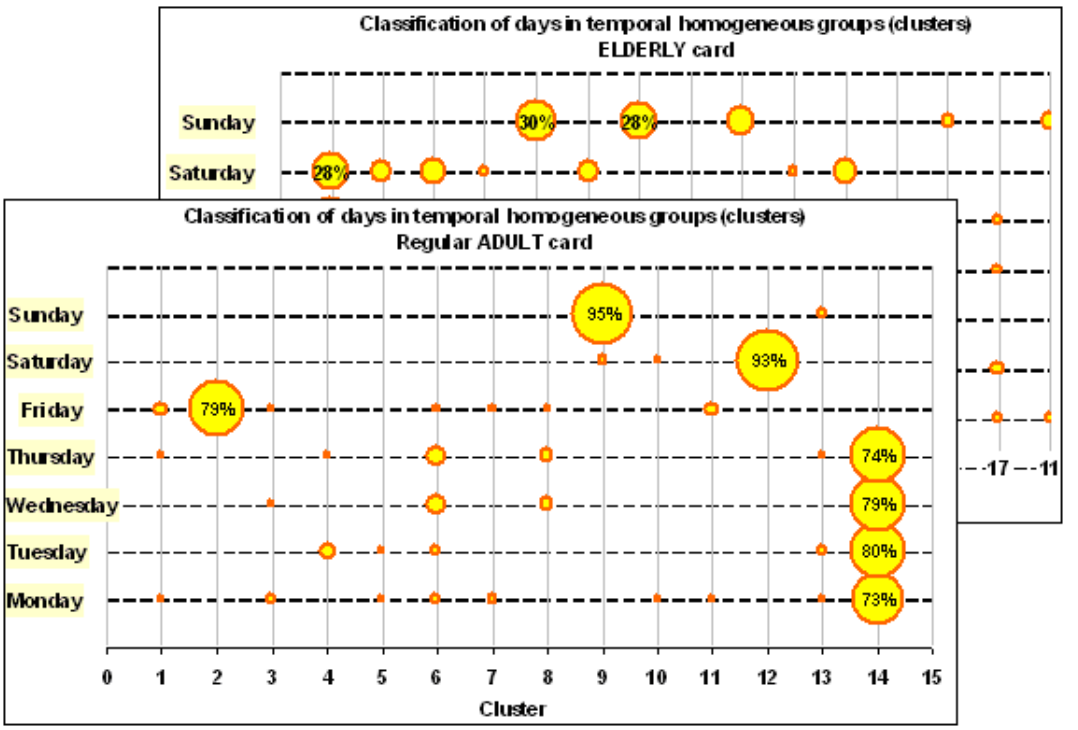

- Application of subgroup discovery to reveal specific patterns in user behaviors.

CONCLUSION

This chapter shows that data mining is a powerful tool for knowledge extraction from a SCAFCS. Used for more than fare collection, an SCAFCS has the potential to reveal hidden patterns which are useful for addressing operational concerns.

The analysis of continuous data makes it possible to extract user transit behaviors and their variability. Data mining tools allow us to obtain interesting information about the overall system. That knowledge will help planners better understand the behaviors of transit users, with a view to improving service.

Trip behavior is an important topic in the transportation literature, and understanding user behavior helps in the design of better networks offering better services.

In the study presented in this chapter, the data generated for fare collection were used in different ways to evaluate the actual use of a public transit system, making it possible to:

- define typical customers and measure their travel behaviors, and
- analyze the variability of use of the system with respect to day, week or season.

With these results, it is possible to improve a transit system by adjusting the balance between customer behaviors and the level of service provided on each route. It is also possible to propose variable fares, which encourage temporal or spatial shifts towards less congested runs and routes.

Smart card data are proving to be richer than the usual travel data that focus on a single day of travel for a single individual. They also constitute a supplementary source for analysis.

KEY TERMS

Activity Pattern: Sequence of activities made by a single person within a day. Each activity is bounded by the trips made before and after.

Board: To go onto or into a transportation vehicle.

Smart Card: Electronic device the size of a credit card which can store a small amount of data. It acts essentially like a radiofrequency identification tag (RFID).

Smart Card Automated Fare Collection System: System used to collect and validate fare payment aboard public transit vehicles.

Transit Mode: Public mean of transportation like bus, subway, commuter train.

Travel Behavior: In the field of transportation research, refers to the trip habits (frequency, purpose, time of departure, trip-end locations, etc.) of individual users on each transportation mode.

Urban Transit Network: Mass transit system which serves an urban population. It comprises modes and the provision of the service is guaranteed in the form of fixed schedules.

Mining Software Specifications

David Lo
National University of Singapore, Singapore

Siau-Cheng Khoo
National University of Singapore, Singapore

INTRODUCTION

Software is a ubiquitous component in our daily life. It ranges from large software systems like operating systems to small embedded systems like vending machines, both of which we frequently interact with. Reducing software related costs and ensuring correctness and dependability of software are certainly worthwhile goals to pursue.

Due to the short-time-to-market requirement imposed on many software projects, documented software specifications are often lacking, incomplete and outdated (Deelstra, Sinnema & Bosch 2004). Lack of documented software specifications contributes to difficulties in understanding existing systems. The latter is termed program comprehension and is estimated to contribute up to 45% of total software cost which goes to billions of dollars (Erlikh 2000, Standish 1984; Canfora & Cimitile 2002; BEA 2007). Lack of specifications also hampers automated effort of program verification and testing (Ammons, Bodik & Larus 2002).

One solution to address the above problems is mining (or automatic extraction of) software specification from program execution traces. Given a set of program traces, candidate partial specifications pertaining to the behavior a piece of software obeys can be mined.

In this chapter, we will describe recent studies on mining software specifications. Software specification mining has been one of the new directions in data mining (Lo, Khoo & Liu 2007a, Lo & Khoo 2007). Existing specification mining techniques can be categorized based on the form of specifications they mine. We will categorize and describe specification mining algorithms for mining five different target formalisms: Boolean expressions, automata (Hopcroft, Motwani & Ullman 2001), Linear Temporal Logic (Huth & Ryan 2003), frequent patterns (Han & Kamber 2006) and Live Sequence Charts (Harel & Marelly 2003).

BACKGROUND

Different from many other engineering products, software changes often during its lifespan (Lehman & Belady 1985). The process of making changes to a piece of software e.g., to fix bugs, to add features, etc., is known as software maintenance. During maintenance, there is a need to understand the current version of the software to be changed. This process is termed as program comprehension. Program comprehension is estimated to take up to 50% of software maintenance efforts which in turn is estimated to contribute up to 90% of total software costs (Erlikh 2000, Standish 1984; Canfora & Cimitile 2002). Considering the $216.0 billion of software component contribution to the US GDP at second quarter 2007, the cost associated with program comprehension potentially goes up to billions of dollars (BEA 2007). One of the root causes of this problem is the fact that documented software specification is often missing, incomplete or outdated (Deelstra, Sinnema & Bosch 2004). Mining software specifications is a promising solution to reduce software costs by reducing program comprehension efforts.

On another angle, software dependability is a well sought after goal. Ensuring software runs correctly at all times and identifying bugs are two major activities pertaining to dependability. Dependability is certainly an important issue as incorrect software has caused the loss of billions of dollars and even the loss of lives (NIST 2002; ESA & CNES 1996; GAO 1992). There are existing tools for performing program verification. These tools take formal specifications and automatically check them against programs to discover inconsistencies, identify bugs or ensure that all possible paths in the program satisfy the specification (Clarke, Grumberg & Peled 1999). However, programmers' reluctance and difficulty in writing formal specifications have been some of the barriers to the widespread adoption

of such tools in the industry (Ammons, Bodik & Larus 2002, Holtzmann 2002). Mining software specifications can help to improve software dependability by providing these formal specifications automatically to these tools.

MAIN FOCUS

There are a number of specification mining algorithms available. These algorithms can be categorized into families based on the target specification formalisms they mine. These include specification miners that mine Boolean expressions (Ernst, Cockrell, Griswold and Notkin 2001), automata (Cook & Wolf 1998; Reiss & Reinieris, 2001; Ammons, Bodik & Larus 2002; Lo & Khoo 2006a; Lo & Khoo 2006b; Mariani, Papagiannakis and Pezzè 2007; Archaya, Xie, Pei & Xu, 2007; etc.), Linear Temporal Logic expressions (Yang, et al. 2006; Lo, Khoo & Liu 2007b; Lo, Khoo & Liu 2008, etc.), frequent patterns (Li & Zhou, 2005; El-Ramly, Stroulia & Sorenson, 2002; Lo, Khoo & Liu 2007a; etc.) and Live Sequence Charts (Lo, Maoz & Khoo 2007a, Lo, Maoz & Khoo 2007b).

These mined specifications can aid programmers in understanding existing software systems. Also, a mined specification can be converted to run-time tests (Mariani, Papagiannakis & Pezzè 2007; Lo, Maoz & Khoo 2007a; Lo, Maoz & Khoo 2007b) or input as properties-to-verify to standard program verification tools (Yang, Evans, Bhardwaj, Bhat and Das, 2006; Lo, Khoo & Liu 2007b).

Preliminaries

Before proceeding further, let us describe some preliminaries. Specifications can be mined from either traces or code. A program trace is a sequence of events. Each event in a trace can correspond to a statement being executed, or a method being called, etc. In many work, an event is simply the signature of a method that is being called. Traces can be collected in various ways. A common method is to instrument a code by inserting `print' statement to various locations in the code. Running the instrumented code will produce a trace file which can then be analyzed.

Mining Boolean Expressions

Ernst, Cockrell, Griswold and Notkin (2001) propose an algorithm that mines Boolean expressions from program execution traces at specific program points. Sample Boolean expressions mined are x=y+z, x>5, etc. The algorithm is based on a set of templates which is then matched against the program execution traces. Template instances that are satisfied by the traces above a certain threshold are outputted to the user.

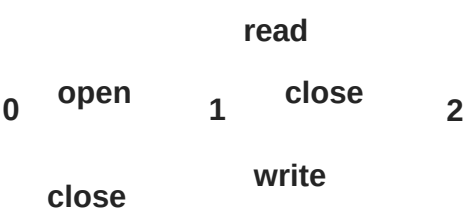
Mining Automata

Simply put, an automaton is a labeled transition system with start and end nodes. Traversing an automaton from start to end nodes will produce a sentence, which will correspond to a program behavior (e.g., file protocol: open-read-write-close). An automaton represents a set of valid sentences that a program can behave. An example of an automaton representing a file protocol is drawn in Figure 1.

One of the pioneering work on mining automata is the work by Ammons, Bodik and Larus (2002). In their work, a set of pre-processed traces are input to an automata learner (Raman & Patrick, 1997). The output of the learner is a specification in the form of an automaton learned from the trace file. This automaton is then presented to end users for fine tuning and modifications.

Lo and Khoo (2006a) define several metrics for assessing the quality of specification mining algorithms that mine automata. Among these metrics, precision and recall are introduced as measures of accuracy to existing specification miners producing automata. Precision refers to the proportion of sentences accepted by the language described by the mined automaton that are also accepted by the true specification. Recall refers to

Figure 1. File protocol specification



the proportion of sentences accepted by the language described by the true specification that are also accepted by the mined automaton. In the same work, a simulation framework is proposed to evaluate existing work on mining automaton-based specifications, which also help identify room for improvement.

Lo and Khoo (2006b) next propose an architecture using trace filtering and clustering to improve the quality of existing specification miners. The architecture pre-processes the traces by first filtering anomalies in the traces and then clustering them into similar groups. Each group is then fed separately to an existing specification mining algorithm to produce an automaton describing a partial specification of a system. These partial specifications are later merged into a unified automaton. It has been shown that the quality of the resultant specification mining algorithm after filtering and clustering are employed is better than before. In particular, in a case study on a Concurrent Versions System (CVS) application, the precision is doubled with a small reduction in recall.

Mariani, Papagiannakis and Pezzè (2007) use an improved automata learner (Mariani and Pezzè, 2005) and a Boolean expressions miner (Ernst, Cockrell, Griswold and Notkin, 2001) to generate regression tests of third party or Commercial off-the-shelf (COTS) components. Their algorithm first learns an automaton and a set of Boolean expressions and then converts them to regression tests to ensure the compatibility of third party components when used together.

Other work on mining automata includes: (Archaya, Xie, Pei & Xu, 2007; Reiss & Reinieris, 2001; Cook & Wolf 1998; etc.)

Mining Linear Temporal Logic Expressions

Linear Temporal Logic (LTL) is a formalism for specifying precise temporal requirements. It models time as a sequence of states where each state is an event from a fixed set. The full description of LTL can be found in (Huth & Ryan, 2004). Here, we focus on 3 temporal operators of LTL namely G, X and F. The operator X refers to the next state, *F* refers to the current or a future state, and *G* captures all future states (globally). In software there are many requirements expressible in LTL, for example:

1. Whenever (globally when) *resource.lock* is called, (from the next state onwards) finally *resource.unlock* is eventually called
   Or
   G(*resource.lock*->XF (*resource.unlock*))
2. Whenever (globally when) a correct pin is entered and user requested money and the balance is sufficient, (from the next state onwards) finally an ATM eventually dispenses money
   Or
   G(*correct_pin*->XG(*request_money*->XG(sufficient->XF(dispense))))

Yang, Evans, Bhardwaj, Bhat and Das (2006) mine significant two-event temporal logic expressions stating "whenever an event E_1 occurs eventually an event E_2 occurs" from program execution traces. An expression is significant if it satisfies a minimum threshold of ``satisfaction rate''. The algorithm is limited to mining two-event temporal logic expressions due to the exponential complexity involved in mining expressions of arbitrary sizes. To capture behaviors involving more than two events, they proposed a partial solution where previously mined two-event expressions are concatenated to form longer expressions. However, not all more-than-two event expressions can be mined this way, and superfluous rules that are not significant might be introduced in this process.

Lo, Khoo and Liu (2007b, 2008) extend this work by devising an algorithm to mine significant LTL expressions of arbitrary sizes. An expression is significant if it obeys minimum thresholds of support and confidence. A novel search space pruning strategy is employed to enable efficient mining of rules of arbitrary size.

Mining Frequent Patterns

Li and Zhou (2005) use a closed itemset mining algorithm by (Grahne & Zhu 2003) in their proposed algorithm called PR-Miner to recover elements of a program (function, variable, etc) that are often used together in a code. These associations among program elements can be composed as rules that reflect implicit programming rules in code.

El-Ramly, Stroulia and Sorenson (2002) propose a new pattern mining algorithm to mine frequent user-usage scenarios of a GUI based program composed of screens – these scenarios are termed as interaction patterns. Given a set of series of screen ids, frequent

Figure 2. A sample iterative pattern (of 32 events) mined from JBoss application server (note: diagram is read top to bottom, left to right)

Connection Set Up	TransactionManagerLocator.getInstance TransactionManagerLocator.locate TransactionManagerLocator.tryJNDI TransactionManagerLocator.usePrivateAPI	**Transaction Commit**	TxManager.commit TransactionImpl.commit TransactionImpl.beforePrepare TransactionImpl.checkIntegrity TransactionImpl.checkBeforeStatus TransactionImpl.endResources TransactionImpl.completeTransaction TransactionImpl.cancelTimeout TransactionImpl.doAfterCompletion TransactionImpl.instanceDone
TxManager Set Up	TxManager.begin XidFactory.newXid XidFactory.getNextId XidImpl.getTrulyGlobalId		
Transaction Set Up	TransactionImpl.associateCurrentThread TransactionImpl.getLocalId XidImpl.getLocalId LocalId.hashCode TransactionImpl.equals TransactionImpl.getLocalIdValue XidImpl.getLocalIdValue TransactionImpl.getLocalIdValue XidImpl.getLocalIdValue	**Transaction Disposal**	TxManager.releaseTransactionImpl TransactionImpl.getLocalId XidImpl.getLocalId LocalId.hashCode LocalId.equals

interaction patterns capturing common user interactions with the GUI are obtained.

Lo, Khoo and Liu (2007a) propose a new pattern mining algorithm to mine frequent patterns of program behavior from program execution traces —these patterns are termed as iterative patterns. Patterns can occur repeatedly within a program trace and across multiple traces. These patterns follow some constraints of Live Sequence Charts (LSC), which is one of the standards in software modeling community. An example of a specification mined from the transaction component of JBoss Application Server is shown in Figure 2. It specifies that a series of connection setup events is followed by transaction manager setup events, transaction setup events, transaction commit events and eventually transaction disposal events.

Mining Live Sequence Charts

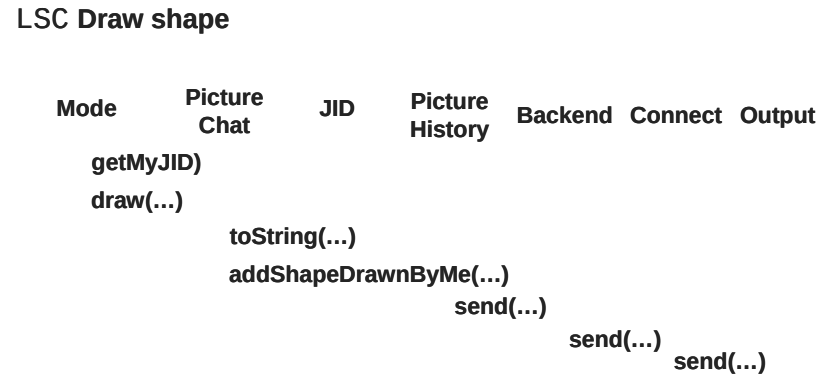
Lo, Maoz and Khoo (2007a, 2007b) extend the work on mining iterative pattern (Lo, Khoo & Liu, 2007a) and propose an algorithm to mine significant Live Sequence Charts (LSC) from program execution traces. A chart is significant if it obeys minimum thresholds of support and confidence. While iterative pattern follows some of the semantics of LSC they are not LSC. LSC is a formal version of UML sequence diagram with pre- and post- chart. An LSC specifies that when the behavior specified by the pre-chart occurs, the behavior specified by the post-chart will also occurs. Mined LSCs are also different from Linear Temporal Logic expressions mined in (Lo, Khoo & Liu, 2007b, Lo, Khoo & Liu, 2008) as the satisfactions of the pre- and post- charts conform to the semantics of LSC (Harel & Marelly 2003). Also for mining LSCs, an event in a trace is a triple (caller, callee, method signature). An example of a mined chart from Jeti instant messaging application (Jeti 2006) is shown in Figure 3. It describes a series of methods that are being called when a user of Jeti draws a line in the shared canvas with another communication party.

We have reviewed various approaches to mine different forms of software specifications. The specifications mined can aid user in understanding existing software and serve as input to other software engineering tasks, e.g., software verification, testing, etc.

FUTURE TRENDS

As program traces can be huge, there is a need to improve the efficiency of existing techniques further. Further industrial case studies are also needed to adapt existing techniques to the industry. A comparison of existing techniques will do well to help users to better understand which technique works best in a particular situation. There is much room for further theoretical and practical contributions to the domain of mining software specifications.

Figure 3. A sample LSC mined from Jeti messaginge application (boxes, arrows, dotted arrows and solid arrows correspond to classes, method calls, pre-chart and post-chart respectively)



CONCLUSION

Software is a ubiquitous component of our daily life. Documented software specifications are often missing, incomplete and outdated. This causes difficulties in understanding software systems. Program comprehension accounts for a significant proportion of total software cost. On another angle, programmers' reluctance and difficulty in writing formal specifications have been some barriers to the wide spread adoption of automatic program verification tools. Specification mining is one of the promising solutions to the above problems. It can provide candidate specifications to aid programmers in understanding existing programs. The specification can also be input to program verification tools and converted to run-time tests to aid program verification and bug detection. In the future, we look forward to more theoretical and technical contribution to this field, as well as more case studies and the availability of more open source tools.

KEY TERMS

Automaton: A labeled transition system with start and end nodes describing a language. A path from the start to an end node corresponds to a sentence in the language.

Linear Temporal Logic: Formalism commonly used to describe temporal requirements precisely. There are a few basic operations given with symbols G, X, F, U, W, R corresponding to English language terms 'Globally', 'neXt', 'Finally', 'Until', 'Weak-until' and 'Release'.

Live Sequence Charts: A formal version of UML sequence diagram. It is composed of a pre- and post-chart. The pre-chart describes a condition which if satisfied entails that the behavior described in the post-chart will occur.

Program Comprehension: A process of understanding a piece of software.

Program Instrumentation: Simply put, it is a process of inserting `print' statements to an existing program such that by running the instrumented program, it will produce a trace file reflecting the behavior of the program when the program is run.

Program Testing: A process find defects in a piece of software by running a set of test cases.

Program Trace: A series of events where each event can correspond to a statement that is being executed, a function that is being called etc., depending on the abstraction level considered in producing the trace.

Program Verification: A process to ensure that software is always correct no matter what input is given with respect to some properties, e.g., whenever a resource is locked for usage, it is eventually released.

Software Maintenance: A process of incorporating changes to existing software, e.g., bug fixes, feature additions, etc., while ensuring the resultant software works well.

Specification Mining or Specification Discovery: A process for automated extraction of software specification from program artifacts. We use artifacts in a liberal sense to include program traces, code, repository, data, etc.

Software Specification: A description on how a piece of software is supposed to behave.

Mining the Internet for Concepts

INTRODUCTION

The Internet has made available a big number of information services, such as file sharing, electronic mail, online chat, telephony and file transfer. However, services that provide effective access to Web pages, such as Google, are the ones that most contributed to the popularization and success of the World Wide Web and the Internet. Pages published at the World Wide Web belong to many different topic areas, such as music, fishing, travel, etc. Some organizations have tried to organize pages in a predefined classification, and have manually built large directories of topics (e.g. *Dmoz* or the *Yahoo!* directory). But given the huge size and the dynamic nature of the Web, keeping track of pages and their topic manually is a daunting task. There is also the problem of agreeing on a standard classification, and this has proved to be a formidable problem, as different individuals and organizations tend to classify things differently. Another option is to rely on automatic tools that mine the Web for "topics" or "concepts" related to online documents. This approach is indeed more scalable than the manual one. However, automatically classifying documents in topics is a major research challenge. This is because the document keywords alone seem to be insufficient to directly convey the meaning of the document to an autonomous system. In some cases, the main difficulty is due to the ambiguity of the terms encountered in the document. Even if the ambiguity problems were solved there is still no guarantee that the vocabulary used to describe the document will match that used by the autonomous system to guide its search.

Central to automatic approaches is the notion of "semantic context", which loosely means the subject or topic where a task like searching is embedded. Of course, we need a way to computationally represent this notion of context, and one possibility is to see context as a collection of interrelated terms in the sense that they appear together in a number of related pages (Ramirez & Brena, 2006). For instance, the word "Java" appears together with "roasted" when talking about coffee, but appears more frequently with "code" when talking about a programming language. Semantic contexts allow performing searches on the Web at the concept level, rather than at the more basic keyword level. In this chapter we present recent advances in automated approaches in web concept mining, emphasizing our own work about mining the Web for semantic contexts.

BACKGROUND

The notion of semantic contexts is closely linked to that of *semantic similarity*. Two documents are semantically similar if they belong to the same topic or to similar topics. Likewise, two words are semantically similar if they represent similar concepts.

The study of semantic similarity between documents and terms has long been an integral part of information retrieval and machine learning, and there is extensive literature on measuring the semantic similarity between entities (Resnik, 1995; Lin, 1998; Hatzivassiloglou et al. 1999; Landauer et al. 1997; Turney, 2001; Maguitman et al. 2005; Ramirez & Brena, 2006; Sahami et al. 2006; Bollegala, 2007). These methods can be roughly classified into two major categories: knowledge-based and corpus-based approaches.

Knowledge-based approaches rely on the use of predefined directories or ontologies to identify semantic relations. Measures of semantic similarity between entities take as a starting point the structure of a directory or ontology where the entities have been previously classified. Examples of such ontologies include

WordNet for the case of terms, and *Dmoz* or the *Yahoo! Directory* for the case of document. Ontologies are a special kind of network and early proposals to estimate semantic similarity have used path distances between the nodes in the network representation (Rada et al. 1989). Some successors have looked into the notion of information content (Resnik, 1995; Lin, 1998) or have combined both distance and information content (Jiang & Conrath, 1997) to assess semantic similarity. In an information theoretic approach, the semantic similarity between two entities is related to their commonality and to their differences. Given a set of entities in a hierarchical taxonomy, the commonality of two entities can be estimated by the extent to which they share information, indicated by the most specific class in the hierarchy that subsumes both. Once this common classification is identified, the meaning shared by two entities can be measured by the amount of information needed to state the commonality of the two objects. Generalizations of the information theoretic notion of semantic similarity for the case of general ontologies (i.e., taxonomies that include both hierarchical and non-hierarchical components) have been proposed by Maguitman et al. (2005).

Keeping these ontologies up-to-date is expensive. For example, the semantic similarity between terms changes across different contexts. Take for instance the term java, which is frequently associated with the java programming language among computer scientist. However, this sense of java is not the only one possible as the term may be referring to the java coffee, the java island or the java Russian cigarettes, among other possibilities. New words are constantly being created as well as new senses are assigned to existing words. As a consequence, the use of knowledge-based approaches has disadvantages because they require that the ontologies be manually maintained.

Corpus-based approaches, on the other hand, can help to automate the process of keeping the ontology up-to-date. They are based on information exclusively derived from large corpora (such as the World Wide Web). A well-known approach of corpora-based method is latent semantic analysis (Landauer et al. 1997), which applies singular value decomposition to reduce the dimensions of the term-document space, harvesting the latent relations existing between documents and between terms in large text corpora. Less computationally expensive techniques are based on mapping documents to a kernel space where documents that do not share any term can still be close to each other (Cristianini et. al 2001; Liu et al. 2004). Another corpus-based technique that has been applied to estimate semantic similarity is PMI-IR (Turney, 2001). This information retrieval method is based on pointwise mutual information, which measures the strength of association between two elements (e.g., terms) by contrasting their observed frequency against their expected frequency.

In general, automatic methods to compute similarity between texts have applications in many information retrieval related areas, including natural language processing and image retrieval from the Web, where the text surrounding the image can be automatically augmented to convey a better sense of the topic of the image. Automatic methods to identify the topic of a piece of text have also been used in text summarization (Erkan and Radev 2004), text categorization (Ko et al. 2004), word sense disambiguation (Schutze 1998), evaluation of text coherence (Lapata and Barzilay 2005) and automatic translation (Liu and Zong 2004), but most of them use human-defined categories for topics, becoming thus prone to the problems we mentioned before, like disagreement, difficulty to update, etc.

MAIN FOCUS

We discuss two completely corpus-based methods proposed by the authors that can be used to identify semantic contexts and applied to mine the Web for concepts. The first is based on the notion of k-core and the second is based on the use of incremental methods.

K-Core Method

In the k-core method, the main idea is to find groups of *k* keywords (for instance, 4 keywords) that appear together in a big number of pages. The basic assumption is that words with related meanings appear together more often than unrelated words. The number of co-occurrences is readily obtained using the current indexing-based search methods; for instance, *Google* search includes this number in every single search results page (upper-right corner). So, co-occurrences based methods could be extremely efficient and well integrated with internet search technology.

A "Semantic Context" is defined in this method as the relative weights of keywords in a given topic. For instance, when talking about coffee, the word sugar is

very important, but it is irrelevant when the subject is automobile engines. Formally, a Semantic Context is a function from keywords to numbers from 0 to 1, 1 meaning that the given word is of utmost importance and 0 of no importance. Semantic Contexts represent conceptual topics, through the relative importance of the words used in documents belonging to that topic in a given corpus.

Now, Semantic Contexts require to locate a group of documents all of them "talking" about a certain topic, and then standard TF-IDF measures are calculated for each keyword. Those documents could of course be compiled manually, but in (Ramirez & Brena, 2006) this is done using a device called "k-cores". As explained before, k-cores are groups of *k* words that appear together in a big number of documents in the corpus, indicating thus that they are semantically linked. In the k-core method a value called "force" is calculated for each possible group of *k* words; the force is a kind of measure of how good are the given words for describing a topic. A formula has been proposed for calculating force, which takes into account the joint frequency of the words in the candidate k-core; for the case of two words k_1 and k_2 the force would be:

$$F(k_1,k_2)/(F(k_1,\sim k_2)+F(k_2,\sim k_1))$$

where $F(k_1,k_2)$ gives the joint document frequency of k_1 and k_2, and "~" represents negation, so $F(k_2,\sim k_1)$ represents the quantity of documents having k_2 but not k_1. For more than 2 words, the formula gets more complicated, but the idea is the same.

Finally, a k-core is just a group of group of *k* words of maximal force, meaning that any single-word replacement would decrease the force.

Once k-cores are calculated, they are used as conjunctive queries against the corpus, obtaining sets of documents belonging to the topic of the corresponding k-core; from those sets of documents, the Semantic Contexts are calculated as explained above. Then, distances between two Semantic Contexts are easily calculated taking them as vectors.

Experimental results (Ramirez & Brena, 2006) show that: 1) the method is able to find k-cores for all the topics in a given corpus, 2) Distances between the calculated k-cores actually correspond to intuitive closeness of topics.

In (Ramirez & Brena, 2006) are presented specific algorithms, as well as applications of this method, such as focusing of Internet searches, helping thus the user to disambiguate an initial search so that only results from a chosen topic are filtered.

Further work is being done in the k-core method in order to increase the efficiency for calculating all the k-cores for a large corpus.

Incremental Methods

When seeking for material semantically related to a document, it is natural to form queries using the most descriptive terms of the documents. We have developed an incremental method that exploits the search context to go beyond the vocabulary of the initial document. The method starts with a small number of terms randomly selected from the document under analysis and uses the full document as the initial search context. Using these terms, a set of queries are built and submitted to a search engine. After the first set of results has been obtained, the search context is used to refine/extend the set of terms used for the context description. Terms that appear *often* in search results similar to the search context tend to be good "descriptors" of the thematic context. On the other hand, terms that tend to occur *only* in results similar to the search context can serve as "discriminators".

Intuitively, we can characterize topic descriptors and discriminators as follows:

1. Terms are good topic descriptors if they answer the question "What is this topic about?"
2. Terms are good topic discriminators if they answer the question "What are good query terms to access similar information?"

In this approach *topic* descriptors and discriminators are considered higher-order notions and distinguished from the more basic notions of *document* descriptors and discriminators.

Formally, given a collection of *m* documents and *n* terms we can build a $m \times n$ matrix *H*, such that $H[i,j]=k$, where *k* is the number of occurrences of term t_j in document d_i. We define discriminating power of a term in a document as a function $\delta: \{t_0,\ldots,t_{n-1}\} \times \{d_0,\ldots,d_{m-1}\} \rightarrow [0,1]$:

$$\delta(t_i, d_j) = \frac{\mathrm{sgn}(H^T[i,j])}{\sqrt{\sum_{k=0}^{m-1} \mathrm{sgn}(H^T[i,k])}}$$

Analogously, we define descriptive power of a term in a document as a function $\lambda: \{d_0,\ldots,d_{m-1}\} \times \{t_0,\ldots,t_{n-1}\} \rightarrow [0,1]$:

$$\lambda(d_i, t_j) = \frac{H[i,j]}{\sqrt{\sum_{k=0}^{n-1} (H[i,k])^2}}$$

These simple notions of document descriptors and discriminators share some insight with standard IR proposals. However here we are interested in a topic-dependant definition of topic descriptors and discriminators. We formally define the descriptive power of a term in the topic of a document as a function $\Lambda: \{d_0,\ldots,d_{m-1}\} \times \{t_0,\ldots,t_{n-1}\} \rightarrow [0,1]$ calculated as follows:

$$\Lambda(d_i, t_j) = \begin{cases} 0 & \text{if } \sum_{k=0,\ k\neq i}^{m-1} \sigma(d_i, d_k) = 0 \\ \dfrac{\sum_{k=0,\ k\neq i}^{m-1} (\sigma(d_i, d_k) \cdot \lambda(d_k, t_j)^2)}{\sum_{k=0,\ k\neq i}^{m-1} \sigma(d_i, d_k)} & \text{otherwise} \end{cases}$$

where $\sigma(d_i,d_j)$ stands for some similarity measure between documents d_i and d_j. Thus the discriminating power of term t_i in the topic of document d_j is an average of the similarity of d_j to other documents discriminated by t_i. Indeed, the descriptive power of a term in a topic is defined using the simpler notions of document similarity and document descriptors: The topic descriptive power of a term *t* in the topic of a document *d* is a measure of the quality of *t* as a descriptor of documents similar to *d*.

Analogously, the discriminating power of a term *t* in the topic of a document *d* is quantified as the average of the similarity of *d* to other documents discriminated by *t* and is formally defined as a function $\Delta: \{t_0,\ldots,t_{n-1}\} \times \{d_0,\ldots,d_{m-1}\} \rightarrow [0,1]$ calculated as follows:

$$\Delta(t_i, d_j) = \sum_{k=0,\ k\neq j}^{m-1} (\sigma(d_k, d_j) \cdot \partial(t_i, d_k)^2)$$

Thus the discriminating power of term t_i in the topic of document d_j is an average of the similarity of d_j to other documents discriminated by t_i.

When used as query terms, topic descriptors are useful to improve recall because they occur in many similar documents. Topic discriminators, on the other hand, help restrict the set of search results to mostly similar material and therefore can help achieve high precision. A formal characterization of topic descriptors and discriminators as well as an evaluation of their usefulness as query terms can be found in (Maguitman et al. 2004).

Our incremental methods identify topic descriptors and topic discriminators by analyzing the terms in retrieved documents. Consequently, they are not restricted to terms occurring in the originating search context, and if novel terms have high descriptive or discriminating power, they expand the vocabulary found in the initial document. In this incremental search process, the generation of second-round and subsequent queries can significantly benefit from a search context refined by the addition of good topic descriptors and discriminators.

Advantages and Disadvantages

The two methods just described are quite similar, because they aim to automatically find relevant terms for characterizing topics. They differ in that k-cores do not distinguish between descriptors and discriminators, but enforce a notion of joint occurrence as a topic definer.

As we previously mentioned, the main quality of both of these two methods is that they compute topics in an automated way, departing thus from many known methods that start with human-defined sets of topics. We insist in saying that automatically computed topics are less prone than human-made ones to arbitrary classifications and thus disagreements, and they can be more comprehensive and easy to update.

We currently do not know if there are disadvantages in automatic methods. It is possible that in real-world applications human and machine-made topic classifications could coexist.

FUTURE TRENDS

Semantic context-based methods to mine the Web for concepts are gradually becoming a key component

of today's Internet infrastructure. The techniques discussed here can be applied to any domain for which it is possible to generate term-based characterizations of a topic. We anticipate that a number of information services will benefit from these methods. The areas of application could include topic-based and task-based search, semantic web navigation, automated translations, and support for knowledge management, among others. To illustrate the automated translation application, consider the situation where a

CONCLUSION

The context in which an Internet task such as a search is done is of huge practical importance to users. Traditional IR techniques fall short for accessing Web resources in many highly context-dependent situations. One very important form of context is the topic or concept to which the task is related. But collecting and organizing topics that serve as contexts is not an easy task. In this chapter we have reviewed techniques that allow for dynamic identification of useful context-specific material, some of them based on the notion of semantic similarity.

Methods that take advantage of the information available in large corpora, such as the Web, to generate a semantic context are particularly useful to go beyond the predefined set of terms in a document. In contrast to knowledge-based approaches, corpus-based approaches, as the two ones described in this chapter, do not require human editors to manually classify documents into topics or to associate term with concepts. They actually aim to mining a given corpus for finding its topics, which can be used as contexts. The advantages of these methods have been cited before: comprehensiveness, objectivity, and capability to adjust to the dynamic nature of the Web and human knowledge in general.

KEY TERMS

Ambiguity: A same phrase having more than one meaning, like "flying planes", that could be a noun (planes that fly) or verb (the activity of flying the planes).

Context: The set of conditions embedding and influencing a given task. In this chapter we focus mainly in contexts understood as topics, subjects or concepts, like music, engines, fishing, etc.

Corpus, Corpora: The set of all available documents.

Disambiguation: The action of selecting one particular meaning among several possible ones in an ambiguous expression (see "ambiguity" above).

Hierarchical taxonomy: Tree-like classification of categories in subcategories, then them in subcategories, etc., like the living beings in animals and plants, etc.

Information retrieval: Field studying the techniques and methods for getting relevant information in an efficient way.

Information Theory: Discipline aiming to measure the quantity of information transmitted or stored.

Keywords: Nouns, verbs and adjectives, excluding thus non-relevant words for purposes of word content, like "in", "or", etc.

Machine Learning: The study of methods that allow computers to improve their performance using past experience.

Ontologies: Definition of classes of objects, attributes, properties and relations to other objects, expressed in Semantic Web markup languages such as "OWL".

Semantic Similarity: Closeness in meaning, using some metric for measuring the distance between words, documents, etc.

Web Mining: The search for patterns in the Web using data mining techniques.

Model Assessment with ROC Curves

Lutz Hamel
University of Rhode Island, USA

INTRODUCTION

Classification models and in particular binary classification models are ubiquitous in many branches of science and business. Consider, for example, classification models in bioinformatics that classify catalytic protein structures as being in an active or inactive conformation. As an example from the field of medical informatics we might consider a classification model that, given the parameters of a tumor, will classify it as malignant or benign. Finally, a classification model in a bank might be used to tell the difference between a legal and a fraudulent transaction.

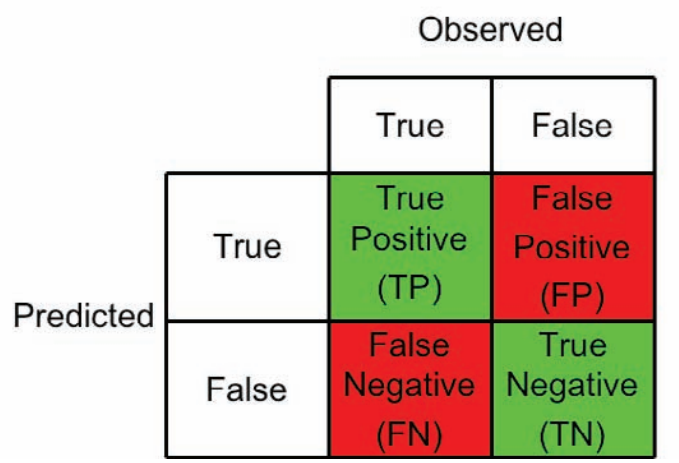
Central to constructing, deploying, and using classification models is the question of model performance assessment (Hastie, Tibshirani, & Friedman, 2001). Traditionally this is accomplished by using metrics derived from the confusion matrix or contingency table. However, it has been recognized that (a) a scalar is a poor summary for the performance of a model in particular when deploying non-parametric models such as artificial neural networks or decision trees (Provost, Fawcett, & Kohavi, 1998) and (b) some performance metrics derived from the confusion matrix are sensitive to data anomalies such as class skew (Fawcett & Flach, 2005). Recently it has been observed that Receiver Operating Characteristic (ROC) curves visually convey the same information as the confusion matrix in a much more intuitive and robust fashion (Swets, Dawes, & Monahan, 2000).

Here we take a look at model performance metrics derived from the confusion matrix. We highlight their shortcomings and illustrate how ROC curves can be deployed for model assessment in order to provide a much deeper and perhaps more intuitive analysis of the models. We also briefly address the problem of model selection.

BACKGROUND

A binary classification model classifies each instance into one of two classes; say a *true* and a *false* class. This gives rise to four possible classifications for each

Figure 1. Format of a confusion matrix



instance: a true positive, a true negative, a false positive, or a false negative. This situation can be depicted as a confusion matrix (also called contingency table) given in Figure 1. The confusion matrix juxtaposes the observed classifications for a phenomenon (columns) with the predicted classifications of a model (rows). In Figure 1, the classifications that lie along the major diagonal of the table are the correct classifications, that is, the true positives and the true negatives. The other fields signify model errors. For a perfect model we would only see the true positive and true negative fields filled out, the other fields would be set to zero. It is common to call true positives *hits*, true negatives *correct rejections*, false positive *false alarms*, and false negatives *misses*.

A number of model performance metrics can be derived from the confusion matrix. Perhaps, the most common metric is *accuracy* defined by the following formula:

$$\text{accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

Other performance metrics include *precision* and *recall* defined as follows:

$$\text{precision} = \frac{TP}{TP + FP},$$

$$\text{recall} = \frac{TP}{TP + FN}$$

Note, that when we apply a model to a test dataset we obtain only one scalar value for each performance metric. Figure 2 shows two confusion matrices of one particular classification model built on the ringnorm data by Breiman (Breiman, 1996). Part (a) shows the classification model being applied to the original test data that consists of 7400 instances roughly split evenly between two classes. The model commits some significant errors and has an accuracy of 77%. In part (b) the model is applied to the same data but in this case the negative class was sampled down by a factor of ten introducing class skew in the data. We see that in this case the confusion matrix reports accuracy and precision values that are much higher than in the previous case. The recall did not change, since we did not change anything in the data with respect to the 'true' class. We can conclude that the perceived quality of a model highly depends on the choice of the test data. In the next section we show that ROC curves are not

Figure 2. Confusion matrices with performance metrics. (a) confusion matrix of a model applied to the original test dataset, (b) confusion matrix of the same model applied to the same test data where the negative class was sampled down by a factor of ten

so dependent on the precise choice of test data, at least with respect to class skew.

MAIN FOCUS OF CHAPTER

ROC Curves: The Basics

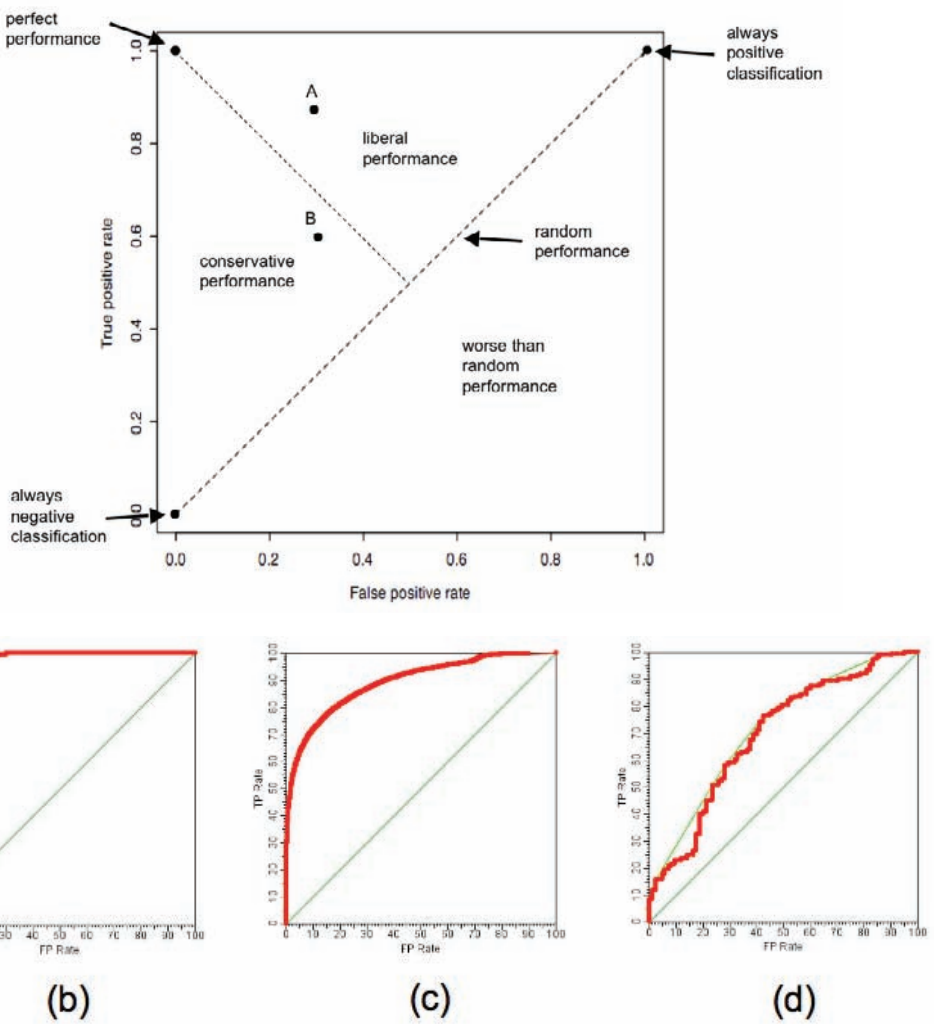
ROC curves are two-dimensional graphs that visually depict the performance and performance trade-off of a classification model (Fawcett, 2004; P. Flach, Blockeel, Ferri, Hernandez-Orallo, & Struyf, 2003; P. Flach, 2004; P. A. Flach, 2003). ROC curves were originally designed as tools in communication theory to visually determine optimal operating points for signal discriminators (Egan, 1975).

We need to introduce two new performance metrics in order to construct ROC curves (we define them here in terms of the confusion matrix), the *true positive rate* (tpr) and the *false positive rate* (fpr):

$$\text{true positive rate} = \frac{TP}{TP + FN} = \text{recall},$$

$$\text{false postive rate} = \frac{FP}{TN + FP}.$$

Figure 3. ROC curves: (a) regions of a ROC graph (b) an almost perfect classifier (c) a reasonable classifier (d) a poor classifier [1]



ROC graphs are constructed by plotting the true positive rate against the false positive rate (see Figure 3(a)). We can identify a number of regions of interest in a ROC graph. The diagonal line from the bottom left corner to the top right corner denotes random classifier performance, that is, a classification model mapped onto this line produces as many false positive responses as it produces true positive responses. To the left bottom of the random performance line we have the conservative performance region. Classifiers in this region commit few false positive errors. In the extreme case, denoted by point in the bottom left corner, a conservative classification model will classify all instances as negative. In this way it will not commit any false positives but it will also not produce any true positives. The region of classifiers with liberal performance occupies the top of the graph. These classifiers have a good true positive rate but also commit substantial numbers of false positive errors. Again, in the extreme case denoted by the point in the top right corner, we have classification models that classify every instance as positive. In that way, the classifier will not miss any true positives but it will also commit a very large number of false positives. Classifiers that fall in the region to the right of the random performance line have a performance worse than random performance, that is, they consistently produce more false positive responses than true positive responses. However, because ROC graphs are symmetric along the random performance line, inverting the responses of a classifier in the "worse than random performance" region will turn it into a well performing classifier in one of the regions above the random performance line. Finally, the point in the top left corner denotes perfect classification: 100% true positive rate and 0% false positive rate.

The point marked with A is the classifier from the previous section with a tpr = 0.90 and a fpr = 0.35. Note, that the classifier is mapped to the same point in the ROC graph regardless whether we use the original test set or the test set with the sampled down negative class illustrating the fact that ROC graphs are not sensitive to class skew.

Classifiers mapped onto a ROC graph can be ranked according to their distance to the 'perfect performance' point. In Figure 3(a) we would consider classifier A to be superior to a hypothetical classifier B because A is closer to the top left corner.

The true power of ROC curves, however, comes from the fact that they characterize the performance of a classification model as a curve rather than a single point on the ROC graph. In addition, Figure 3 shows some typical examples of ROC curves. Part (b) depicts the ROC curve of an almost perfect classifier where the performance curve almost touches the 'perfect performance' point in the top left corner. Part (c) and part (d) depict ROC curves of inferior classifiers. At this level the curves provide a convenient visual representation of the performance of various models where it is easy to spot optimal versus sub-optimal models.

ROC Curve Construction

In order to interpret ROC curves in more detail we need to understand how they are constructed. Fundamental to the construction of ROC curves is the notion of instance ranking or prediction confidence value. ROC curves can be directly computed for any classification model that attaches a probability, confidence value, or ranking to each prediction. Many models produce such rankings as part of their algorithm (e.g. Naïve Bayes (Mitchell, 1997), Artificial Neural Networks (Bishop, 1995), Support Vector Machines (Cristianini & Shawe-Taylor, 2000)). Techniques exist that compute an instance ranking for classification models that typically do not produce such rankings, i.e., decision trees (Breiman, Friedman, Olshen, & Stone, 1984). The instance ranking is used by the ROC algorithm to sweep through different decision thresholds from the maximum to the minimum ranking value in predetermined increments. The ranking values are typically normalized to values between 0 and 1 (as an aside, the default decision threshold for most classifiers is set to .5 if the ranking value expresses the actual probability value of the instance being classified as true). At each threshold increment, the performance of the model is computed in terms of the true positive and false positive rates and plotted. This traces a curve from left to right (maximum ranking to minimum ranking) in the ROC graph. That means that the left part of the curve represents the behavior of the model under high decision thresholds (conservative) and the right part of the curve represents the behavior of the model under lower decision thresholds (liberal).

The following algorithm[2] makes this construction a little bit more concrete:

Function Draw-ROC

Inputs:
D: test set
p(i): ranking of instance i in D, indicates the probability or confidence that the instance i is positive, normalized to [0,1]
P: set of observed positive instances in D, where $P \subseteq D$
N: set of observed negative instances in D, where $N \subseteq D$

```
for threshold = 1 to 0 by -.01 do
  FP ⇐ 0
  TP ⇐ 0
  for i ∈ D do
      if p(i) ≥ threshold then
              if i  ∈ P then
                      TP ⇐ TP + 1
              else
                      FP ⇐ FP + 1
              endif
      endif
  endfor
  tpr ⇐ TP/#P
  fpr ⇐FP/#N
  Add point (tpr, fpr) to ROC curve
endfor
```

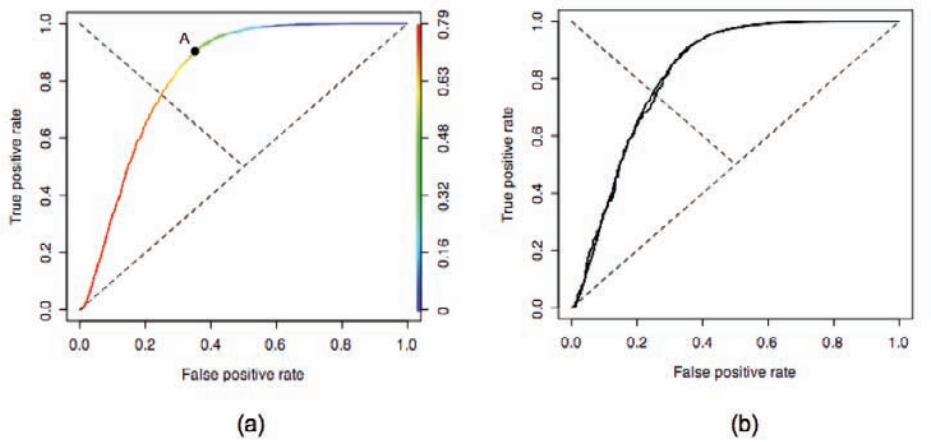
Notice how this algorithm sweeps through the range of thresholds from high to low and measures the number of mistakes the classifier makes at each threshold level. This gives rise to the tpr and fpr at each threshold level. This in turn can be interpreted as a point on the ROC curve.

Figure 4(a) shows the ROC curve of the classifier from Figure 2 with the decision thresholds annotated in color. From this we can see that the optimal decision threshold for this model (maximum tpr, minimum fpr, also called optimal operating point) occurs at a threshold of .35 in the green region representing a tpr = .95 and an fpr = .45. As we would expect from our confusion matrix analysis, we can observe that it is a reasonable classifier. We can also observe that it is a liberal classifier in that the optimal decision threshold of the curve lies in the liberal region of the ROC graph. It is also interesting to observe that the performance given by the confusion matrix maps to a suboptimal point on the curve (given as 'A' on the curve). This is due to the fact that the classification reported in the confusion matrix is based on the default decision threshold value of .5 instead of the optimal threshold value of .35.

In Figure 4(b) we can see two ROC curves for the same classifier as in part (a), one is based on the original test data and the other one is based on the skewed test data. Both curves are virtually identical illustrating that ROC curves are not sensitive to class skew.

Returning to Figure 3 above, we can now interpret these curves a little bit more carefully. In part (b) we see that the model only begins to commit false positive errors after it has almost reached a true positive rate of 100%. This means that at this point the decision

Figure 4. ROC curves of the classifier given in Fig. 2. (a) ROC curve with decision threshold values, (b) ROC curves of the classifier evaluated against original test data and the down sampled data



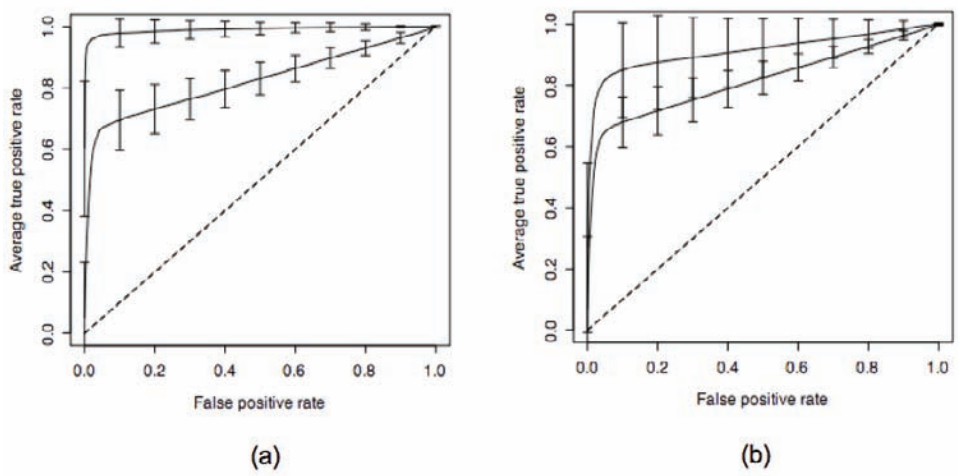
threshold has been lowered to a point that observed, negative instances are classified as positive. Thus, when the decision threshold is set too low, a model will commit false positive errors. However, in a near perfect classification model this will not happen until the curve has almost reached the 'perfect performance' point.

In Figure 3(c) we see that the model also behaves very nicely for a large range of decision threshold values. However, compared to the model in part (b) it starts to commit false positive errors much earlier and therefore the slope of the curve in part (c) is flatter. Another way of stating this is, that there exists no decision threshold for which the model is able to separate the classes perfectly. The model in Figure 4(d) is not only inferior because its curve is the farthest away from the 'perfect performance' point but we can observe that for large ranges of the ranking values the model commits more false positive errors than it provides true positive classifications. This shows up as concavities in the curve indicating that for certain ranges of the decision threshold the classification model performs worse than a random classifier.

Model Selection

A key notion in model assessment is model selection, that is, given two or more classification models, we need to pick one in order to be deployed. The criterion to pick one model over the other(s) has to answer two fundamental questions: (a) it needs to be general enough to describe model performance over a broad range of possible scenarios and (b) it needs to be able to discern whether the performance difference between models is statistically significant. It turns out that ROC curves answer both of these questions in a highly visual manner. Consider Figure 5(a), here we have two classifiers plotted in a ROC graph together with their respective 95% confidence bands (vertical bars) (Macskassy & Provost, 2004). It is easy to see that the curve that stretches almost into the top left corner represents the performance of the superior model (for a tpr = 0.9 this model commits virtually no false positives). In addition, because the confidence bands of the two curves are clearly separated we can state that the performance difference between the two models is statistically significant. In Figure 5(b) the situation is not so clear-cut. We again have two classifiers and the curve that reaches closer to the top left corner of the graph denotes the better performing model. However, since the confidence bands overlap, the performance difference between these two models is not statistically significant. In addition, closer inspection reveals that the confidence band for the upper curve is slightly wider than for the lower curve suggesting greater variability in the performance of the better performing model.

Figure 5. ROC curves with 95% confidence bands. (a) Two classifiers with a statistically significant difference in their performance. (b) Two classifiers whose difference in performance is not statistically significant



Future Trends

ROC analysis enjoys a continued growth of interest. Since 2004 there have been regularly scheduled workshops, the *Workshops on ROC Analysis in Machine Learning* (ROCML), which bring together an international group of researchers. Robust tools such as the ROCR package[3] for the R environment (Sing, Sander, Beerenwinkel, & Lengauer, 2005) contribute to the rapid adoption of ROC analysis as the preferred model analysis technique. At a technical level, the most important development is the extension of this analysis technique from binary classification problems to multi-class problems providing a much wider applicability of this technique (Everson & Fieldsend, 2006; Lane, 2000; Srinivasan, 1999).

CONCLUSION

Although brief, we hope that this overview provided an introduction to the fact that ROC analysis provides a powerful alternative to traditional model performance assessment using confusion matrices. We have shown that in contrast to traditional scalar performance metrics such as accuracy, recall, and precision derived from the confusion matrix, ROC analysis provides a highly visual account of a model's performance over a range of possible scenarios. We have also shown that ROC analysis is robust with respect to class skew, making it a reliable performance metric in many important application areas where highly skewed data sets are common (e.g. fraud detection).

KEY TERMS

Class Skew: In probability theory and statistics skewness is a measure of asymmetry of a distribution. Class skew refers to the asymmetry of the class distribution.

Classification Model/Classifier: A mathematical construct such as a decision tree or neural network that models the relationship between independent and dependent variables of a classification problem. Once such a model has been constructed it can be used to predict classifications on new data instances.

Confusion Matrix: A table that relates actual and predicted classifications by a model.

Model Assessment/Evaluation: The process of evaluating the key performance characteristics of a classification model. This is usually done within the context of a problem domain with specific model performance requirements.

Model Selection: The process of selecting a model from a set of potential models given a specific classification problem. The selection is usually based on a specific set of performance metrics dictated by the problem domain.

Optimal Operating Point: The point on the ROC curve where a model has the largest true positive rate while committing the smallest number of false positives.

Performance Metric: A performance-related measurement.

Receiver Operating Characteristic (ROC) Curve: A cost-benefit plot that describes the performance of a classification model.

INTRODUCTION

One standard Data Mining setting is defines by a set of n observations on a variable of interest Y and a set of p explanatory variables, or features, $x = (x_1,...,x_p)$, with the objective of finding a 'dependence' of Y on x. Such dependencies can either be of direct interest by themselves or used in the future to predict a Y given an observed x. This typically leads to a model for a conditional central tendency of $Y|x$, usually the mean $E(Y|x)$. For example, under appropriate model assumptions, Data Mining based on a least squares loss function (like linear least squares or most regression tree approaches), is as a maximum likelihood approach to estimating the conditional mean.

This chapter considers situations when the value of interest is not the conditional mean of a continuous variable, but rather a different property of the conditional distribution $P(Y|x)$, in particular a specific quantile of this distribution. Consider for instance the 0.9^{th} quantile of $P(Y|x)$, which is the function $c(x)$ such that $P(Y<c(x)|x) = 0.9$. As discussed in the main section, these problems (of estimating conditional mean vs. conditional high quantile) may be equivalent under simplistic assumptions about our models, but in practice they are usually not. We are typically interested in modeling extreme quantiles because they represent a desired 'prediction' in many business and scientific domains. Consider for example the motivating Data Mining task of estimating customer wallets from existing customer transaction data, which is of great practical interest for marketing and sales. A customer's wallet for a specific product category is the total amount this customer can spend in this product category. The vendor observes what the customers actually bought from him in the past, but does not typically have access to the customer's budget allocation decisions, their spending with competitors, etc. Information about customer's wallet, as an indicator of their potential for growth, is considered extremely valuable for marketing, resource planning and other tasks. For a detailed survey of the motivation, problem definition, see Rosset et al. 2005. In that paper we propose the definition of a customer's REALISTIC wallet as the 0.9^{th} or 0.95^{th} quantile of their conditional spending - this can be interpreted as the quantity that they may spend in the best case scenario. This task of modeling what a vendor can hope for rather than could expect turns out to be of great interest in multiple other business domains, including:

- When modeling sales prices of houses, cars or any other product, the seller may be very interested in the price they may aspire to get for their asset if they are successful in negotiations. This is clearly different from the 'average' price for this asset and is more in line with a high quantile of the price distribution of equivalent assets. Similarly, the buyer may be interested in the symmetric problem of modeling a low quantile.
- In outlier and fraud detection applications we may often have a specific variable (such as total amount spent on a credit card) whose degree of 'outlyingness' we want to examine for each one of a set of customers or observations. This degree can often be well approximated by the quantile of the conditional spending distribution given the customer's attributes. For identifying outliers we may just want to compare the actual spending to an appropriate high quantile, say 0.95.
- The opposite problem of the same notion of 'how bad can it get' is a very relevant component of financial modeling and in particular Value-at-Risk (Chernozhukov and Umantsev, 2001).

Addressing this task of quantile predictions, various researches have proposed methods that are often adaptations of standard expected value modeling approaches to the quantile modeling problem, and demonstrated that their predictions are meaningfully different from traditional expected value models.

BACKGROUND

Building and Evaluating Quantile Models

This section reviews some of the fundamental statistical and algorithmic concepts underlying the two main phases of predictive modeling - model building and model evaluation and selection - when the ultimate data mining goal is to predict high quantiles. Let us start from the easier question of model evaluation and model selection: given several models for predicting high quantiles and an evaluation data set not used for modeling, how can we estimate their performance and choose among them? The key to this problem is finding a loss function which describes well our success in predicting high quantile and evaluate the performance using this loss function. Clearly, the most important requirement from a loss function for evaluation is that the model which always predicts the conditional quantile correctly will have the best expected performance. Such a loss function indeed exists (Koenker, 2005).

Define the quantile loss function for the p^{th} quantile to be:

$$L_p(y,\hat{y}) = \begin{cases} p(y-\hat{y}) & \text{if } y \geq \hat{y} \\ (1-p)(\hat{y}-y) & \text{otherwise} \end{cases} \quad (1)$$

Figure 1 shows the quantile loss function for $p \in \{0.2, 0.5, 0.8\}$. With p=0.5 this is just absolute error loss. Expected quantile loss is minimized by correctly predicting the (conditional) p^{th} quantile of the conditional distribution. That is, if we fix a prediction point x, and define $c_p(x)$ to be the p^{th} quantile of the conditional distribution of Y given x:

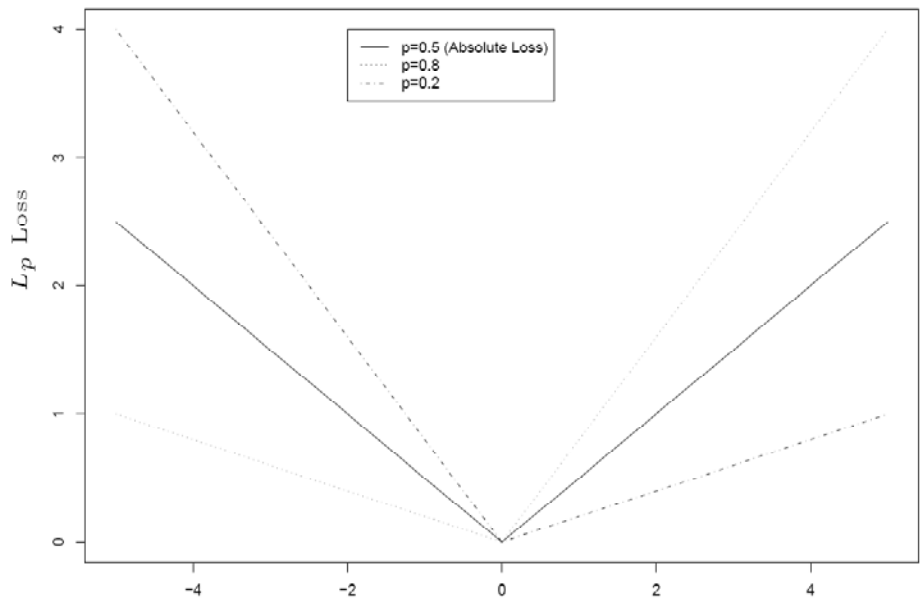
$$P(Y \leq c_p(x) \mid x) = p, \forall x$$

then the loss is optimized in expectation at every point by correctly predicting $c_p(x)$:

$$\arg\min_c E(L_p(Y,c) \mid x) = c_p(x)$$

With p=0.5, the expected absolute loss is minimized by predicting the median, while when p=0.9 we are in

Figure 1. Quantile loss functions for some quantiles



fact evaluating a model's ability to correctly predict the 90th percentile of the distribution $P(Y|x)$.

A different approach to evaluation is to look at the proportion of positive and negative residuals on the holdout data. A perfect prediction model for the 0.9th quantile will predict a value that is higher than the actual observed holdout response 90% of the time, on average. Thus we can examine whether the actual percentage of the time that the predictions are higher than observed response is indeed close to that, as a way of 'evaluating' high-quantile models. This is dangerous, of course, because a model which predicts $+\infty$ 90% of the time and $-\infty$ the other 10% would be perfect according to this measure.

On the modeling side, our first observation is that any property of the conditional distribution $P(Y|x)$ can be estimated well if we estimate well the whole distribution. In particular, if we have a parametric model for $P(Y|x)$ which we believe is true and which we have enough data to estimate, then it is often the best policy to apply all our effort towards estimating this model's parameters well (e.g., using a maximum likelihood approach), regardless of what property of $P(Y|x)$ we are ultimately interested in. For example, if we believe that $P(Y|x)$ is homoscedastic Gaussian and $E(Y|x) = \beta x$ is linear in x, then a maximum likelihood approach would call for fitting a linear regression model of Y on x. Furthermore, this would also trivially imply that the 0.9th quantile of $P(Y|x)$ is linear in x, and is simply $E(Y|x)$+ constant.

However, parametric assumptions are usually over-simplifications of realistic modeling problems, especially those encountered in complex data-mining domains, and one should either dispose with them completely (and choose non-parametric approaches), or treat them with skepticism. An alternative to the parametric approach is to build the model by minimizing an 'empirical risk' over the training data, which represents well the prediction task. In the case of quantile modeling, the quantile estimation loss function certainly qualifies (a similar approach leads Friedman et al. 2000 to advocate the logistic regression loss function for boosting, for example).

In practice, both of these approaches may have advantages and disadvantages. An additional consideration is one of variance, especially when modeling high quantiles - does the high-quantile loss function allow us to make efficient use of the data for modeling?

MAIN FOCUS

Over the recent past, the modeling of quantiles has received increasing attention. The modeling objectives were either prediction or to gain insights how the statistical dependencies for quantiles differ from expected value models. We are aware several such quantile estimation methods, of which we discuss two below. In addition, we present how two of the best studied and also practically most common modeling approaches in machine learning (k-nearest neighbors and regression trees) can be adjusted to model the quantiles.

Linear Quantile Regression

A standard technique for quantile regression that has been developed and extensively applied in the Econometrics community is linear quantile regression (Koenker, 2005). In linear quantile regression, we assume that the conditional quantile function is a linear function of the explanatory variables of the form $\beta \cdot x$ and we estimate the parameters $\hat{\beta}$ that minimize the quantile loss function (Equation 1). It can be shown that this minimization is a linear programming problem and that it can be efficiently solved using interior point techniques (Koenker, 2005). Implementations of linear quantile regression are available in standard statistical analysis packages such as R and SAS. The obvious limitation of linear quantile regression is that the assumption of a linear relationship between the explanatory variables and the conditional quantile function may not be true. To circumvent this problem, Koenker (2005) suggests using nonlinear spline models of the explanatory variables. Recently, a kernel quantile regression approach has also been proposed for the same purpose.

Kernel Quantile Estimation

Takeuchi et al. (2005) have recently proposed a technique for nonparametric quantile estimation that applies the two standard features of kernel methods to conditional quantile estimation: regularization and the kernel trick. They show that a regularized version of the quantile loss function can be directly minimized using standard quadratic programming techniques. By choosing an appropriate kernel, such as a radial basis function kernel, one can obtain nonlinear conditional quantile estimates. They compare their method experimentally

to linear quantile regression and to the nonlinear spline approach suggested by Koenker (2005) on many small datasets for different quantiles and find that it performs the best in most cases.

The main disadvantage of this technique as a data mining method is that it is not scalable, as the computational time grows super-linearly with the number of examples. This is worsened by the fact that the kernel parameters have to be chosen through cross-validation on the training data. Such limitations render the approach unsuitable for most realistic modeling problems.

Quantile k-Nearest Neighbor

The traditional k-nearest neighbor model (kNN) is defined as

$$\hat{y}(x) = 1/k \sum_{x_i \in N_k(x)} y \tag{2}$$

where $N_k(x)$ is the neighborhood of x defined by the k closes points x_i in the training sample for a given distance measure (e.g., Eucledian). From a statistical perspective we can view the set $y_j \in N_k(x)$ as a sample from the approximated conditional distribution of $P(Y|x)$. The standard kNN estimator of $\hat{y}$ is simply the expected value of this conditional distribution approximated by a local neighborhood. For quantile estimation we are not interested in the expected value (i.e., an estimate of $E(Y|x)$) but rather a particular quantile $c_p(x)$ of the conditional distribution $P(Y|x)$ such that $P(Y>c_p(x)|x)=q$. Accordingly we can estimate $c_p(x)$ in a k-nearest neighbor setting as the q^{th} quantile of the empirical distribution of $\{y_j : x_j \in N_k(x)\}$. If we denote that empirical distribution by:

$$\hat{G}_x(c) = 1/k \sum_{x_j \in N_k(x)} 1\{y_j \le c\} \tag{3}$$

then our kNN estimate of the q^{th} quantile of $P(Y|x)$ would be $\hat{G}_x^{-1}(q)$.

The interpretation is similarly that the values of Y in the neighborhood $N_k(x)$ are a sample from the conditional distribution $P(Y|x)$ and we are empirically estimating its q^{th} quantile. An important practical aspect of this estimate is that, in contrast to the standard kNN estimates, it imposes a constraint on k. While k=1 produces an unbiased (while high variance) estimate of the expected value, the choice of k has to be at least 1/(1-q) to provide an upper bound for the estimate of the q^{th} 'high' quantile (more generally we have $k \ge \max(1/q, 1/(1-q))$).

The definition of neighborhood is determined based on the set of variables, the distance function and implicit properties such as scaling of the variables. The performance of a kNN model is very much subject to the suitability of the neighborhood definition to provide a good approximation of the true conditional distribution - this is true for the standard problem of estimating the conditional mean and no less so for estimating conditional quantiles.

Quantile Regression Tree

Tree-induction algorithms are very popular in predictive modeling and are known for their simplicity and efficiency when dealing with domains with large number of variables and cases. Regression trees are obtained using a fast divide and conquer greedy algorithm that recursively partitions the training data into subsets. Therefore, the definition of the neighborhood that is used to approximate the conditional distribution is not predetermined as in the case of the kNN model but optimized locally by the choice of the subsets. Work on tree-based regression models traces back to Morgan and Sonquist (1963) but the major reference is the book on classification and regression trees (CART) by Breiman et al. (1984). We will limit our discussion to this particular algorithm. Additional regression tree implementation include RETIS (Karalic, 1992), CORE (Obnik-Sikonja, 1997,) M5 (Quinlan, 1993), RT (Torgo, 1997).

A tree-based modeling approach is determined predominantly by three components:

1. The **splitting criterion** which is used to select the next split in the recursive partitioning,
2. The **pruning method** that shrinks the overly large tree to an optimal size after the partitioning has finished in order to reduce variance,
3. The **estimation method** that determines the prediction within a given leaf.

The most common choice for the splitting criterion is the least squares error (LSE). While this criterion is consistent with the objective of finding the conditional expectation, it can also be interpreted as a measure

of the improvement of the approximation quality of the conditional distribution estimate. Tree induction searches for local neighborhood definitions that provide good approximations for the true conditional distribution *P(Y|x)*. So an alternative interpretation of the LSE splitting criterion is to understand it as a measure of dependency between *Y* and an x_i variable by evaluating the decrease of uncertainty (as measured by variance) through conditioning. In addition, the use of LSE leads to implementations with high computational efficiency based on incremental estimates of the errors for all possible splits.

Pruning is the most common strategy to avoid overfitting within tree-based models. The objective is to obtain a smaller sub-tree of the initial overly large tree, excluding those lower level branches that are unreliable. CART uses Error-Complexity pruning approach which finds a optimal sequence of pruned trees by sequentially eliminating the subtree (i.e., node and all its ancestors) that minimizes the increase in error weighted by the number of leaves in the eliminated subtree:

$$g(t,T_t) = \frac{Err(t) - Err(T_t)}{S(T_t) - 1}$$

where $Err(T_t)$ is the error of the subtree T_t containing t and all its ancestors, and *Err(t)* is the error if it was replaced by a single leaf, and $S(T_t)$ is the number of leaves in the subtree. *Err()* is measured in terms of the splitting criterion (i.e., for standard CART it is squared error loss). Given an optimal pruning sequence, one still needs to determine the optimal level of pruning and Breiman et al. (1984) suggest cross validation on a holdout set.

Finally CART estimates the prediction for a new case that falls into leaf node *l* similarly to the kNN algorithm as the mean over the set of training responses D_l in the leaf:

$$\hat{y}_l(x) = \frac{1}{n_l} \sum_{y_j \in D_l} y_i$$

where n_l is the cardinality of the set D_l of training cases in the leaf. Given our objective of quantile estimation, the most obvious adjustment to CART is to replace the sample mean estimate in the leaves with the quantile estimate using the empirical local estimate $\hat{G}_{D_l}(c)$ of *P(Y|x)* as in equation (3).

In initial empirical work we observe that the empirical results suggest that changing the splitting to quantile loss does not improve the predictive performance of quantile trees. This is consistent with the interpretation of LSE as a measure of variance-reduction and thereby of the dependency between *Y* and an x_i.

FUTURE TRENDS

The importance of quantile modeling in Data Mining application areas will continue to grow as more and more researchers and practitioners discover the utility of moving beyond conditional-mean estimation, into estimation of conditional quantiles, as a way of expressing optimistic aspirations (like in the wallet estimation problem) or conservative loss estimates (like when modeling value at risk). Some of the interesting research questions that need to be addressed include:

- Can effective quantile modeling approaches be devised for extreme quantiles (like 0.999), to serve in outlier detection, fraud analysis etc.
- What is the effect of the strong hetero-skedasticity often present in the data we model in Data Mining applications on the effectiveness of conditional quantile estimation? How does it compare to the effect on conditional mean estimation? Can we describe the conditions under which quantile modeling may be a better approach in general?

CONCLUSION

In this chapter we presented a new class of quantile modeling problems that are highly relevant in many business domains, including wallet estimation, price/salary prediction and value-at-risk. We reviewed the statistical considerations involved in designing methods for high-quantile estimation and described some existing quantile modeling methods, as well as our own adaptations of kNN and CART to quantile modeling.

In summary, there is a set of algorithms readily available to address the relevant issue of quantile modeling. The necessary adjustments to classical machine learning techniques such as tree induction are straight forward and result in reliable, interpretable, and efficient solutions.

KEY TERMS

Customer Wallet Estimation: A modeling problem, of estimating how much money a company's customers could potentially be spending with it (as opposed to how much they are actually spending). It is important for marketing and planning purposes.

Linear Quantile Regression: Linear regression model of the form $\beta \cdot x$ where β is estimated subject to minimization of quantile loss using linear programming.

Nearest Neighbors and Regression Trees: Two of the most commonly used approaches for regression modeling. Both seek to define for every point $\boldsymbol{x}$ a 'neighborhood' of similar points and then predict the response Y at point $\boldsymbol{x}$ as the average of the neighborhood.

Quantile: Given a random variable Y, the p^{th} quantile of Y with $0 \leq p \leq 1$ is the value c such that $P(Y \leq c) = p$.

Quanting: Reduction approach to quantile estimation that constructs an ensemble of classifiers from observations that are weighted according to the quantile loss.

Quantile Loss: An asymmetric loss function, parameterized by p whose expected loss is minimized by correctly predicting the conditional p^{th} quantile. Thus, it is useful both for building and evaluating quantile models.

Quantile Modeling: A predictive modeling problem which seeks to model the conditional p^{th} quantile of the response Y given the features $\boldsymbol{x}$.

Quantile Nearest Neighbors and Quantile Regression Trees: Versions of these two methods that have been adapted to predicting quantiles of Y given $\boldsymbol{x}$, by changing either the neighborhood definition, or the averaging method, or both.

Modeling Score Distributions

Anca Doloc-Mihu
University of Louisiana at Lafayette, USA

INTRODUCTION

The goal of a web-based retrieval system is to find data items that meet a user's request as fast and accurately as possible. Such a search engine finds items relevant to the user's query by scoring and ranking each item in the database. Swets (1963) proposed to model the distributions of these scores to find an optimal threshold for separating relevant from non-relevant items. Since then, researchers suggested several different score distribution models, which offer elegant solutions to improve the effectiveness and efficiency of different components of search systems.

Recent studies show that the method of modeling score distribution is beneficial to various applications, such as outlier detection algorithms (Gao & Tan, 2006), search engines (Manmatha, Feng, & Rath, 2001), information filtering (Zhang & Callan, 2001), distributed information retrieval (Baumgarten, 1999), video retrieval (Wilkins, Ferguson, & Smeaton, 2006), kernel type selection for image retrieval (Doloc-Mihu & Raghavan, 2006), and biometry (Ulery, Fellner, Hallinan, Hicklin, & Watson, 2006).

The advantage of the score distribution method is that it uses the statistical properties of the scores, and not their values, and therefore, the obtained estimation may generalize better to not seen items than an estimation obtained by using the score values (Arampatzis, Beney, Koster, & van der Weide, 2000). In this chapter, we present the score distribution modeling approach, and then, we briefly survey theoretical and empirical studies on the distribution models, followed by several of its applications.

BACKGROUND

The primary goal of information retrieval is to retrieve all the documents which are relevant to a user query, while retrieving as few non-relevant documents as possible (Baeza-Yates & Ribeiro-Neto, 1999). This is achieved by ranking the list of documents according to their relevance to the user's query. Since relevance is a subjective attribute, depending on the user's perception of the closeness between the user submitted query and the real query from her or his mind, building a better way to retrieve data is a challenge that needs to be addressed in a retrieval system.

In other words, a retrieval system aims at building the request (query) that best represents the user's information need. This optimal request is defined by using an explicit data-request matching (Rocchio, 1971) that should produce a ranking in which all relevant data are ranked higher than the non-relevant data. For the matching process, a retrieval system uses a retrieval function, which associates each data-query pair with a real number or score (the retrieval status value). Then, the retrieval system uses these scores to rank the list of data.

However, researchers (Swets, 1963; Arampatzis, Beney, Koster, & van der Weide, 2000; Manmatha, Feng, & Rath, 2001) raised the question of whether or not the statistical properties of these scores, displayed by the shape of their distribution, for a given query, can be used to model the data space or the retrieval process. As a result, they proposed and empirically investigated several models of the score distributions as solutions to improve the effectiveness and efficiency of the retrieval systems. The next section introduces the score distribution method.

MAIN FOCUS

The Score Distribution Method

The probability ranking principle (Robertson, 1977) states that a search system should rank output in order of probability of relevance. That is, the higher the score value of the document, the more relevant to the query is considered the document to be. In the binary relevance case, which is the case we are interested in, the ideal retrieval system associates scores to the relevant and non-relevant data such that the two groups are well

separated, and relevant data have higher scores than the non-relevant data. In practice, retrieval systems are not capable to completely separate the relevant from the non-relevant data, and therefore, there are non-relevant data with higher score values than those of some relevant data.

The score distribution method tries to find a good way to separate these two groups of data by using statistical properties of their scores. The method assumes that the relevant and non-relevant data form two separate groups, with each group being characterized by its own characteristics different from the other group. For each group, the method plots the corresponding score values within the group, and then, tries to find the shape of the curve generated by these scores. In fact, this curve is approximated with a distribution usually chosen via experimental results (the best fit from a set of known distributions, such as normal, exponential, Poisson, gamma, beta, Pareto). Once the two distributions are known (or modeled), they are used to improve the search system.

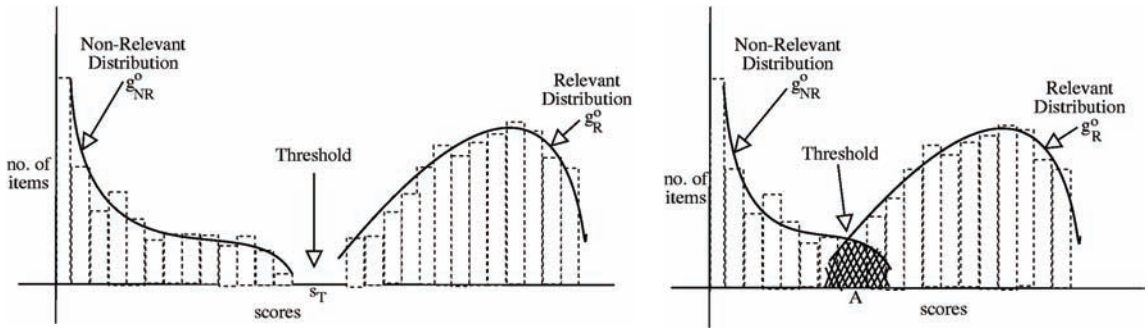
Figure 1 illustrates the score distribution method, (a) in the ideal case, when the relevant and non-relevant data are well separated by the retrieval system, and (b) in a real case, when there are non-relevant data with score values higher than those of some relevant data. The scores of non-relevant data are grouped toward the left side of the plot, and the scores of relevant data are grouped toward the right side of the plot. A curve shows the shape of the score distribution of each group (of relevant and non-relevant data, respectively). Note that, in this figure, the two curves (given as densities $g^{O}_{R}(s)$ and $g^{O}_{NR}(s)$) do not display any particular distribution; they represent the curves of some arbitrary distributions. Basically, the score distribution method consists in choosing the best possible shapes of the distributions of the two groups. Then, any relevant (non-relevant) data is assumed to follow its chosen relevant (non-relevant) distribution.

Ideally, the two distribution curves do not meet (Figure 1 (a)), but in reality, the two curves meet at some point. However, as shown in Figure 1 (b), there is a common region between the two score distribution curves (named A). This area is of most interest for researchers; it includes relevant data with score values very close (lower or not) to the score values of non-relevant data. Therefore, by finding a way to minimize it, one finds a way to approximately separate the two data. Another solution is to find a threshold that separates optimally the relevant data from non-relevant ones.

The advantage of the score distribution method is that it uses the statistical properties of the scores (the shape of their distribution) and not their values, which conducts to an estimation of the threshold or the area A (Figure 1 (b)) that may generalize better to not seen data than an estimation method, which uses the score values (Arampatzis, Beney, Koster, & van der Weide, 2000).

We presented the method in the case that the entire data from collection is used. However, for efficiency reason, in practice, researchers prefer to return to user only the top most relevant N data. In this case, as Zhang and Callan (2001) noticed, the method is

Figure 1. Score distributions for relevant and non-relevant data



(a) Ideal case, at which a retrieval system aims, with a clear separation between the relevant and non-relevant data.

(b) Real case, which shows a common region for scores of the relevant and non-relevant data.

biased, especially for low scoring items, which do not occur between these top N chosen items. However, for high scoring data, the model offers a relatively good estimation (Zhang & Callan, 2001; Manmatha, Feng, & Rath, 2001).

Models of Score Distributions

Since introduced by Swets (1963), researchers used various combinations of the two distributions. Some chose the same type of distribution for both groups of data, whereas others argued that these should have different shapes. For example, Swets (1963) proposed two normal distributions of equal variance and later, two unequal variance normals or two exponentials (Swets, 1969); Bookstein (1977) used two Poisson distributions; Baumgarten (1999) used two gamma distributions. From the proposed models that use different distributions, the Gaussian-exponential model, which uses a normal for relevant data and an exponential for non-relevant data, is the most used model (Arampatzis & van Hameren, 2001; Manmatha, Feng & Rath, 2001; Zhang, & Callan, 2001; Collins-Thompson, Ogilvie, Zhang & Callan, 2003; Gao & Tan, 2006; Wilkins, Ferguson & Smeaton, 2006; Doloc-Mihu & Raghavan, 2006).

As shown by these examples, researchers investigated different specific distributions, such as normal, exponential, gamma, Poisson, but, to date, there is no agreement on either one of them as being the best distribution that models the scores or either relevant or not-relevant data. As Robertson (2007) noted recently, "clearly a strong argument for choosing any particular combination of distributions is that it gives a good fit to some set of empirical data" (p. 40). However, researchers addressed this issue in two ways. Some researchers base their models on the empirical evidence, while others try to find theoretical evidence. In the following, we briefly present such recent work on score distributions.

Theoretical Advances on Score Distribution Models

Rijsbergen (1979) observed that for search engines like SMART there is no evidence that the two score distributions should have similar shapes or that they follow Gaussian distributions as proposed by Swets (1963). Recently, some researchers try to find theoretical evidence to this observation. For example, Madigan, Vardi & Weissman (2006) presented an interesting mathematical analysis on the different combinations of distributions. They applied the extreme value theory (Resnick, 1987) to study why early precision increases as collection size grows. Their analysis showed that the asymptotic behavior of two retrieval measures (of effectiveness), P@K, the proportion of the top K documents that are relevant, and C@K, the number of non-relevant documents amongst the top K relevant documents, depends on the score distributions and on the relative proportion between relevant and non-relevant documents in the collection. The results contradict the normal-exponential model of Manmatha et al. (2001), and sustain Swets (1963) model with the remark that different choices (like, exponential-exponential, Pareto-Pareto, Beta-Beta) can result in early precision approaching zero or one or a constant as the number of ranked documents increases.

Robertson (2007) proposes the convexity hypothesis, which is a generalization of the hypothesis of the inverse recall-precision relationship and states that "for all good systems, the recall-fallout curve is convex" (p. 43). This hypothesis can be formulated as a condition on the probability of relevance of a document at an exact score: the higher the score, the higher the probability of relevance. The author proves that models like exponential-exponential (Swets, 1969), normal-normal with equal variances (Swets, 1963), Poisson-Poisson (Bookstein, 1977), gamma-gamma (Baumgarten, 1999) for certain settings of the parameters b and c, hold the convexity condition, and that the normal-normal model with different variances and the normal-exponential model (Manmatha, Feng & Rath, 2001) violate the condition. In conclusion, this theoretical result shows that the distribution models, which do not hold the convexity hypothesis, do not provide general solutions, but they are just reasonable approximations to the real distributions.

Empirical Studies on Score Distribution Models

Manmatha, Feng, & Rath (2001) show empirically that Gaussian-exponential models can fit approximately well the score distributions of the relevant and non-relevant documents corresponding to a given query. Moreover, they propose a model in which these score distributions are used to calculate the posterior prob-

abilities of relevance given the score via Bayes's rule. Experimental results on TREC-3, TREC-4, and TREC-6 data show that this method works for both probabilistic search engines, like INQUERY, and vector space search engines, like SMART, but it offers only an empirical approximation to the real distributions. In the same study, the authors also show that when relevance information is not available, these distributions can be recovered via the expectation-maximization algorithm by fitting a mixture model consisting of a Gaussian and an exponential function.

Applications of Score Distribution Method

As noted by Manmatha et al. (2001), once known, the score distributions can be used to map the scores of a search engine to probabilities. Score distributions can be beneficial to several tasks. A first example concerns the combination of the outputs of different search engines operating on one or more databases in different languages or not. This combination can be performed for example, by averaging the probabilities, or by using the probabilities to select the best engine for each query (Manmatha, Feng, & Rath, 2001).

Another example deals with the task of filtering thresholds. Here, Arampatzis and van Hameren (2001) proposed a score-distributional threshold optimization method for adaptive binary classification tasks. The method was tested on the TREC-9 Filtering Track and obtained the best results when using a Gaussian to model the distribution scores of the relevant documents, and an exponential for the distribution scores of the non-relevant documents. Zhang and Callan (2001) propose an algorithm that addresses the bias aspect of training data in information filtering, which happens because relevant information is not available for documents with scores below the threshold. Based on the Maximum Likelihood Principle, this algorithm estimates the parameters of the two score distributions (Gaussian-exponential model) and the ratios of the relevant and the non-relevant documents. The authors report significant improvement on the TREC-9 Filtering Track.

Baumgarten (1999) proposed a probabilistic solution based on a gamma-gamma model to select and fuse information from document subcollections over a distributed document collection. The model integrates acceptable non-heuristic solutions to the selection and fusion issues in a distributed environment, and shows encouraging experimental results that outperforms its non-distributed counterpart.

Gao and Tan (2006) proposed two approaches to convert output scores from outlier detection algorithms into well-calibrated probability estimates. Their second approach is similar to the one proposed by Manmatha et al. (2001) for search engines; it models the score distributions of outliers as a mixture of a Gaussian and an exponential probability function and calculates the posterior probabilities via Bayes's rule. The reported results show that the method helps in improving the selection of a more appropriate outlier threshold, and in improving the effectiveness of an outlier detection ensemble. Also, as in the case of search engines, the missing labels of outliers can be considered as hidden variables that can be learnt via the expectation-maximization algorithm together with the distribution model parameters.

Recently, the score distribution method was applied to multimedia data. For example, Doloc-Mihu and Raghavan (2006) used score distribution models to address the problem of automatically selecting the kernel type (Cristianini & Shawe-Taylor, 2000; Chapelle, Haffner, & Vapnik, 1999) for a given query in image retrieval. The authors empirically observed a correlation between the different kernel types and the different shapes of the score distributions. The proposed method selects the kernel type for which the surface of the intersection area (A) between the two distributions (see Figure 1 (b)) is minimal. The best retrieval results were obtained for the Gaussian-exponential model of the relevant and non-relevant images represented by color histograms in RGB color space. Further, this model gave also the best fit for fused multi-modal data (Doloc-Mihu & Raghavan, 2007).

Wilkins, Ferguson and Smeaton (2006) proposed a model based on score distributions to automatically generate the weights needed for multi-modal data fusion in video retrieval. Their model was formulated based on empirical observations, and compares features according to the score distribution of the scores of data returned by them on a per query basis. Reported results on TRECVid 2004 and 2005 collections demonstrate the applicability of the model.

Finally, we mention the study performed recently by Ulery et al. (2006) of score-level fusion techniques involving different distribution models for biometric data. The authors used fingerprint and face data to evalu-

ate the effectiveness of eight score fusion techniques. The study concluded that fusing scores is effective, but it depends on a series of factors such as the ability to model score distributions accurately.

FUTURE TRENDS

Future research should focus on developing a well-founded theoretical model for choosing the score distributions that describes the correlations, empirically observed, between score distributions and relevance. Further, such a model should be tested on real-world data to investigate its entire potential.

Different Data Mining tasks, such as mining Web information, mining multimedia, and biomedical data, and information retrieval tasks, such as multi-lingual retrieval, and relevance feedback may benefit from modeling score distributions. Other potential applications such as feature selection and fusion for image, video and sound retrieval need to be considered for multimedia engines.

CONCLUSION

In this chapter, we presented the score distribution modeling approach, which offers elegant solutions to improve the effectiveness and efficiency of different components of search systems. We surveyed several such models used for various tasks, such as ensemble outlier detection, finding thresholds for document filtering, combining the outputs of different search engines, selecting the kernel type in an Image Retrieval System, and fusion of multimodal data in video retrieval and biometry. These applications demonstrate, mostly through empirical testing, the potential of the score distribution models to real world search systems.

KEY TERMS

Expectation-Maximization Algorithm: An iterative algorithm used for finding maximum likelihood estimates of parameters in probabilistic models, where the model depends on unobserved hidden variables.

Fusion: Process of combining two distinct things. **Data fusion** and **Information Fusion** used in Data Mining are generally defined as the set of techniques that combine/merge data/information from multiple sources.

Information Filtering: Process of monitoring information in order to present to the user information items the user is interested in.

Information Retrieval: Science of searching for information in documents, searching for documents themselves, searching for metadata which describe documents, or searching within databases, whether relational stand-alone databases or hypertextually-networked databases such as the World Wide Web (Wikipedia, 2007a). Similarly, Image Retrieval is the science of searching and retrieving images from a large database of digital images (del Bimbo, 2001; Doloc-Mihu, 2007).

Kernel Methods: Class of algorithms for pattern analysis, which use kernel functions that allow to operate in the feature space without ever computing the coordinates of the data in that space, but rather by simply computing the inner products between the corresponding features of all pairs of data in the feature space (Wikipedia, 2007b).

Kernel Type Selection: Process of selecting the form of the kernel function.

Outlier: Data objects from a database, which do not comply with the general behavior or model of the data (Han and Kamber, 2006). **Outlier detection and analysis** is an important data mining task, named **outlier mining**, with applications, for example, in fraud detection.

Score Distribution Model: Model associated with a particular combination of the distributions of the score values of relevant and non-relevant data. There are several models proposed so far, such as exponential-exponential, normal-normal, Gaussian-exponential, gamma-gamma, and so on. However, a good reason for choosing any particular model is based on how good the distributions fit a set of empirical data.

TREC: Text Retrieval Conference that focuses on different information retrieval research areas, or tracks, and provides the infrastructure necessary for large-scale evaluation of text retrieval methodologies.

TRECVID: A conference separate from the TREC conference that focuses on a list of different information retrieval (IR) research areas in content based retrieval of video.

Modeling the KDD Process

Vasudha Bhatnagar
University of Delhi, India

S. K. Gupta
IIT, Delhi, India

INTRODUCTION

Knowledge Discovery in Databases (KDD) is classically defined as the "nontrivial process of identifying valid, novel, potentially useful, and ultimately understandable patterns in large databases" (Fayyad, Piatetsky-Shapiro & Smyth, 1996a). The recently developed KDD technology is based on a well-defined, multi-step "**KDD process**" for discovering knowledge from large data repositories. The basic problem addressed by the KDD process is one of mapping low-level data (operational in nature and too voluminous) to a more abstract form (descriptive approximation or model of the process that generated the data) or a useful form (for example, a predictive model) (Fayyad, Piatetsky-Shapiro & Smyth, 1996b). The KDD process evolves with pro-active intervention of the domain experts, data mining analyst and the end-users. It is a 'continuous' process in the sense that the results of the process may fuel new motivations for further discoveries (Chapman et al., 2000). Modeling and planning of the KDD process has been recognized as a new research field (John, 2000).

In this chapter we provide an introduction to the *process of knowledge discovery in databases (KDD process),* and present some models (conceptual as well as practical) to carry out the KDD endeavor.

BACKGROUND

The process of Knowledge Discovery in Databases consists of multiple steps, and is inherently iterative in nature. It requires human interaction for its applicability, which makes the process subjective. Various parameters require to be adjusted appropriately before the outcome of the process can be applied for decision making.

The process starts with the task of understanding the domain in the context of the goal of the endeavor, and ends with the task of interpretation and evaluation of the discovered patterns. Human centric nature of the process has been emphasized since the early days of inception of the KDD technology (Brachman & Anand, 1996) and vindicated by the veterans (Ankerst, M. 2002). The core of KDD process employs "data mining" algorithms, which aim at searching for interesting models and patterns in the vast search space, and are responsible for actually discovering nuggets of knowledge (Fayyad, Piatetsky-Shapiro & Smyth, 1996a). Often, the key to a successful KDD effort lies not so much in the act of data mining alone but in the pre and post mining steps of the process. Understanding the whole KDD process therefore becomes imperative for the success of the knowledge discovery exercise. Further, a formal model of the KDD process also helps in differentiating and comparing two or more approaches for KDD endeavor.

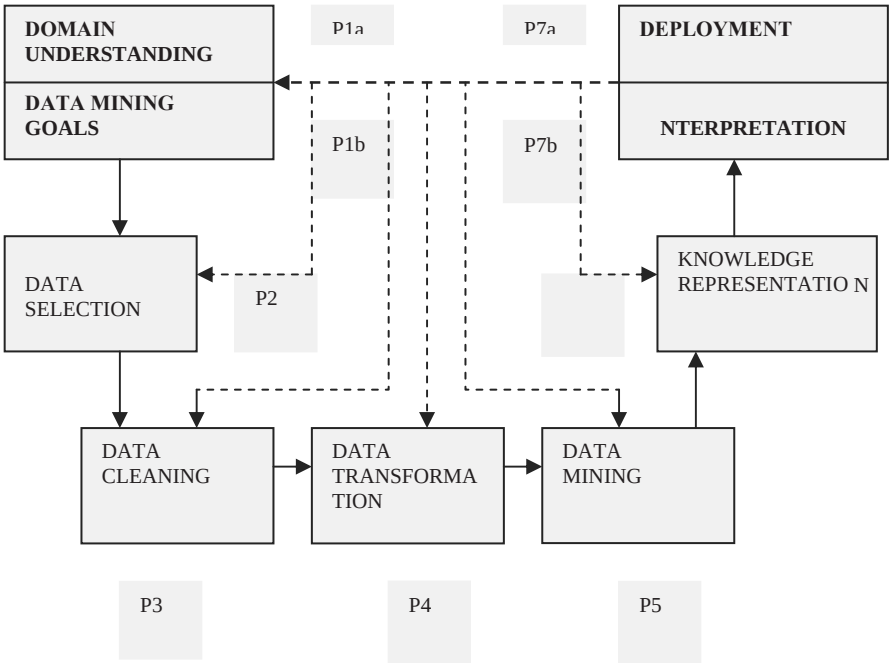
GENERIC STEPS OF THE KDD PROCESS

Figure 1 shows a simple model of the KDD process exhibiting the logical sequencing of the various process steps. The model allows the data miner to effortlessly map the logical process steps (P1 to P7) to the corresponding physical computing processes.

The data flows in a straight forward manner from each process step to the subsequent step as shown by solid lines. The dash lines show the control flow and indicate optional iteration of process steps after the discovered knowledge has been evaluated. We describe below the generic steps of a KDD process.

Domain Understanding and Defining Data Mining Requirements (Step P1(a, b)) are the tasks that

Figure 1. Steps of the KDD process



comprise the first step of the KDD process. Identifying and defining the project goals, assessing the feasibility, planning and preparation of subsequent steps, are some of the sub-tasks that need to be performed during this step. Understanding of the basic characteristics of available data and knowledge of the domain, play an important role in crystallizing the project objectives. Experience and expertise of the domain experts, decision-makers and the end users help in translating the project objectives into knowledge discovery goals.

Data Selection (Step P2) involves laying down the criteria for including the data to be analyzed or excluding the unwanted data. Since all the data may not be relevant for the knowledge discovery goals, the data mining analyst selectively identifies the relevant data, depending on the business questions that need to be answered. For instance, in order to explore the buying patterns of the customers of a particular geographical area, customer addresses can be the selection criterion.

Data Cleaning (Step P3) is performed to ensure domain and semantic validity of data with respect to the goals set in Step P1b. Faulty data capturing methods, transmission errors or legal issues are some causes of "noisy data" in a database apart from the practical data gathering pitfalls. Strategies to handle missing and noisy data have to be decided by the end user and/or domain expert, and must be implemented faithfully before applying the mining algorithm.

Data cleaning assumes added significance for the successful outcome of the KDD process, since most of the mining algorithms do not address the problem of dirty or missing data.

Data Transformation (Step P4) is often required because of syntactic reasons. For example, in a distributed database if the salary attribute is stored in different currencies then it has to be transformed to a pre-decided common currency before undertaking mining. Some data mining algorithms require data to be in a specific format. Transforming numerical attributes to categorical attributes is commonly required before applying *clustering* or *classification* algorithms. For *multilevel association rule* mining, data transformations are required to facilitate mining at different levels of abstraction.

Data Mining (Step P5) results into discovery of hidden patterns by applying a suitable mining algorithm over the "*pre-processed*" (selected, cleaned and transformed) data. The choice of the mining algorithm is influenced by the specification of the discovery goals, type of knowledge to be discovered and nature of data. The mining analyst may have to re-engineer an algo-

rithm in case no suitable algorithm exists to meet the requirement. Scrupulous execution of the earlier steps of the KDD process significantly improves the quality of patterns discovered by the mining algorithm.

Presentation of the Discovered Knowledge (Step P6) facilitates the interpretation of the mining results. Recent advances made in the area of visualization of discovered knowledge make presentation of discovered knowledge more intuitive and meaningful. State-of-art visualization tools for displaying the discovered knowledge to the user are available in most of the data mining packages.

Interpretation and Deployment of the Discovered Knowledge (Step P7(a, b)) are the final steps in an iteration of the KDD process. These steps are crucial for the flow of control, since they involve evaluation of the discovered patterns, either by analysis or by their deployment, and deciding the next action. If the discovered patterns are useful in the context of the mining goals, the KDD project is considered to be successful. Otherwise there may be a need to refine or redefine the goals, or take another look at each of the steps in the KDD process and make necessary changes in steps P2 – P6. This makes KDD an *iterative* and *interactive* process.

It is worth noting that process steps P1 and P7 require intense involvement of the mining analyst, domain expert and the end user - the human elements in the knowledge discovery process.

KDD PROCESS MODELS

The task of modeling the KDD process is challenging because of the diversity of the processes and their uniqueness with respect to each application. In actual practice even within a single domain, the details of the process may vary for each application. We give a brief account of some popular models.

William's Model

A four element - four stage model of the KDD process has been proposed by William and Huang (1996). Being a *conceptual model*, it attempts to capture elements of the process in an abstract way. Motivation for such a model comes from the necessity of a formal theory to guide the practitioners in the effective use of KDD technology.

William's model uses a 4-tuple {*D, L, F, S*} to identify necessary and sufficient elements of the KDD process. Here *D* is the target database, *L* is the knowledge representation language for expressing the discovered model, *F* is the pattern evaluation function and *S* is the set of operations performing the knowledge discovery. *S* is a four stage, operative process element shown in Figure 2, which subsumes the traditional KDD process model (Figure 1). Summarization of several lower level steps in the traditional model to lesser number of higher-level steps does not undermine the complex iterative nature of the KDD process, and importance of human interaction during the process.

William's model provides a framework for distinguishing between different KDD approaches in terms of their constituent elements. Interestingly the process steps that support the KDD operations, themselves form an element in this model.

Reinartz's Model

A practical KDD process model based on the overview of the life cycle of KDD projects at a generic level is shown in Figure 3 (Reinartz, 1997). The model permits need based data flow and control flow in both directions and exhibits an ideal sequence of seven generic tasks in a KDD project.

Reinartz's model combines the tasks of data selection, cleaning and transformation as a single data preparation task. The next task is data exploration, which helps in understanding the interesting data characteristics using statistical and/or visualization tools. For example, identifying areas of high density in the data space using a visualization tool can give an idea of the probable clusters. In this model the interrelationship between the process steps is substantially improved. The transitions between different steps provide a structured and smooth road to go back to any of the previous process step at any stage during the KDD process. The explicit presentation of the transitions emphasizes the importance of evaluation (of the outcome of the current step) and decision-making (what next?) at the end of each process step. Involvement of human elements in the KDD process is reinforced effectively in this model.

Figure 2. The fourth element of the Williams' Model

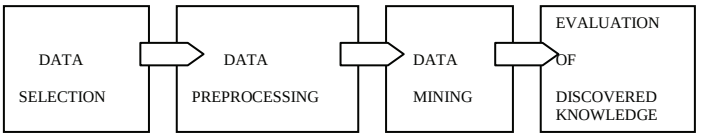


Figure 3. Life cycle of a KDD project (Reinartz 1997)

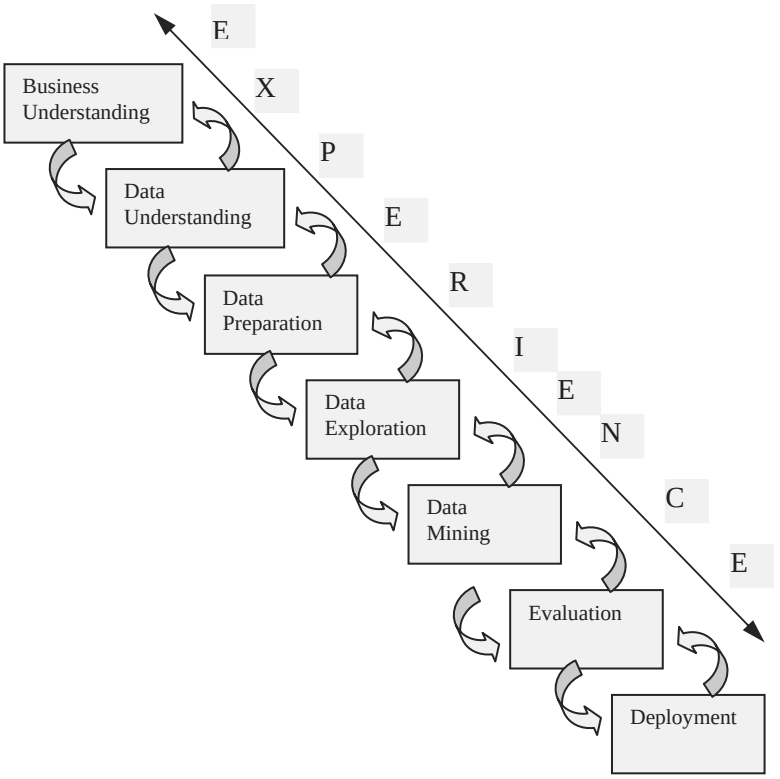
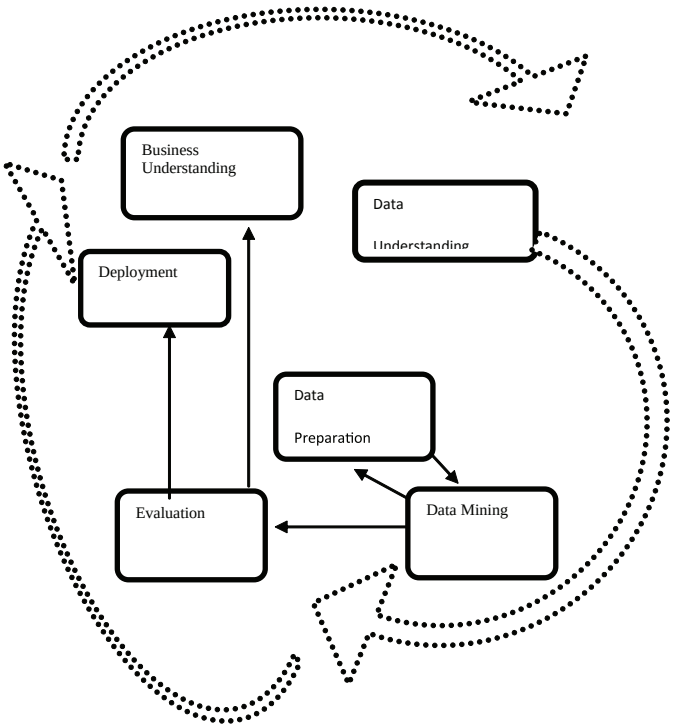


CRISP-DM Model

CRISP-DM (CRoss-Industry Standard Process for Data Mining) is an industry initiative, which aims to develop, validate and promote a standard data mining methodology for knowledge discovery in databases (Chapman et al., 2000). The CRISP-DM model shown in Figure 4 was developed by an industry consortium and it advocates a data mining methodology based on a formal KDD process. The methodology is non-proprietary and freely available. The proposed data mining methodology consists of tasks described at four level of abstraction (from general to specific) - phase, generic tasks, specialized tasks and process instances. We however restrict our attention to the underlying model on which the CRISP-DM methodology is based.

Figure 4 shows the CRISP-DM model, which offers systematic understanding of step-by-step direction, tasks and objectives for every stage of the process - from business understanding, data understanding, data preparation, modeling, to evaluation and deployment. The straight block arrows indicate some of the important and frequent dependencies between stages, though more such dependencies can arise in practice. Back and forth transitions may be unpredictable, complex and unique for each KDD endeavor. The circular arrows in the figure symbolize the continuous nature of the KDD process, indicating its continuity even after a solution has been deployed. It is premised that lessons learned during the process can trigger new, often more focused business questions. Continuity of the KDD process also

Figure 4. CRISP-DM methodology for KDD



ensures that the subsequent KDD exercises will benefit from the experiences of previous ones.

The CRISP-DM model is highly demanding in terms of user interaction and considers the discovery process to be continuous in nature. These features of this model are important since they distinguish it from the earlier models. Due attention is given to the need based transitions from one stage to another, emphasizing the need for critical and decisive evaluation of the outcome at the end of each stage. Although the model is not based on theoretical or academic principles, yet it is very successful because of its neutrality with respect to industry, tools and applications.

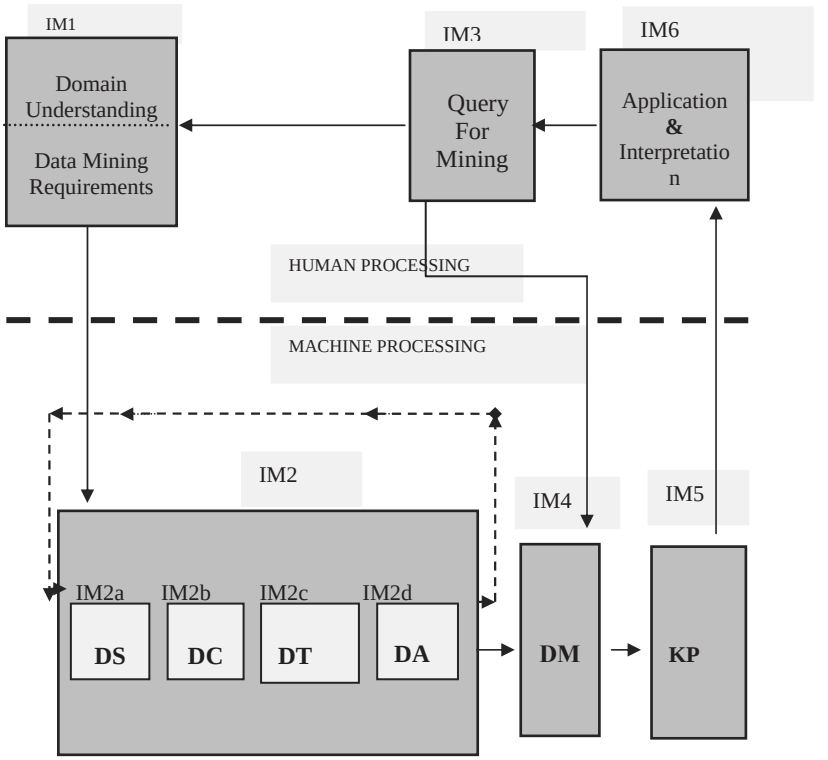
I-MIN Model

The I-MIN model for KDD Process (Figure 5) is based on *Intension Mining* scheme in which the mining requirements are formally documented as schema (Bhatnagar, 2001). This model inherently supports experimentation and monitoring, both functionalities desirable in business and scientific data explorations. Mining queries can be formulated and applications can be developed for experimentation in the KDD process, by varying the target dataset and the mining parameters. The model is downward compatible and provides full functionality available from the traditional KDD process model. Designing and integrating the agents for each of the process steps can realize the model

Step IM1 corresponds to step P1 of the traditional KDD process model (Figure 1) and results into design of a knowledge discovery schema, which formally documents the knowledge discovery goals. The schema is compiled and the resulting meta-data is stored for future use during subsequent steps of the process.

Step IM2 is a compound step in which steps (IM2a - IM2c) are data preparation tasks that map to steps (P2 - P4) of traditional KDD process model. Step IM2d is novel and is responsible for aggregation and possibly partial data analysis, which is carried out in step P5 of traditional KDD process model. Aggregation results into synopsis in a format specific for a mining algorithm. Since the functions for pre-mining and aggregation are already specified in schema, they are performed

Figure 5. I-MIN model for KDD process (DS : Data Selection, DC : Data Cleaning, DT : Data Transformation, DA : Data Aggregation, DM : Data Mining, KP : Knowledge Presentation)



without any human intervention. The dotted line around IM2 (with arrows) indicates that this compound step is periodically and automatically repeated. On each invocation the incremental database is processed and a corresponding aggregated knowledge structure (synopsis) is produced.

Step IM3 signifies initiation of the actual data mining phase. This user-initiated step commences with either formulation of mining query or execution of an application. During step IM4, the query or application is vetted against the corresponding schema and mining algorithm specified in the schema is invoked. The actual mining takes place over the synopsis aggregated during Step IM2d. Step IM4 together with step IM2d corresponds to step P5 of traditional KDD process model. Repeated querying on aggregated data with different sets of parameters facilitates experimentation. Designing applications to analyze the aggregates generated during Step IM2d, helps in monitoring the changing data characteristics in an evolving database.

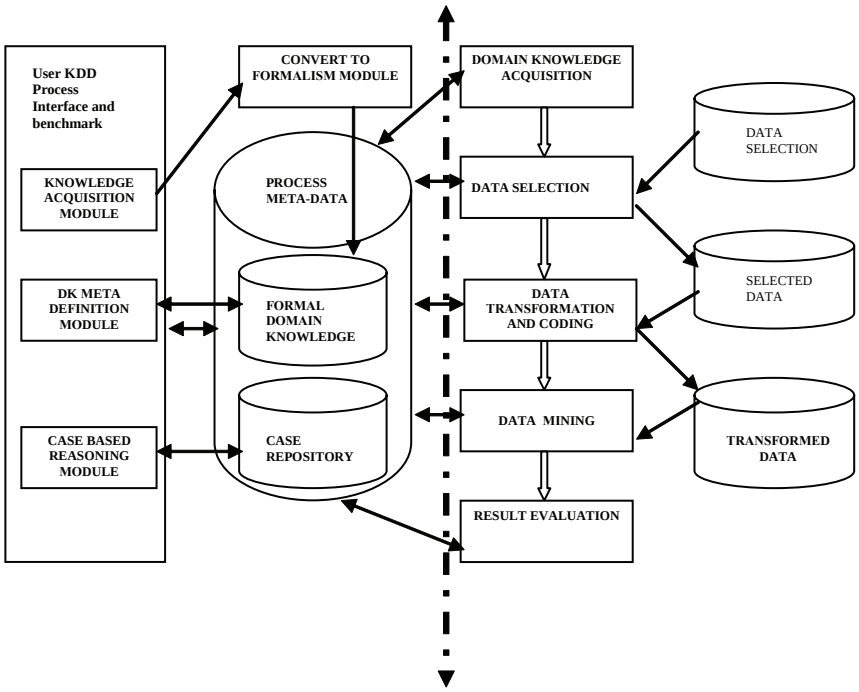
The resulting knowledge is presented and interpreted/applied in steps (IM5 - IM6) as in (P6 - P7). The arrow from IM6 to IM3 permits experimentation and monitoring, useful in real life KDD endeavors, where answers to the business questions set as goal, often fuel the need to answer more questions.

Redpath's Model

Successful automation of the KDD process is a challenging task because of the multiplicity of approaches that often need to be combined for each endeavor. Redpath & Srinivasan (2004) have argued that capturing domain knowledge before starting the endeavor helps in reducing the complexity of the process and facilitates automation. Architecture for partial automation of the KDD process is shown in Figure 6. The architecture is based on the premise that domain knowledge can be exploited to assist in most of the steps of the KDD process including data selection, algorithm selection, results evaluation and results interpretation. This model also utilizes elements like Case Based Reasoning, Process Metadata to optimize the partially automated KDD process.

To the left of the central line lies the process of acquisition of domain knowledge and on the right the

Figure 6. Architecture for a partially automated KDD system (Redpath & Srinivasan, 2004)



KDD process is shown. The arrows across the central line show the role of domain knowledge in executing various KDD process steps automatically.

FUTURE TRENDS

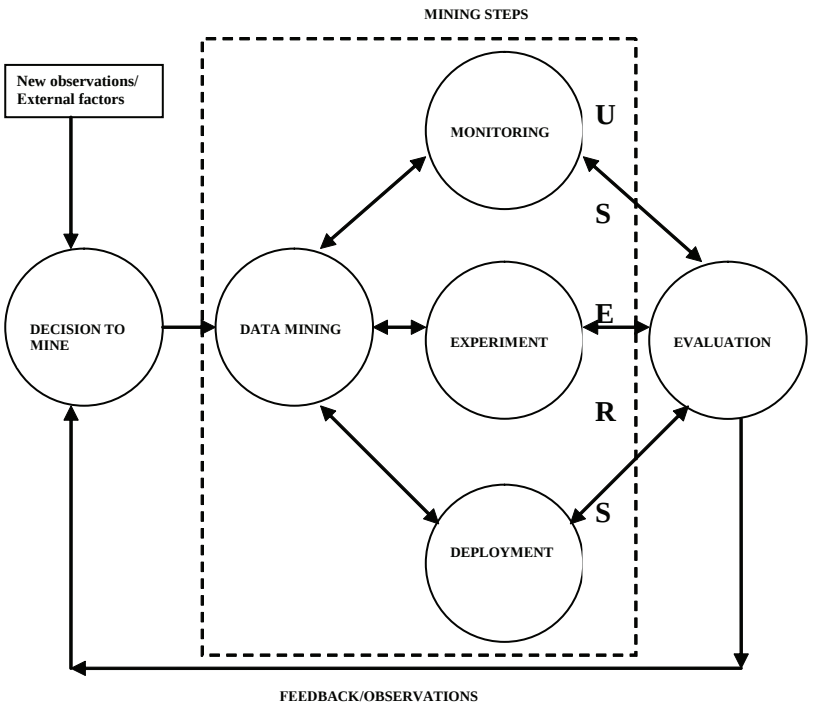
In practice, discovery of knowledge fuels needs to discover more knowledge with varying perspectives. Growth in demands for new mining applications, particularly in environments with evolving database, can be satisfied by either designing a new KDD process for each requirement, or by modeling the process in such a manner that it can meet multiple logically related requirements. It is envisaged that an organization would have several KDD endeavors running either concurrently or at different points in time, for different needs. A need to control, monitor and audit these endeavors would naturally emerge in a big way. Consequently, issues of security, privacy and proper accounting would need to be addressed. A complete and structured documentation of all KDD operations in an organization would help to some extent.

Figure 7 summarizes the real life needs in a KDD savvy organization. KDD process models that satisfy these needs and have a sound theoretical background need to be developed for deeper penetration of KDD technology in decision sciences. Designing new mining algorithms that can be used in I-MIN model assumes importance, since I-MIN model meets most of the functionalities desired in the real life KDD projects.

CONCLUSION

Knowledge Discovery in Databases is a complex human centric process requiring different tools. The success of a KDD project depends on a good mix of tools and skilled analyst. Several models have been proposed to capture the real life KDD endeavors. All

Figure 7. Desired functionality in KDD projects (Bhatnagar, 2001)



the models are unanimous as far as the process steps and data flow are concerned. The differences in the control flow set the models apart. The complex and unique control flow of each endeavor has retarded attempts for full automation of the KDD process. A mechanism to support knowledge discovery operations by allowing interactive explorations, experimentation and monitoring during the mining step is required for a truly user-centric KDD system to facilitate flexibility, efficiency and applicability.

KEY TERMS

Domain Knowledge: The knowledge about the environment in which the KDD endeavor is to be carried out, acquired by the past experiences of the users/experts.

Data Mining: Step in the KDD process that invokes a data-mining algorithm and serves to actually discover patterns that are hidden within the data.

Intension Mining: Is a scheme of knowledge discovery, where the mining needs are documented as *Knowledge Discovery Schema*. The Intension Mining based system pre-processes the incoming data as it arrives in the database at periodic intervals and accumulates partial knowledge. These aggregates (knowledge concentrates) can be mined by the end-user by formulating a suitable query in a specific language (Bhatnagar, 2001).

Interestingness: It is an overall measure of the value of a pattern to the user. It is a combination of the measures of validity, novelty, usefulness, and simplicity of the discovered pattern and is subjective with respect to time and user.

KDD Process: The nontrivial process of discovering hidden knowledge from large data repositories.

Knowledge Discovery in Databases (KDD): Extraction of novel, valid, interesting and useful trends and patterns (nuggets of knowledge) from large data repositories.

Pattern: A pattern is a form/template/model (or, more abstractly, a set of rules) which can be used to make or to generate things or parts of a thing.

INTRODUCTION

An Electronic-Service (E-Service) can be defined as a collection of network-resident software programs that collaborate for supporting users in both accessing and selecting data and services of their interest present in a provider site. Examples of e-services are e-commerce, e-learning, e-government, e-recruitment and e-health applications. E-Services are undoubtely one of the engines presently supporting the Internet Revolution. Indeed, nowadays, a large number and a great variety of providers offer their services also or exclusively via the Internet.

BACKGROUND

In spite of their spectacular development and present relevance, E-Services are far to be considered a stable technology and various improvements could be thought for them. Many of the present suggestions for improving them are based on the concept of adaptivity, i.e., on the capability to make them more flexible in such a way as to adapt their offers and behaviour to the "environment" they are operating in. In this context, systems capable of constructing, maintaining and exploiting suitable profiles for users accessing E-Services appear capable of playing a key role in the future (Kobsa, 2007).

Both in the past and in the present, various E-Service providers exploit (usually rough) user profiles for proposing personalized offers. However, in most cases, the profile construction methodology adopted by them presents some problems. In fact, it often requires a user to spend a certain amount of time for constructing and updating his profile; in addition, the profile of a user stores only information about the proposals which he claims to be interested in, without considering other ones, somehow related to those just provided, possibly interesting him in the future and that he disregarded to take into account in the past.

In spite of present user profile handlers, generally, when accessing an E-Service, a user must personally search the proposals of his interest through it. We argue that, for improving the effectiveness of E-Services, it is necessary to increase the interaction between the provider and the user, on one hand, and to construct a rich profile of the user, taking his interests, needs and past behaviour into account, on the other hand.

In addition, a further important factor must be taken into account. Nowadays, electronic and telecommunications technology is rapidly evolving in such a way as to allow cell phones, palmtops and wireless PDAs to navigate on the Web. These mobile devices do not have the same display or bandwidth capabilities as their desktop counterparts; nonetheless, present E-Service providers deliver the same contents to all device typologies (Communications of the ACM, 2002; ; Smith, Cotter & Oman, 2007).

In the past, various approaches have been proposed for handling E-Service activities; some of them are agent-based. As an example:

- In (Anand, Kearney & Shapcott, 2007) an approach to helping users looking for relevant items

is described. In order to generate its recommendations, this approach integrates user ratings with an ontology describing involved items. This approach is particularly suited for the e-commerce domain.

- In (Mahmood & Ricci, 2007) a travel recommender system, based on the Intelligent Agent technology, is presented. This system builds user profiles by exploiting Reinforcement Learning techniques, and models the recommendation process as a Markov Decision Process.
- In (Medjahed & Bouguettaya, 2005) the Authors propose WebSenior, a system using ontologies to automatically generate Web Services customized to senior citizen needs and government laws. WebSenior is able to manage both simple and composite services. In order to generate these last, it defines a graph, called dependency diagram, in which each vertex is associated with a simple service and each edge denotes a dependency relationship between a pair of services. The problem of computing composite services is, then, regarded as the problem of computing paths in the dependency diagram; this last problem is solved by applying the Floyd-Warshall dynamic programming algorithm.
- In (Ahn, Brusilovsky, Grady, He & Syn, 2007) YourNews, a system capable of helping users in accessing news located on the Web, is proposed. YourNews relies on a user profile built by unobtrusively monitoring user behaviour; this profile is open, in the sense that the corresponding user can interactively provide feedbacks that will be exploited by YourNews to enhance its accuracy.
- In (De Meo, Quattrone, Terracina & Ursino, 2007) a XML-based multi-agent recommender system for supporting online recruitment services is presented. This system handles user profiles for supporting a personalized job search over the Internet. In order to perform its recommendations, it exploits some advanced techniques (e.g., least square error and Pavlovian learning).
- In (Fang & Sheng, 2005) ServiceFinder, a system conceived for supporting citizens in their selection of relevant e-government services, is proposed. ServiceFinder uses Web Mining techniques to discover the *N* services best matching user needs and modifies the home page of an institutional e-government portal by adding to it *N* hyperlinks pointing to these services.
- In (Srivihok & Sukonmanee, 2005) a system capable of supporting e-tourism activities is proposed. This system analyzes past user behaviours and applies the Q-Learning algorithm to build a user profile. After this, it applies a reinforcement algorithm on both user and trip profiles in such a way as to associate a score with each trip proposal. These last are, then, ranked on the basis of their scores and only the top five are presented to the user.

All these systems construct, maintain and use rich data structures regarding both user needs and behaviours; therefore, we can consider them adaptive w.r.t. the user; however, none of them is adaptive w.r.t. the device.

On the other side, in many areas of computer science research, a large variety of approaches that adapt their behaviour on the basis of the device the user is exploiting, has been proposed. As an example:

- In (Samaras & Panayiotou, 2004) the system mPERSONA, aiming to support users equipped with wireless devices to access information sources located on the Web, is proposed. mPERSONA relies on a mobile multi-agent architecture; it associates a user profile (consisting of a set of keywords) with each user and represents the contents of an information source as a hierarchy (called metadata tree). Each time a user submits a query to an information source, mPERSONA isolates the portion of hierarchy (and the corresponding information objects) best fitting his requests; after this, it considers the features of the device he is currently exploiting and adapts the selected contents to them.
- In (Lee, Kang, Choi & Yang, 2006) an approach to Web content adaptation for mobile users is presented. This approach stores user preferences in a suitable profile. When a user is involved in Web browsing activities, it partitions a Web page into blocks, filters out those judged unnecessary and sorts the other ones on the basis of their relevance to the user. Finally, it presents sorted blocks to the user.

- In (Muntean & McManis, 2006) an approach to supporting mobile users in their browsing activities is proposed. This approach considers both user preferences (encoded in a user profile) and device features to suitably modify the content of the Web pages visited by the user; for instance, it can compress or eliminate images, if their sizes are excessive.
- In (Wei, Bhandarkar & Li, 2007) an approach to delivering multimedia data, taking both user preferences and device constraints into account, is proposed. This approach estimates how much a multimedia information object fits both the exigencies of a user and the constraints of the device he is currently exploiting. This information is used to define a knapsack-like problem whose solution allows the selection of the objects to deliver.

These approaches are particularly general and interesting; however, none of them has been conceived for handling E-Services.

MAIN THRUST OF THE CHAPTER

Challenges to Face

In order to overcome the problems outlined above, some challenges must be tackled.

Firstly, a user can access many E-Services, operating in the same or in different application contexts; a faithful and complete profile of him can be constructed only by taking his behaviour on accessing all these sites into account, and by storing the corresponding profile in a unique data structure on his side.

Secondly, for a given user and E-Service provider, it should be possible to compare the profile of the user with the offers of the provider for extracting those proposals that probably will interest him. Existing techniques for satisfying such a requirement are mainly based on either log files or cookies. In the former case they cannot match user preferences and E-Service proposals; in the latter one they need to know and exploit some personal information that a user might consider private.

Thirdly, the typical "one-size-fits-all" philosophy of present E-Service providers should be overcome by developing systems capable of adapting their behaviour to both the profile of the user and the characteristics of the device he is exploiting for accessing them (Communications of the ACM, 2002).

Fourthly, relationships and interactions among users should be taken into account; in fact, they can be exploited to guarantee a certain proactivity degree to the E-Service provider, on one hand, and to create communities of citizens showing similar needs and desires, on the other hand.

System Description

The system we present in this chapter (called *E-Service Adaptive Manager*, ESA-Manager) aims to tackle all challenges mentioned above. It is a multi-agent system for handling user accesses to E-Services, capable of adapting its behaviour to both user and device profiles.

In ESA-Manager a *Service Provider Agent* is present for each E-Service provider, handling the proposals stored therein, as well as the interaction with users. In addition, an agent is associated with each user, adapting its behaviour to the profiles of both the user and the device he is currently exploiting. Actually, since a user can access E-Service providers by means of different devices, his profile cannot be stored in only one of them; indeed, it must be handled and stored in a support different from the devices generally exploited by him for accessing E-Service providers. As a consequence, it appears compulsory the exploitation of a *Profile Agent*, storing the profiles of both involved users and devices, and a *User-Device Agent*, associated with a specific user operating by means of a specific device, supporting him in his activities. As a consequence of the previous reasoning, for each user, a unique profile is mined and maintained, storing information about his behaviour in accessing all E-Service providers. In this way, ESA-Manager tackles the first challenge mentioned above.

Whenever a user accesses an E-Service by means of a certain device, the corresponding Service Provider Agent sends information about its proposals to the User-Device Agent associated with him and the device he is exploiting. The User-Device Agent determines similarities among the proposals presented by the provider and the interests of the user. For each of these similarities, the Service Provider Agent and the User-Device Agent cooperate to present to the user a group of Web

pages, adapted to the exploited device, illustrating the proposal. We argue that this behaviour provides ESA-Manager with the capability of supporting the user in the search of proposals of his interest delivered by the provider. In addition, the algorithms underlying ESA-Manager allow it to identify not only the proposals probably of interest to him in the present but also other ones possibly of interest to him in the future and that he disregarded to take into account in the past. In our opinion, this is a particularly interesting feature for a new approach devoted to deal with E-Services. Last, but not the least, it is worth observing that, since user profile management is carried out at the user side, no information about the user profile is sent to E-Service providers. In this way, ESA-Manager solves privacy problems left open by cookies. All reasonings presented above show that ESA-Manager is capable of tackling also the second challenge mentioned previously.

In ESA-Manager device profile plays a central role. Indeed, the proposals of a provider shown to a user, as well as their presentation formats, depend on the characteristics of the device the user is presently exploiting. However, the ESA-Manager capability of adapting its behaviour to the device the user is exploiting is not restricted to the presentation format of the proposals; in fact, exploited device can influence also the computation of the *interest degree* associated with the proposals presented by each provider. Specifically, one of the parameters which the interest degree associated with a proposal is based on, is the time the user spends in visiting the corresponding Web pages. In ESA-Manager, this time is not considered as an absolute measure, but it is normalized w.r.t. both the characteristics of the exploited device and the navigation costs. This reasoning allows us to argue that ESA-Manager tackles also the third challenge mentioned above.

In addition, ESA-Manager uses a Social Network to partition citizens accessing the system into homogeneous clusters called *communities*; these communities are set up on the basis of shared interests/needs of their members rather than on demographic data. Each time a citizen submits a query, ESA-Manager forwards the corresponding answers (i.e., the corresponding service proposals) also to the members of his community.

All these activities are carried out by a *Social Network Agent* which catches user queries and exploits them to both organize communities and handle communications with them. This confers a high level of *proactivity* to our system because it can recognize and recommend potentially relevant services to a citizen even though he is not aware of their existence. In addition, if, for a citizen, interests/needs have been changed, the Social Network Agent automatically assigns him to another community and, at the same time, suggests him the latest services recommended to the members of his new community. In this way, our system tackles also the fourth challenge mentioned above.

A final important characteristic of our system is that it encourages a socially inspired mechanism for service management. In fact, users can freely discuss among them to propose new services; as a consequence, the top-down approach for service delivery (in which providers push their services to users and impose them their formalism, terminology, access policy, features, etc.) is coupled and, hopefully, substituted by a bottom-up one (in which users join up to form communities who raise their requirements about desired services to providers). This provides our system with notable social capabilities in that it can suitably channelize user demands. In fact, in this scenario, users are encouraged to debate in such a way as to propose the activation of new services of interest to them.

FUTURE TRENDS

The spectacular growth of the Internet during the last decade has strongly conditioned the E-Service landscape. Such a growth is particularly surprising in some application domains, such as financial services or e-government.

As an example, the Internet technology has enabled the expansion of financial services by integrating the already existing, quite variegate, financial data and services and by providing new channels for information delivery. However, E-Services are not a leading paradigm only in business contexts; for instance, they are vigorously applied by governmental units at national, regional and local levels around the world.

A further interesting research trend consists of investigating the possibility to integrate an E-Service access system with a Decision Support one; in this way, user behaviour could be analyzed (for instance, by means of a Data Mining tool) for determining the key features of the most appreciated services. This information could be particularly useful for provider managers when they need to decide the new services to propose. This last feature would allow the realization of a hybrid E-

Service system, embodying the functionalities of both seeker-oriented and company-oriented systems.

CONCLUSION

In this paper we have proposed ESA-Manager, an adaptive multi-agent system for supporting a user, accessing an E-Service provider, in the search of proposals appearing to be appealing according to his interests and behaviour.

We have shown that ESA-Manager is adaptive w.r.t. the profile of both the user and the device he is currently exploiting. Finally, we have seen that it is proactive in that it suggests potentially interesting services to a user even if he did not explicitly require them.

As for future work, we would like to investigate whether a hierarchical clustering algorithm can be fruitfully exploited to improve the quality of user community management. The output of this algorithm would be a tree-like data structure whose nodes represent potential communities. This data structure would allow specialization/generalization relationships among communities to be handled; in fact, nodes placed at the top of the hierarchy would represent wide communities of loosely linked users (e.g., the community of students), whereas nodes at the bottom would be associated with narrow communities of tightly linked users (e.g., the community of working students). This hierarchical community organization could be extremely useful in the proactive suggestion of services, carried out by our system. In fact, in order to find the citizen communities potentially interested to a service, our system could run across the hierarchy, starting from its root, in such a way as to find the widest community potentially interested to it.

KEY TERMS

Agent: A computational entity capable of both perceiving dynamic changes in the environment it is operating in and autonomously performing user delegated tasks, possibly by communicating and cooperating with other similar entities.

Agent Ontology: A description (like a formal specification of a program) of the concepts and relationships that can exist for an agent or a community of agents.

Adaptive System: A system adapting its behaviour on the basis of the environment it is operating in.

Device Profile: A model of a device storing information about both its costs and capabilities.

E-Service: A collection of network-resident software programs that collaborate for supporting users in both accessing and selecting data and services of their interest handled by a provider site.

Multi-Agent System (MAS): A loosely coupled network of software agents that interact to solve problems that are beyond the individual capacities or knowledge of each of them.

User Modeling: The process of gathering information specific to each user either explicitly or implicitly. This information is exploited in order to customize the content and the structure of a service to the user's specific and individual needs.

User Profile: A model of a user representing both his preferences and his behaviour.

Multiclass Molecular Classification

Chia Huey Ooi
Duke-NUS Graduate Medical School Singapore, Singapore

INTRODUCTION

Molecular classification involves the classification of samples into groups of biological phenotypes. Studies on molecular classification generally focus on cancer for the following reason: Molecular classification of tumor samples from patients into different molecular types or subtypes is vital for diagnosis, prognosis, and effective treatment of cancer (Slonim, Tamayo, Mesirov, Golub, and Lander, 2000). Traditionally, such classification relies on observations regarding the location (Slonim et al., 2000) and microscopic appearance of the cancerous cells (Garber et al., 2001). These methods have proven to be slow and ineffective; there is no way of predicting with reliable accuracy the progress of the disease, since tumors of similar appearance have been known to take different paths in the course of time.

With the advent of the microarray technology, data regarding the gene expression levels in each tumor sample may now prove to be a useful tool in molecular classification. This is because gene expression data provide snapshots of the activities within the cells and thus, the profile of the state of the cells in the tissue. The use of microarrays for gene expression profiling was first published in 1995 (Schena, Shalon, Davis, and Brown, 1995). In a typical microarray experiment, the expression levels of up to 10,000 or more genes are measured in each sample. The high-dimensionality of the data means that feature selection (FS) plays a crucial role in aiding the classification process by reducing the dimensionality of the input to the classification process. In the context of FS, the terms *gene* and *feature* will be used interchangeably in the context of gene expression data.

BACKGROUND

The objective of FS is to find from an overall set of N features, the subset of features, S, that gives the best classification accuracy. This feature subset is also known as the *predictor set*. There are two major types of FS techniques, filter-based and wrapper techniques. Filter-based techniques have several advantages over wrapper techniques:

a. Filter-based techniques are computationally less expensive than wrapper techniques.
b. Filter-based techniques are not classifier-specific; they can be used with any classifier of choice to predict the class of a new sample, whereas with wrapper-based techniques, the same classifier which has been used to form the predictor set must also be used to predict the class of a new sample. For instance, if a GA/SVM (wrapper) technique is used to form the predictor set, the SVM classifier (with the same classifier parameters, e.g., the same type of kernel) must then be used to predict the class of a new sample.
c. More importantly, unlike the typical 'black-box' trait of wrapper techniques, filter-based techniques provide a clear picture of why a certain feature subset is chosen as the predictor set through the use of scoring methods in which the inherent characteristics of the predictor set (and not just its prediction ability) are optimized.

Currently, filter-based FS techniques can be grouped into two categories: *rank-based selection* (Dudoit, Fridlyand, and Speed, 2002; Golub et al., 1999; Slonim et al., 2000; Su, Murali, Pavlovic, Schaffer, and Kasif, 2003; Takahashi & Honda, 2006; Tusher, Tibshirani, and Chu, 2001) and state-of-the-art *equal-priorities scoring methods* (Ding & Peng, 2005; Hall & Smith, 1998; Yu & Liu, 2004). This categorization is closely related to the two existing criteria used in filter-based FS techniques. The first criterion is called relevance – it indicates the ability of a gene in distinguishing among samples of different classes. The second criterion is called redundancy – it indicates the similarity between

pairs of genes in the predictor set. The aim of FS is to maximize the relevance of the genes in the predictor set and to minimize the redundancy between genes in the predictor set.

Rank-based selection methods use only relevance as the criterion when forming the predictor set. Each of the *N* genes in the dataset is first ranked based on a score which indicates how relevant the gene is (i.e., its ability to distinguish among different classes). The *P* top-ranked genes are then chosen as the members of the predictor set. The choice of the value *P* is often based on experience or some heuristics (Dudoit et al., 2002; Li, Zhang, and Ogihara, 2004).

Due to the need for fast and simple reduction of dimensionality for gene expression datasets, the most ample instances of existing filter-based FS techniques for molecular classification are those of the rank-based category. This is because rank-based techniques consider only one criterion in forming the predictor set, resulting in lower computational cost than more complex techniques where two criteria are considered. Compared to rank-based techniques, there are considerably fewer existing instances of equal-priorities scoring methods, which use two criteria in forming the predictor set: relevance and redundancy (Ding & Peng, 2005; Hall & Smith, 1998; Yu & Liu, 2004). More importantly, in these methods *equal priority* is assigned to each of the two criteria (relevance and redundancy), hence the term 'equal-priorities scoring methods'.

MAIN FOCUS

There are two areas of focus in this article. The first is the area of FS for gene expression data. The second is the area of molecular classification based on gene expression data.

In existing studies on filter-based FS, at most two criteria are considered in choosing the members of the predictor set: relevance and redundancy. Furthermore, even in studies where both relevance and redundancy are considered (Ding & Peng, 2005; Hall & Smith, 1998; Yu & Liu, 2004), both criteria are given *equal* weights or priorities. Based on a two-class example used in another study (Guyon & Elisseeff, 2003), we begin to ask the question if the two criteria should *always* be given equal priorities regardless of dataset characteristics, namely the number of classes. To find the answer, Ooi, Chetty, and Gondal (2004) introduced the concept of differential prioritization as a third criterion to be used in FS along with the two existing criteria of relevance and redundancy. The concept was then tested on various gene expression datasets (Ooi, Chetty, and Teng, 2006; Ooi, Chetty, and Teng, 2007b). Differential prioritization works better than existing criteria in FS by forming a predictor set which is most optimal for the particular number of classes in the FS problem (Ooi, Chetty, and Teng, 2007a).

In the area of molecular classification, there is a lack of formal approach for systematically combining the twin problems of FS and classification based on the decomposition paradigm used in each problem. A multiclass problem is a problem in which there are three or more classes. It can be *decomposed* into several two-class sub-problems. The number of derived two-class sub-problems will depend on the type of the *decomposition paradigm* used. The rationale for doing this is that the two-class problem is the most basic, and thus, the easiest of classification problems (divide-and-conquer strategy). Furthermore, many classifiers such as Support Vector Machine (SVM) (Vapnik, 1998) are originally devised for the two-class problem.

Predictor Set Scoring Method

A FS technique is made of two components: the predictor set scoring method (which evaluates the goodness of a candidate predictor set) and the search method (which searches the gene subset space for the predictor set based on the scoring method). The FS technique is wrapper-based when classifiers are invoked in the predictor set scoring method. Filter-based FS techniques, on the other hand, uses criteria which are not classifier-based in order to evaluate the goodness of the predictor set. The criteria are listed below:

1. **Relevance:** The relevance of a predictor set tells us how well the predictor set is able to distinguish among different classes. It is summarized in the form of the average of the correlation between a member of the predictor set and the target class vector, which, in turn, represents the relevance of the particular feature (Hall & Smith, 1998). The target class vector (consisting of class labels of the training samples) represents the target class concept. Relevance is to be maximized in the search for the predictor set.

2. **Redundancy:** The redundancy in a predictor set indicates the amount of repetitions or similarity in terms of the information conveyed by the members of the predictor set. To measure the redundancy in a predictor set *S*, one possible scheme is to use the measure of *direct redundancy*, or measure of *redundancy* for short. This measure is defined as the sum of the pairwise correlations from all unique pairwise combinations of the members of *S*, normalized by dividing by the square of the size of *S*, $|S|^2$. Redundancy is to be minimized in the search for the predictor set.
3. **Antiredundancy:** It is necessary to consider an alternative to the measure of redundancy in the predictor set. The existing method directly minimizes the sum of the correlation between genes in the predictor set by making this sum the denominator in the score for measuring the goodness of the predictor set (Ding & Peng, 2005). We observe that this can present the problem of singularity at near-minimum redundancy. To avert this problem, Ooi et al. (2004) proposed an alternative method. In this method, a measure called antiredundancy represents the sum of the *lack* of correlation between genes in the predictor set. Antiredundancy is a measure opposite to the measure of redundancy in terms of quality, and is to be maximized in the search for the predictor set.
4. **Degree of differential prioritization (DDP):** The DDP is a parameter (domain from 0 to 1) which controls the ratio of the priority of maximizing relevance to the priority of minimizing redundancy. The application of the DDP in FS compels the search method to prioritize the optimization of one criterion (either relevance or redundancy) at the cost of the optimization of the other criterion. Thus, unlike other existing correlation-based techniques, in the DDP-based FS technique, the optimizations of both elements of relevance and redundancy need *not* necessarily have equal priorities in the search for the predictor set (Ooi et al., 2006).

A predictor set found using larger value of the DDP has more features with strong relevance to the target class vector, but also more redundancy among these features. Conversely, a predictor set obtained using smaller value of the DDP contains less redundancy among its member features, but at the same time also has fewer features with strong relevance to the target class vector.

The optimal value of the DDP decreases in an exponential-like manner as the number of classes increases. For instance, minimizing redundancy is more important for a 14-class problem than it is for a 2-class problem. The optimal value of the DDP is not necessarily 0.5 (equal-priorities scoring methods) or 1 (rank-based selection). Therefore, a degree of freedom in adjusting the priorities between maximizing relevance and maximizing antiredundancy is necessary in order to produce the best predictor set. This degree of freedom is embodied by the DDP and should be adjusted based on the number of classes in the dataset.

Decomposition Paradigm and FS-CA Combinations

In theory, it is possible to decompose a multiclass problem for either or both FS and classification. (The decomposition of the classification problem is also called classifier aggregation. The term classification here indicates both the process of building a classifier and the process of using that classifier to predict the class of a sample.) However, in studies where FS is conducted prior to molecular classification, decomposition is not consistently implemented for both FS and classification.

In some studies, the type of decomposition is the same for both FS and classification, e.g., *undecomposed* FS with *undecomposed* classification (Dudoit et al., 2002), or decomposed FS with similarly decomposed classification (Ramaswamy et al., 2001; Yeang et al., 2001). In other cases, decomposition may only be implemented for classification but not for FS (Chai & Domeniconi, 2004; Ding & Peng, 2005; Li et al., 2004), or vice versa. We note that the occurrence of the former (*undecomposed* FS with decomposed classification) is quite frequent in multiclass molecular classification studies. In fact, to the best of our knowledge, no study on multiclass molecular classification has presented the opposite combination of paradigms (decomposed FS with *undecomposed* classification).

In existing studies (Chai & Domeniconi, 2004; Ding & Peng, 2005; Li et al., 2004), if the decomposition type differs between FS and classification, the multiclass problem is often decomposed in classification, but *undecomposed* in FS. This occurs even in those

studies which focus on FS instead of classifier techniques. One possible reason is that studies proposing new FS techniques prefer to first test their techniques in the undecomposed paradigm since undecomposed FS is the most basic and natural form of FS. Hence, decomposition in FS, with applications to multiclass molecular classification, has not been investigated as widely as either *undecomposed* FS or decomposed classification.

Overall, there has been a lack of a formal, systematic approach for combining the distinct problems of FS and classification in the context of problem decomposition for multiclass molecular classification. To solve this problem, the FS-CA system is devised (Ooi et al., 2007b) in which FS and classification are systematically combined based on the decomposition paradigms.

In this system, three decomposition paradigms are considered for FS: ACA (all-classes-at-once or non-decomposition), OVA (one-vs.-all), and PW (pairwise). For classification, three classifier aggregation methods are considered: SM (single machine or non-decomposition), OVA, and PW. The nine possible FS-CA combinations are: ACA-SM, ACA-OVA, ACA-PW, OVA-SM, OVA-OVA, OVA-PW, PW-SM, PW-OVA, and PW-PW. An X-Y combination combines an 'X' FS decomposition paradigm with a 'Y' classifier aggregation method. For instance, the PW-OVA combination combines PW-decomposed FS with OVA classifier aggregation.

Predictor Set Size Framework

In the predictor set size framework, a system of comparisons is devised by fixing, to a predetermined constant, one of these size factors:

a. predictor set size formed per FS sub-problem, $P_{sp,q}$,
b. average number of genes used to induce one component classifier, $P_{cc,b}$, and
c. number of total genes used in all component classifiers, P.

The purpose of this framework is to fairly compare classification performance across the nine FS-CA combinations, or more specifically, across the three types of problem decomposition used in FS (ACA, OVA, and PW). The framework is necessary due to the fact that FS with no decomposition (ACA) is expected to perform worse when compared to FS with decomposition (OVA and PW) using the simple criterion of fixing $P_{sp,q}$ to a constant for all FS-CA combinations.

This is because while the number of genes selected per FS sub-problem, $P_{sp,q}$, is the same for all three paradigms, the number of genes used in inducing all component classifiers, P, is often greater when FS with decomposition (OVA or PW) is used compared to when FS with no decomposition (ACA) is used. In fact, it is possible to simply conclude that the better performance of the former (FS with decomposition) is due to the bulk of genes used in the overall classifier induction procedure. At the same time, it is possible that the difference in the values of $P_{cc,b}$ (whether for a given value of $P_{sp,q}$ or of P) may contribute to the disparity in performance among the FS-CA combinations as well.

FUTURE TRENDS

Advancements in the microarray technology mean increases in the dimensionality of the gene expression data and consequently, growth in demands for a good FS technique. The number of samples and classes analyzed are also increasing as a result of the improvement in the microarray technology. This means an increase in the need for a combination of FS and classification technique which can deal efficiently with both high-dimensional and multiclass data.

CONCLUSION

Aside from the conventional criteria of relevance and redundancy, the balance between the priorities assigned to each of these criteria is an important element in determining the goodness of the predictor set, especially for multiclass problems. Classification problems with larger number of classes (e.g., 14) require more emphasis on minimizing redundancy than problems with smaller number of classes (e.g., two classes).

Together with the predictor set size framework, the system of FS-CA combinations is useful in providing a framework for comparing classification performance across different combinations of decomposition paradigms in FS and classification.

In this article, we have discussed our approaches to the problems of FS and classification in the context

of multiclass molecular classification based on gene expression data. However, the approaches presented here are applicable, without any modification, to any high-dimensional, multiclass feature selection/classification problems, regardless of the domain.

KEY TERMS

Antiredundancy: A measure of the *lack* of correlation between genes in the predictor set – it is a measure opposite to the measure of redundancy in terms of quality.

Differential Prioritization: A parameter which controls the ratio of the priority of maximizing relevance to the priority of minimizing redundancy.

Equal-Priorities Scoring Methods: FS techniques in which relevance and redundancy have equal priorities as criteria in evaluating the goodness of the predictor set.

FS-CA: A combination of a particular FS decomposition paradigm and a particular classifier aggregation method.

Predictor Set Score: Measure of goodness of the predictor set – it is to be maximized in the search for the predictor set.

Rank-Based Selection Methods: FS techniques in which relevance alone is used as the criterion in forming the predictor set.

Redundancy: An indicator of the amount of repetitions or similarity in terms of the information conveyed by the members of the predictor set.

Relevance: A measure of the ability of a predictor set or a feature to distinguish among different classes.

Multidimensional Modeling of Complex Data

University of Jijel, Algeria

INTRODUCTION

While the classical databases aimed in data managing within enterprises, data warehouses help them to analyze data in order to drive their activities (Inmon, 2005).

The data warehouses have proven their usefulness in the decision making process by presenting valuable data to the user and allowing him/her to analyze them online (Rafanelli, 2003). Current data warehouse and OLAP tools deal, for their most part, with numerical data which is structured usually using the relational model. Therefore, considerable amounts of unstructured or semi-structured data are left unexploited. We qualify such data as "complex data" because they originate in different sources; have multiple forms, and have complex relationships amongst them.

Warehousing and exploiting such data raise many issues. In particular, modeling a complex data warehouse using the traditional star schema is no longer adequate because of many reasons (Boussaïd, Ben Messaoud, Choquet, & Anthoard, 2006; Ravat, Teste, Tournier, & Zurfluh, 2007b). First, the complex structure of data needs to be preserved rather than to be structured linearly as a set of attributes. Secondly, we need to preserve and exploit the relationships that exist between data when performing the analysis. Finally, a need may occur to operate new aggregation modes (Ben Messaoud, Boussaïd, & Loudcher, 2006; Ravat, Teste, Tournier, & Zurfluh, 2007a) that are based on textual rather than on numerical data.

The design and modeling of decision support systems based on complex data is a very exciting scientific challenge (Pedersen & Jensen, 1999; Jones & Song, 2005; Luján-Mora, Trujillo, & Song; 2006). Particularly, modeling a complex data warehouse at the conceptual level then at a logical level are not straightforward activities. Little work has been done regarding these activities.

At the conceptual level, most of the proposed models are object-oriented (Ravat et al, 2007a; Nassis, Rajugan, Dillon, & Rahayu 2004) and some of them make use of UML as a notation language. At the logical level, XML has been used in many models because of its adequacy for modeling both structured and semi structured data (Pokorný, 2001; Baril & Bellahsène, 2003; Boussaïd et al., 2006).

In this chapter, we propose an approach of multidimensional modeling of complex data at both the conceptual and logical levels. Our conceptual model answers some modeling requirements that we believe not fulfilled by the current models. These modeling requirements are exemplified by the Digital Bibliography & Library Project case study (DBLP)[1].

BACKGROUND

The DBLP (Ley & Reuther, 2006) represents a huge tank of data whose usefulness can be extended from simple reference searching to publication analysis, for instance:

- Listing the publications ordered by the number of their authors, number of citations or other classification criteria;
- Listing the minimum, maximum or average number of an author's co-authors according to a given publication type or year;
- Listing the number of publications where a given author is the main author, by publication type, by subject or by year;
- For a given author, knowing his/her publishing frequency by year, and knowing where he/she publishes the most (conferences, journals, books).

Currently, the DBLP database is not structured in such a way that allows data analysis. Along with this chapter, we propose a new structure for DBLP making further and richer data analysis possible. The DBLP case study raises many requirements that are worth

considering when modeling the data warehouse. Here follows the main requirements.

Complex Objects to Analyze

The objects to be analyzed may be characterized by simple linear attributes such as numerical measures or dimension attributes we find in the classical data warehouse (Kimball & Ross, 2002). However, in real life, an object may have a more complex structure (tree-like or graph-like). For instance, authors may be characterized by their names and affiliations, but publications are rather semi-structured and composed of sections, paragraphs, internal and external links, etc.

Complex Objects as Analysis Axes

Like the facts, the analysis axes may also be complex. For instance, an academic institution may be interested in evaluating authors according to their contributions, which may have a complex structure.

Objects Being Simultaneously Facts and Dimensions

In classical data warehouse modeling, facts and dimensions are treated separately. Even in symmetric models, they remain distinct at a given time. However, a need may occur to analyze an object according to objects of the same nature, and thus, one object may occur in dimension objects and facts objects simultaneously. For instance, it may be interesting to analyze the authors according to their co-authors in publications. Another example is the citation relationship between publications when we want to evaluate a publication according to its referencing publications.

Explicit and Richer Relationships Between Objects

In the classical star schema, the relationships between facts and dimensions are implicit. For instance, when relating "sales" as measures to "departments", "products" and "time" as dimensions, we know implicitly that our schema models product sales for each department during periods of time. However, in real-life applications, the relationships need to be explicit. Moreover, there may be more than one relationship between two objects. For example, we can distinguish two relationships between authors and publications: authoring and reviewing.

Complex Aggregations

Traditionally, aggregation functions such as SUM and AVERAGE deal with numerical data, but these are not the only aggregation needs we face. For example, Ravat et al (2007a) propose to aggregate documents using a function TOP_KEYWORDS that returns the most used keywords of some analyzed documents.

MAIN FOCUS

Three concepts compose the core of our model: the complex object, the relationship, and the hierarchy. In addition, we separate the definition of the (multi)dimensional model from that of the cube in one hand and the description of metadata from that of data in the other hand. In the following, we present our conceptual and logical models.

Conceptual Model

The model we define is composed of the following elements:

1. **Complex Object:** A complex object is a focus of analysis either as a subject (fact) or as an axis (dimension). An object can be unstructured, semi-structured, or structured. It can hold numerical or textual data relating to each other in different ways (linear, tree-like and graph-like).
   Formally, we refer to an object using the abbreviation "obj" and to a class of objects using "Obj". The set of object instances is noted E_{obj} where $E_{obj} = \{obj_i, i=1, n$ *where n is the number of instances of Obj}*.
2. **Relationships between objects:** A relationship is a three-tuple "R" where:
   $R = (Obj_1$, *relationship_name,* $Obj_2)$. Similarly, a relationship instance is a three-tuple "*r*" where $r = (obj_1$, *relationship_name,* $obj_2)$. The set of relationship instances is noted E_r where
   $E_r = \{r_i, i=1, m$ *where m is the number of instances of R}*.
3. **Hierarchies:** A hierarchy is an n-tuple of objects *H* where $H= (Obj_1, Obj_2, \ldots, Obj_n)$ *where*

"n" is the number of object classes composing the hierarchy. A hierarchy instance is a tuple of objects "*h*" where $h= (obj_1, obj_2, \ldots, obj_n)$ *where "n"* is the number of object classes composing the hierarchy. The set of a hierarchy instances is noted E_h where
$E_h = \{h_i, i=1, n$ *where n is the number of hierarchy instances}*.

4. **Dimensional Model for Complex Data:** we define the complex dimensional model (*CDM*) as composed of a set of complex objects, a set of relationships, and a set of hierarchies.
CDM $=(E_{Obj}, E_R, E_H)$ *where* $E_{Obj}= \{Obj_i, i =1, n$ *where "n" represents the number of objects serving as analysis subjects, analysis axes or both}*, $E_R = \{R_i, i = 1, m$ *where "m" represents the number of relationships that are interesting for analysis }*, $E_H = \{H_i, i =1, p$ *where "p" represents the number of hierarchies needed for aggregation}*. Similarly, we define a complex dimensional model instance as composed of the sets of object instances, the sets of relationship instances, and the of sets of hierarchy instances.
5. **The complex cube:** We define a complex cube as a selection among the sets E_{Obj}, E_R and E_H of the following elements:
   - One object serving as the analysis subject (fact). We note such object Obj_S
   - Many objects serving as the analysis axes (dimensions). We note respectively each object and the set of these objects Obj_A , E_{ObjA}
   - Many relationships linking Obj_S to each Obj_A. The set of these relationships is noted E_{RC}
   - Hierarchies including each Obj_A. The set of these hierarchies is noted E_{HC}.

   We define a complex cube as a four-tuple CC, where $CC = (Obj_S, E_{ObjA}, E_{RC}, E_{HC})$. Similarly, we define a complex cube instance as a four-tuple composed of:
   - The set of the instances of the object Obj_S, noted E_{objS},
   - The sets of Obj_{Ai} instances, each one noted E_{objAi},
   - The sets of relationship instances, each one noted E_{rci},
   - The sets of hierarchy instances, each one noted E_{hci}.

   $cc = (E_{objS}, \{E_{objA}i, i=1,n\}, \{E_{rcj}, j=1, m\}, \{E_{hck}, k=1, p\})$ where n is the number of axes selected for analysis, m is the number of relationships selected for analysis, and p is the number of hierarchies selected for analysis.

To illustrate the abovementioned defined concepts, we map the content of the DBLP database on our conceptual model:

Complex Objects and Classes of Objects

We identified many objects in the database falling into classes. The main classes are: "Publication", "Publication type" (article, inproceedings, incollection, …) , "Author", "Editor", "Publisher", "Proceedings", "Series", "Journal_issue", "Subject" and "Time".

Regarding the object structures, a publication of the class "Publication" for instance is identified by a "key", has a title, a modification date, page ranges, and other descriptors depending on the type of publication. Here follows an example of a publication from DBLP:

Publication 1

Key = {"conf/ISCApdcs/GrahamA03"}
Title = {Efficient Allocation in Distributed Object Databases}
Modification date = {"2006-09-20"}
Pages = {471-480}
URL = {db/conf/ISCApdcs/ISCApdcs2003.html#GrahamA03}

Relationships Between (Classes of) Objects

In DBLP, we can distinguish many relationships between the aforementioned object classes. An example of relationships with instances is:

R_1 = (Publication, "is_authored_by", Author); E_{r1} = {(publication 1, "is_authored_by", author1), (publication2, "is_authored_by", author2), …}. In this example, "author1" and "author2" refer to "Jonathan Graham" and "Jim Alves-Foss" whereas "publication 1" refers to the previous example.

Hierarchies

We can distinguish many hierarchies: publication hierarchy, conference hierarchy, journal hierarchy and time hierarchy. For instance, the conference hierarchy with instances is described as follows: H_1 = (Proceedings, Conference); E_{h1}= {(Proceedings11, conference1), (Proceedings12, conference1), (Proceedings21, conference2), …}. The corresponding objects in E_{h1} are as follows:

Proceedings11: Proceedings of Challenges, 2000 ADBIS-DASFAA Symposium on Advances in Databases and Information Systems,
Proceedings12: 5th East-European Conference on Advances in Databases and Information Systems, Vilnius, Lithuania; 25-28 September 2001
Proceedings21: ISCA PDCS 2006: San Francisco, California, USA
Conference1: Advances in Databases and Information Systems
Conference2: ISCA International Conference on Parallel and Distributed Computing Systems

Complex Dimensional Schema

Let's suppose we want to analyze the DBLP to answer the needs cited in Background section. Then, the complex dimensional schema is defined as shown in Table 1.

Complex Cube Schema

Let's now suppose we want to focus on Authors, and to analyze them in order to answer the three last questions of the needs cited in Background section. Then, the corresponding complex cube schema is defined as shown in Table 2.

Logical Model

In order to describe the logical structure of the complex dimensional model, we use XML. The main components of this logical model are described as follows:

1. **Complex Objects and classes of Objects:** We model each class of objects as an XML document. We represent an object as an XML element of a root element. The root element is named like the class but in plural whereas objects are named like the class but in singular. Each object is uniquely identified inside the document by an ID-typed XML Attribute "name" that allows referencing it from outside the document. A class document is structured as shown in Table 3.

Table 1. An example of complex dimensional schema for DBLP

CDM =(EObj, ER, EH) where EObj= {Publication, Subject, Proceedings, Journal_issue, Series, Author, Year} ER = {R1, R2, R3, R4, R5, R6} EH= {H1, H2, H3} R1 = (Publication, "Is_authored_by", Author), R2 = (Publication, "is_of_subject", Subject), R3 = (Publication, "appeared_in1", Proceedings) R4 = (Publication, "appeared_in2", Journal_issue) R5 = (Publication, "appeared_in3", Series) R6 = (Publication, "appeared_during", Year) H1 = (Publication, Publication_type) H2 = (Proceedings, Conference) H3 = (Journal_issue, Journal_volume, Journal)

Table 2. An example of a complex cube for DBLP

CC = (Obj_S, E_{ObjA}, E_{RC}, E_{HC}) Where: Obj_S= Publication E_{ObjA}= {Publication, Subject, Proceedings, Author, Year} E_{RH} = {R_1, R_2, R_3, R_6} E_{HC} = {H_1, H_2}

2. **Relationships between (classes of) objects:** We describe all the relationships in an XML document "Relationships.xml". Each relationship is then modeled as an XML element within Relationships.xml and uniquely identified by the ID-typed XML Attribute "name".
   To each relationship element in Relationships.xml corresponds an XML document named like the relationship and holding the relationship's instances. Each instance is then modeled as an XML element structured as shown in Table 4.
3. **Hierarchies:** We describe all the hierarchies in an XML document "Hierarchies.xml". Each hierarchy is then modeled as an XML element within Hierarchies.xml and uniquely identified by the ID-typed attribute "name".
   To each hierarchy in Hierarchies.xml corresponds an XML document named like the hierarchy and holding the hierarchy's instances. Each instance is then modeled as an XML element named like the hierarchy with small letters. A hierarchy instance is structured as shown in Table 5.
4. **Logical complex dimensional schema:** The complex dimensional schema description is fully based on XML which we use to define both the complex warehouse metadata and data. Thus, the warehouse metadata is composed of three XML documents: Classes.xml, Relationships.xml and Hierarchies.xml, whereas the warehouse data is disseminated through many XML documents each one named like the XML elements in the metadata documents.
5. **Logical complex cube:** We design a cube as composed of three kinds of XML documents (a) a fact document, (b) several dimension documents, and (c) several hierarchy documents.

We represent a fact object as an XML element of a root element. Furthermore, we link each fact object to its corresponding target objects using an XML element characterized by a name. This name corresponds to the ID of a relationship between the fact and the given dimension using XML sub-elements. Thus, each XML sub-element corresponds to an object linked to the fact object via the relationship evoked above. In addition, in order to avoid confusing the fact object's real data with its corresponding dimension references, we nest the former under the "Data" element and the latter under "Dimensions" element.

Table 3. The Class XML document structure

```
<class_name_in_plural>
        <class_name name = object _ID>
                …(complex structure)
        </class_name>
        …
</class_name_in_plural>
```

Table 4. The Relationship XML document structure

```
<relationship_name>
      < source target_class_ID = source_object_path/>
   < target target_class_ID = target_object_path/>
</relationship_name>
```

Table 5. The hierarchy XML document structure

```
<hierarchy_name>
        <hitem class_ID1 = object_path1 level = objec1s_level/>
        <hitem class_ID2 = object_path2 level= objec2s_level />
        …
        <hitem class_IDn = object_pathn level= objecns_level />
<hierarchy_name>
```

We represent a dimension object as an XML element. Moreover, if the dimension possesses hierarchies, we link the dimension object to its corresponding objects in each hierarchy using an XML element. This latter is characterized by a name that corresponds to the hierarchy's ID, a "*level*" XML Attribute describing the object's level in the hierarchy and sub-elements. Each sub-element corresponds to one member of the hierarchy and it is characterized by its level in the hierarchy. In addition, in order to avoid confusing the dimension object's real data with its corresponding hierarchy references, we nest the former under the "Data" element and the latter under "Hierarchies" element.

FUTURE TRENDS

Integrating complex data into the decision making process will lead to rethink many aspects of a data warehouse, from data preparation to data analysis through data management.

Moreover, using XML to describe the data warehouse at the logical level raises new challenges such as defining an XML algebra for the XML-based OLAP tools, enriching the XML query language XQuery with aggregation functions, and rethinking the performance optimization techniques of the traditional data warehouses in the context of an XML warehouse (N. Wiwatwattana, & H. V. Jagadish, Laks &V. S. Lakshmanan & Divesh Srivastava, 2007).

CONCLUSION

In this chapter, we proposed a conceptual and logical model for complex data warehouses. Our conceptual model answers new modeling requirements exemplified by the DBLP case study, which we believe are not answered by the existing models.

At the core of our model, we defined the concepts of complex object, relationship, and hierarchy. The most benefit of our model is that it gives the user plenty of possibilities to analyze the complex data while preserving its complexity in term of structure or relationships. Furthermore, the user can choose a same class of objects as an analysis subject and axis simultaneously. At the logical level, our model is fully based on XML and makes use of the main XML modeling concepts "Element" and "Attribute". At the physical level, our model offers some flexibility with respect to the physical storage. In fact, the RDF-like reference mechanism allows distributing (fragmenting) a class' instances through different documents which will have a considerable impact on query performance.

KEY TERMS

Class: Abstraction of a set of objects of the same nature.

Complex Cube Model: A class selected as the analysis' subject and surrounded by a set of classes selected as the analysis' axes where each class may have one or more related hierarchy.

Complex Dimensional Model: A set of classes related to each other with relationships and where some classes are organized as hierarchies.

Complex Object: An object characterized with a complex structure, which is interesting to the analyst either as a fact, or as an axis.

Formal Model: A model whose concepts and components are defined using formal notations amongst which there are mathematical notations.

Logical Model: A model whose concepts and components are defined using an implementation-oriented language.

Hierarchy: A set of ordered complex classes or objects extending the hierarchy concept defined between simple attributes of a dimension.

Relationship: An explicit link between complex objects or classes extending the traditional implicit link between fact and dimensions and ranging from simple associations to composition and inheritance.

INTRODUCTION

Data classification is a supervised learning strategy that analyzes the organization and categorization of data in distinct classes. Generally, a training set, in which all objects are already associated with known class labels, is used in classification methods. The data classification algorithms work on this set by using input attributes and builds a model to classify new objects. In other words, the algorithm predicts output attribute values. Output attribute of the developed model is categorical (Roiger & Geatz, 2003). There are many applications of data classification in finance, health care, sports, engineering and science. Data classification is an important problem that has applications in a diverse set of areas ranging from finance to bioinformatics (Chen & Han & Yu, 1996; Edelstein, 2003; Jagota, 2000). Majority data classification methods are developed for classifying data into two groups. As multi-group data classification problems are very common but not widely studied, we focus on developing a new multi-group data classification approach based on mixed-integer linear programming.

BACKGROUND

There are a broad range of methods for data classification problem including Decision Tree Induction, Bayesian Classifier, Neural Networks (NN), Support Vector Machines (SVM) and Mathematical Programming (MP) (Roiger & Geatz, 2003; Jagota, 2000; Adem & Gochet, 2006). A critical review of some of these methods is provided in this section. A major shortcoming of the neural network approach is a lack of explanation of the constructed model. The possibility of obtaining a non-convergent solution due to the wrong choice of initial weights and the possibility of resulting in a non-optimal solution due to the local minima problem are important handicaps of neural network-based methods (Roiger & Geatz, 2003). In recent years, SVM has been considered as one of the most efficient methods for two-group classification problems (Cortes & Vapnik, 1995; Vapnik, 1998). SVM method has two important drawbacks in multi-group classification problems; a combination of SVM has to be used in order to solve the multi-group classification problems and some approximation algorithms are used in order to reduce the computational time for SVM while learning the large scale of data.

There have been numerous attempts to solve classification problems using mathematical programming (Joachimsthaler & Stam, 1990). The mathematical programming approach to data classification was first introduced in early 1980's. Since then, numerous mathematical programming models have appeared in the literature (Erenguc & Koehler, 1990) and many distinct mathematical programming methods with different objective functions are developed in the literature. Most of these methods modeled data classification as linear programming (LP) problems to optimize a distance function. In addition to LP problems, mixed-integer linear programming (MILP) problems that minimize the misclassifications on the design data set are also widely studied. There have been several attempts to formulate data classification problems as MILP problems (Bajgier & Hill, 1982; Gehrlein 1986; Littschwager, 1978; Stam & Joachimsthaler, 1990). Since MILP methods suffer from computational difficulties, the efforts are mainly focused on efficient solutions for two-group supervised classification problems. Although it is possible to solve a multi-group data classification problem by solving several two-group problems, such approaches also have drawbacks including computational complexity resulting in long computational times (Tax & Duin, 2002).

MAIN FOCUS

The objective in data classification is to assign data points that are described by several attributes into a predefined number of groups. The use of hyper-boxes for defining boundaries of the sets that include all or some of the points in that set as shown in Figure 1 can be very accurate for multi-group problems. Hyper-boxes are high dimensional geometrical shapes that have lower and upper boundaries for each attribute. If it is necessary, more than one hyper-box can be used in order to represent a group as shown in Figure 1.

The data classification problem based on this idea is developed in two parts: training and testing. During the training part, characteristics of data points that belong to a certain group are determined and differentiated from the data points that belong to other groups. After the distinguishing characteristics of the groups are determined, then the effectiveness of the classification must be tested. Predictive accuracy of the developed model is performed on a test data set during the testing stage.

Training Problem Formulation

Training is performed on a training data set composed of a number of instances *i*. The data points are represented by the parameter a_{im} that denotes the value of attribute *m* for the instance *i*. The group *k* that the data point *i* belongs to are given by the set D_{ik}. Each existing hyper-box *l* encloses a number of data points belonging to group *k*. Moreover, bounds *n* (*lower, upper)* of each hyper-box is determined by solving the training problem.

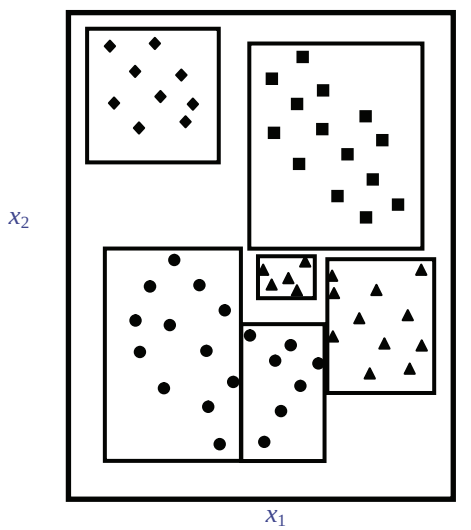
Given these parameters and the sets, the following variables are sufficient to model the multi-group data classification problem with hyper-boxes. The binary variable yb_l is indicates whether the box *l* is used or not. The position (inside or outside) of the data point *i* with regard to box *l* is represented by ypb_{il}. The assigned group *k* of box *l* and data point *i* is symbolized by ybc_{lk} and ypc_{ik}, respectively. If the data point *i* is within the bound *n* with respect to attribute *m* of box *l*, then the binary variable $ypbn_{ilmn}$ takes the value of 1, otherwise 0. Similarly, $ypbm_{ilm}$ indicates whether the data point *i* is within the bounds of attribute *m* of box *l* or not. Finally, yp_{ik} indicate the misclassification of data point *i* to group *k*. In order to define the boundaries of hyper-boxes, two continuous variables are required: X_{lmn} is the one that models bounds *n* for box *l* on attribute *m*. Correspondingly, bounds *n* for box *l* of group *k* on attribute *m* are defined with the continuous variable $XD_{l,k,m,n}$.

The following MILP problem models the training part of multi-group data classification method using hyper-boxes:

$$\min \; z = \sum_{l}\sum_{k} yp_{ik} + \sum_{l} yb_l \qquad (1)$$

subject to

Figure 1. Schematic representation of multi-group data classification using hyper-boxes.



$$XD_{lkmn} \le a_{im} ypb_{il} \quad \forall i\ k,l,m,n \,|\, n = lo \qquad (2)$$

$$XD_{lkmn} \ge a_{im} ypb_{il} \quad \forall i\ k,l,m,n \,|\, n = up \qquad (3)$$

$$XD_{lkmn} \le Q\ ybc_{lk} \quad \forall k,l,m,n \qquad (4)$$

$$\sum_k XD_{lkmn} = X_{lmn} \quad \forall l,m,n \qquad (5)$$

$$ypbn_{ilmn} \ge (1/Q)(X_{lmn} - a_{im}) \quad \forall i\ l,m,n \,|\, n = up \qquad (6)$$

$$ypbn_{ilmn} \ge (1/Q)(a_{im} - X_{lmn}) \quad \forall i\ l,m,n \,|\, n = lo \qquad (7)$$

$$\sum_l ypb_{il} = 1 \quad \forall i \qquad (8)$$

$$\sum_k ypc_{ik} = 1 \quad \forall i \qquad (9)$$

$$\sum_l ypb_{il} = \sum_k ypc_{ik} \quad \forall i \qquad (10)$$

$$\sum_k ybc_{lk} \le yb_l \quad \forall l \qquad (11)$$

$$ybc_{lk} - \sum_i ypb_{il} \le 0 \quad \forall l\ k \qquad (12)$$

$$ybc_{lk} - \sum_i ypc_{ik} \le 0 \quad \forall l\ k \qquad (13)$$

$$\sum_n ypbn_{ilmn} - ypbm_{ilm} \le \mathrm{N} - 1 \quad \forall i,l,m \qquad (14)$$

$$\sum_m ypbm_{ilm} - ypb_{il} \le \mathrm{M} - 1 \quad \forall i\ l \qquad (15)$$

$$ypc_{ik} - yp_{ik} \le 0 \quad \forall i\ k \notin D_{ik} \qquad (16)$$

$$X_{lmn}, XD_{lkmn} \ge 0,\ yb_l\ \ ybc_{lk}, ypb_{il}, ypc_{ik}, ypbn_{ilmn}, ypbm_{ilm}, yp_{ik} \in \{0,1\} \qquad (17)$$

The objective function of the MILP problem (Eq. (1)) is to minimize the misclassifications in the data set with the minimum number of hyper-boxes. The lower and upper bounds of the boxes are given in Eqs. (2) and (3), respectively. The lower and upper bounds for the hyper-boxes are determined by the data points that are enclosed within the hyper-box. Eq. (4) enforces the bounds of hyper-boxes exist if and only if this hyper-box is assigned to a group. Eq. (5) is used to relate the two continuous variables that represent the bounds of the hyper-boxes. The position of a data point with respect to the bounds on attribute *m* for a hyper-box is given in Eqs. (6) and (7). The binary variable $ypbn_{ilmn}$ helps to identify whether the data point *i* is within the hyper-box *l*. Two constraints, one for the lower bound and one for the upper bound, are needed for this purpose (Eqs. (6) and (7)). Since these constraints establish a relation between continuous and binary variables, an arbitrarily large parameter, *Q*, is included in these constraints. The Eqs. (8) and (9) state that every data point must be assigned to a single hyper-box, *l*, and a single group, *k*, respectively. The equivalence between Eqs. (8) and (9) is given in Eq. (10); indicating that if there is a data point in the group *k*, then there must be a hyper-box *l* to represent the group *k* and vice versa. The existence of a hyper-box implies the assignment of that hyper-box to a group as shown in Eq. (11). If a group is represented by a hyper-box, there must be at least one data point within that hyper-box as in Eq. (12). In the same manner, if a hyper-box represents a group, there must be at least a data point within that group as given in Eq. (13). The Eq. (14) represents the condition of a data point being within the bounds of a box in attribute *m*. If a data point is within the bounds of all attributes of a box, then it must be in the box as shown in Eq. (15). When a data point is assigned to a group that it is not a member of, a penalty applies as indicated in Eq. (16). Finally, last constraint gives non-negativity and integrality of decision variables. By using this MILP formulation, a training set can be studied and the bounds of the groups are determined for the multi-group data classification problem.

Testing Problem Formulation

The testing phase is straight forward. If a new data point whose membership to a group is not known arrives, it is necessary to assign this data point to one of the groups. There are two possibilities for a new data point when determining its group:

i. the new data point is within the boundaries of a single hyper-box,
ii. the new data point is not enclosed in any of the hyper-boxes determined in the training problem.

When the first possibility is realized for the new data point, the classification is made by directly assigning this data to the group that was represented by the

hyper-box enclosing the data point. In the case when the second possibility applies, the assignment of the new data point to a group requires further analysis. If the data point is within the lower and upper bounds of all but not one of the attributes (i.e., *m'*) defining the hyper-box, then the shortest distance between the new point and the hyper-box is calculated using the minimum distance between hyper-planes defining the hyper-box and the new data point as given in Eq. (18).

$$\min_{l,m,n}\left\{\left(a_{jm}-X_{lmn}\right)\right\} \tag{18}$$

When the data point is between the bounds of smaller than or equal to M-2 attributes, then the smallest distance between the point and the hyper-box is obtained by calculating the minimum distance between edges of the hyper-box and the new point as given in Eq. (25).

$$\vec{W}_{jlmn}=\vec{A}_j-\vec{P0}_{lmn} \tag{19}$$

$$\vec{V}_{jlmn}=\vec{P1}_{lmn}-\vec{P0}_{lmn} \tag{20}$$

$$C1_{jlmn}=(W_{jlmn}\cdot V_{jlmn})/\left\|W_{jlmn}\right\|\left\|V_{jlmn}\right\| \tag{21}$$

$$C2_{jlmn}=(V_{jlmn}\cdot V_{jlmn})/\left\|V_{jlmn}\right\|\left\|V_{jlmn}\right\| \tag{22}$$

$$b_{jlmn}=C1_{jlmn}/C2_{jlmn} \tag{23}$$

$$Pb_{jlmn}=P0_{jlmn}+b_{jlmn}V_{jlmn} \tag{24}$$

$$\min_{l,n}\left\{\sqrt{\sum_m\left(a_{jm}-pb_{jlmn}\right)^2}\right\} \tag{25}$$

When data point is not within the lower and upper bounds of any attributes defining the box, then the shortest distance between the new point and the hyper-box is calculated using the minimum distance between extreme points of the hyper-box and the new data as given in Eq. (26).

$$\min_{l,n}\left\{\sqrt{\sum_m\left(a_{jm}-X_{lmn}\right)^2}\right\} \tag{26}$$

Application

We applied the mathematical programming method on a set of 20 data points in 4 different groups given in Figure 2.

In this problem, 16 of these points were used in training and 4 of them used in testing. The training problem classified the data into four groups using 5 hyper-boxes as shown in Figure 2. It is interesting to note that Group1 requires two hyper-boxes while the other groups are represented with a single hyper-box. The reason for having two hyper-boxes for Group1 is due to the fact that a single hyper-box for this group would include one of the data points from another group, Group3. In order to eliminate inconsistencies in training data set, the method included one more box for Class1. After the training is completed successfully, the test data is processed to assign them to hyper-boxes that classify the data perfectly. The test problem also classified the data points with 100% accuracy as shown in Figure 2.

This illustrative example is also tested by different data classification models existing in the literature in order to compare the results and to measure the performance of the proposed model. Table 1 shows the examined models and their accuracies for this illustrative example. It can be concluded that the MILP approach performs better than other data classification methods that are listed in Table 1 for the illustrative example. The accuracy of the MILP approach is tested on IRIS, protein folding type and drug activity datasets. The results indicate that the MILP approach has better accuracy than other methods on these datasets [Uney & Turkay, 2005; Turkay & Uney & Yılmaz, 2006; Kahraman & Turkay, 2007; Uney & Yilmaz & Turkay, 2008].

FUTURE TRENDS

Future studies include evaluation of the performance of the proposed approach on other benchmark datasets. Moreover, by the help of artificially generated data sets, we plan to observe the performance of methods on data sets with distinct characteristics. Hence, we will determine the most suitable and unsuitable kind of data sets to this approach.

CONCLUSION

Multi-group data classification problem can be very effectively modeled as an MILP problem. One of the most important characteristics of the MILP approach is allowing the use of hyper-boxes for defining the boundaries of the groups that enclose all or some of the points in that set. In other words, if necessary, more than one hyper-box is constructed for a specific group in the training phase. Moreover, well-construction of the boundaries of each group provides the lack of misclassifications in the training set and indirectly improves the accuracy of the model. The suggested approach has shown to be very effective on the benchmark datasets studied so far. Furthermore, the proposed model can be used for both binary and multi-group data classification problems.

KEY TERMS

Bayesian Classifier: Bayesian Classifier is a simple probabilistic classifier based on applying Bayes' Theorem with strong independence assumptions.

Data Classification (DC): DC is a supervised learning strategy that tries to build models which able to assign new instances to a set of well-defined classes.

Decision Tree Induction: It is a predictive model that maps observations of training instances to conclusions using a tree structure.

Linear Programming (LP): LP problems involve the optimization of a linear function subject to linear equality and/or inequality constraints.

Mathematical Programming (MP): MP refers to study of problems in which one seeks to minimize

or maximize a real function by systematically choosing the values of real or integer variables within an allowed set.

Mixed Integer Linear Programming (MILP): MILP is a special case of LP problems where some of the unknown variables are integer and some of them are continuous.

Neural Network (NN): A neural network is a data structure that attempts to simulate the behavior of neurons in a biological brain.

Support Vector Machines (SVM): SVM approach operates by finding a hyper surface that will split the classes so that the distance between the hyper surface and the nearest of the points in the groups has the largest value.

Multi-Instance Learning with MultiObjective Genetic Programming

Amelia Zafra
University of Cordoba, Spain

Sebastián Ventura
University of Cordoba, Spain

INTRODUCTION

The multiple-instance problem is a difficult machine learning problem that appears in cases where knowledge about training examples is incomplete. In this problem, the teacher labels examples that are sets (also called bags) of instances. The teacher does not label whether an individual instance in a bag is positive or negative. The learning algorithm needs to generate a classifier that will correctly classify unseen examples (i.e., bags of instances).

This learning framework is receiving growing attention in the machine learning community and since it was introduced by Dietterich, Lathrop, Lozano-Perez (1997), a wide range of tasks have been formulated as multi-instance problems. Among these tasks, we can cite content-based image retrieval (Chen, Bi, & Wang, 2006) and annotation (Qi and Han, 2007), text categorization (Andrews, Tsochantaridis, & Hofmann, 2002), web index page recommendation (Zhou, Jiang, & Li, 2005; Xue, Han, Jiang, & Zhou, 2007) and drug activity prediction (Dietterich et al., 1997; Zhou & Zhang, 2007).

In this chapter we introduce MOG3P-MI, a multiobjective grammar guided genetic programming algorithm to handle multi-instance problems. In this algorithm, based on SPEA2, individuals represent classification rules which make it possible to determine if a bag is positive or negative. The quality of each individual is evaluated according to two quality indexes: sensitivity and specificity. Both these measures have been adapted to MIL circumstances. Computational experiments show that the MOG3P-MI is a robust algorithm for classification in different domains where achieves competitive results and obtain classifiers which contain simple rules which add comprehensibility and simplicity in the knowledge discovery process, being suitable method for solving MIL problems (Zafra & Ventura, 2007).

BACKGROUND

In the middle of the 1990's, Dietterich et al. (1997) described three Axis-Parallel Rectangle (abbreviated as APR) algorithms to solve the problem of classifying aromatic molecules according to whether or not they are "musky". These methods attempted to search the appropriate axis-parallel rectangles constructed by their conjunction of features. Their best performing algorithm (iterated-discrim) started with a point in the feature space and grew a box with the goal of finding the smallest box covered at least one instance from each positive bag and no instances from any negative bag. The resulting box was then expanded (via a statistical technique) to get better results.

Following Dietterich et al.'s study, a wide variety of new methods of multi-instance learning has appeared. Auer (1997) tried to avoid some potentially hard computational problems that were required by the heuristics used in the iterated-discrim algorithm and presented a theoretical algorithm, MULTINST. With a new approach, Maron and Lozano-Perez (1998) proposed one of the most famous multi-instance learning algorithms, Diverse Density (DD), where the diverse density of a point, p, in the feature space was defined as a probabilistic measure which considered how many different positive bags had an instance near p, and how far the negative instances were from p. This algorithm was combined with the Expectation Maximization (EM) algorithm, appearing as EM-DD (Zhang & Goldman, 2001). Another study that extended the DD algorithm to maintain multilearning regression data sets was the EM-based multi-instance regression algorithm (Amar, Dooly, Goldman, & Zhang, 2001).

In 1998, Long and Tan (1998) described a polynomial-time theoretical algorithm and showed that if instances in the bags were independently drawn from product distribution, then the APR was PAC-learnable. Following with PAC-learnable research, Kalai and Blum (1998) described a reduction from the problem of PAC-learning under the MIL framework to PAC-learning with one-sided random classification noise, and presented a theoretical algorithm with less complexity than the algorithm described in Auer (1997).

The first approaches using lazy learning, decision trees and rule learning were researched during the year 2000. In the lazy learning context, Whang and Zucker (2000) proposed two variants of the k nearest-neighbour algorithm (KNN) that they referred to as Citation-KNN and Bayesian-KNN; these algorithms extended the k-nearest neighbor algorithm for MIL adopting Hausdorff distance. With respect to decision trees and learning rules, Zucker and Chevaleyre (2000) implemented ID3-MI and RIPPER-MI, which are multi-instance versions of decision tree algorithm ID3 and rule learning algorithm RIPPER, respectively. At that time, Ruffo (2000) presented a multi-instance version of the C4.5 decision tree, which was known as RELIC. Later, Zhou et al. (2005) presented the Fretcit-KNN algorithm, a variant of Citation-KNN that modified the minimal Hausdorff distance for measuring the distance between text vectors and using multiple instance perspective.
There are also many other practical multiple instance (MI) algorithms, such as the extension of standard neural networks to MIL (Zhang & Zhou, 2006). Also there are proposals about adapting Support Vector Machines to multi-instance framework (Andrews et al., 2002; Qi and Han, 2007) and the use of ensembles to learn multiple instance concepts, (Zhou & Zhang, 2007).

We can see that a variety of algorithms have been introduced to learn in multi-instance settings. Many of them are based on well-known supervised learning algorithms following works such as Ray and Craven's (2005) who empirically studied the relationship between supervised and multiple instance learning, or Zhou (2006) who showed that multi-instance learners can be derived from supervised learners by shifting their focuses from the discrimination on the instances to the discrimination on the bags. Although almost all popular machine learning algorithms have been applied to solve multiple instance problems, it is remarkable that the first proposals to adapt Evolutionary Algorithm to this scenario have not appeared until 2007 (Zafra, Ventura, Herrera-Viedma, & Romero 2007; Zafra & Ventura, 2007) even though these algorithms have been applied successfully in many problems in supervised learning.

MAIN FOCUS

Genetic Programming is becoming a paradigm of growing interest both for obtaining classification rules (Lensberg, Eilifsen, & McKee, 2006), and for other tasks related to prediction, such as characteristic selection (Davis, Charlton, Oehlschalager, & Wilson, 2006) and the generation of discriminant functions. The major considerations when applying GP to classification tasks are that a priori knowledge is not needed about the statistical distribution of the data (data distribution free). It can operate directly on the data in their original form, can detect unknown relationships that exist among data, expressing them as a mathematical expression and can discover the most important discriminating features of a class. We can find different proposals that use the GP paradigm to evolve rule sets for different classification problems, both two-class ones and multiple-class ones. Results show that GP is a mature field that can efficiently achieve low error rates in supervised learning, hence making it feasible to adapt to multiple instance learning to check its performance.

We propose, MOG3P-MI, a multiobjective grammar guided genetic programming algorithm. Our main motivations to introduce genetic programming into this field are: (a) grammar guided genetic programming (G3P) is considered a robust tool for classification in noisy and complex domains where it achieves to extract valuable information from data sets and obtain classifiers which contain simple rules which add comprehensibility and simplicity in the knowledge discovery process and (b) genetic programming with multiobjective strategy allows us to obtain a set of optimal solutions that represent a trade-off between different rule quality measurements, where no one can be considered to be better than any other with respect to all objective functions. Then, we could introduce preference information to select the solution which offers the best classification guarantee with respect to new data sets.

In this section we specify different aspects which have been taken into account in the design of the MOG3P-MI algorithm, such as individual representa-

tion, genetic operators, fitness function and evolutionary process.

Individual Representation

The choice of adequate individual representation is a very important step in the design of any evolutionary learning process to determine the degree of success in the search for solutions. In the proposed algorithm the representation is given by two components: a phenotype and a genotype. An individual phenotype represents a full classifier which is applied to bags. This classifier labels a bag as being a positive bag if it contains at least one instance which satisfies the antecedent, otherwise it is labelled as a negative bag. The representation has the structure shown in Figure 1.

The antecedent consists of tree structures and is applied to instances. It represents the individual genotype which can contain multiple comparisons attached by conjunction or disjunction according to a grammar to enforce syntactic constraints and satisfy the closure property (see Figure 2).

Genetic Operators

The elements of the following population are generated by means of two operators: mutation and crossover, designed to work in grammar guided genetic programming systems.

Mutation

The mutation operator randomly selects a node in the tree and the grammar is used to derive a new subtree which replaces the subtree in this node. If the new offspring is too large, it will be eliminated to avoid having invalid individuals. Figure 3 shows an example of this mutation.

Figure 1. Classifier applied to multi-instance learning

Cover$_{\text{bag}}$**(bag$_i$)** → *IF* $\exists$ instance$_j$ $\in$ bag$_i$ where Coverinstance(instance$_j$) is positive
THEN The bag is positive.
ELSE The bag is negative.

Coverinstance(instance$_i$) → *IF* (antecedent is satisfied by instance$_i$)
THEN The instance is positive.
ELSE The instance is negative.

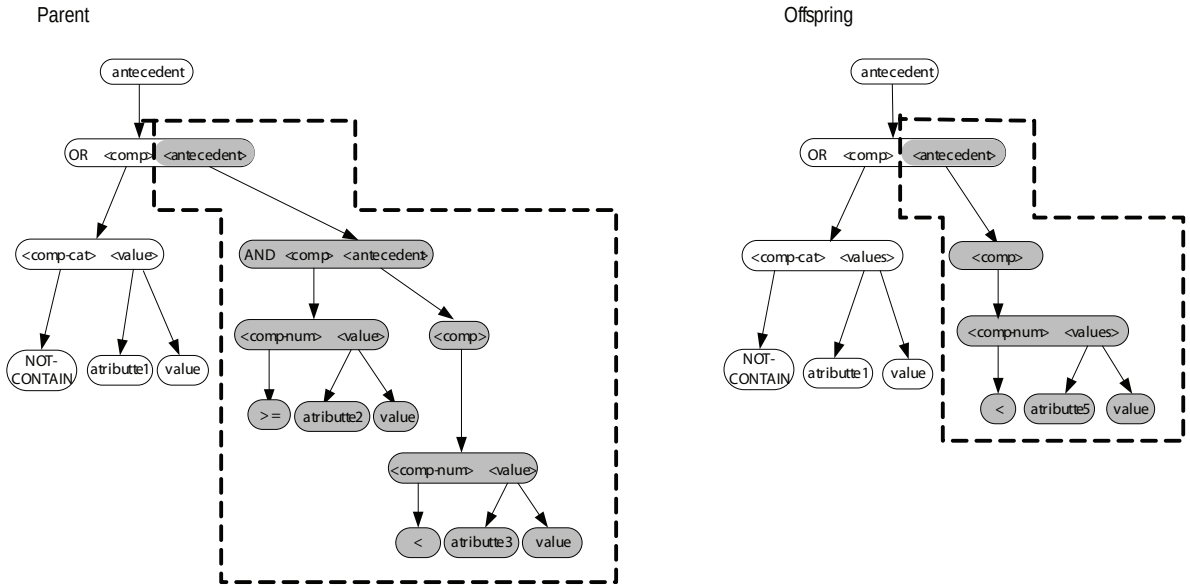
Figure 3. Example of mutation process



Crossover

The crossover is performed by swapping the sub-trees of two parents for two compatible points randomly selected in each parent. Two tree nodes are compatible if their subtrees can be swapped without producing an invalid individual according to the defined grammar. If any of the two offspring is too large, they will be replaced by one of their parents. Figure 4 shows an example of the crossover operator.

Fitness Function

The fitness function evaluates the quality of each individual according to two indices that are normally used to evaluate the accuracy of algorithms in supervised classification problems. These are sensitivity and specificity. Sensitivity is the proportion of cases correctly identified as meeting a certain condition and specificity is the proportion of cases correctly identified as not meeting a certain condition.

The adaptation of these measures to the MIL field needs to consider the bag concept instead of the instance concept. In this way, their expression would be:

$$specificity = \frac{t_n}{t_n + t_p} \; ; \; sensitivity = \frac{t_p}{t_p + f_n}$$

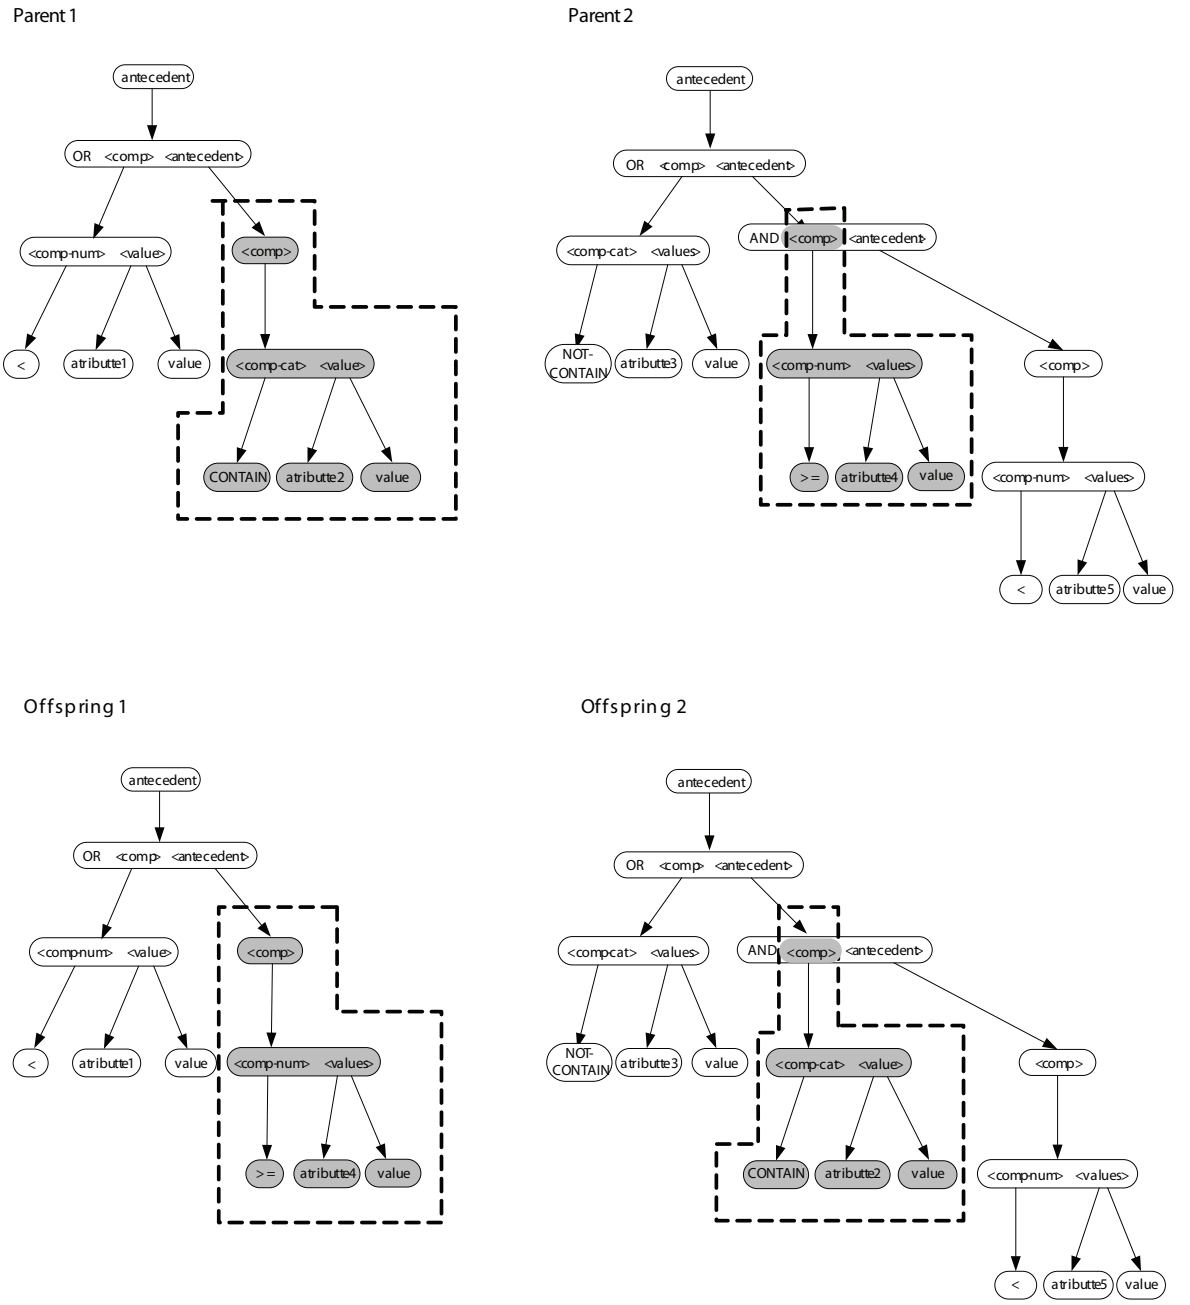
where *true positive* (t_p) represents the cases where the rule predicts that the bag has a given class and the bag does have that class. *True negative*, (t_n), are cases where the rule predicts that the bag does not have a given class, and indeed the bag does not have it. *False negative*, (f_n) cases are where the rule predicts that the bag does not have a given class but the bag does have it. Finally, P, is the number of positive bags and N, is the number of negative bags.

The evaluation involves a simultaneous optimization of these two conflicting objectives where a value of 1 in both measurements represents perfect classification. Normally, any increase in sensitivity will be accompanied by a decrease in specificity. Thus, there is no single optimal solution, and the interaction among different objectives gives rise to a set of compromised solutions, largely known as the Pareto-optimal solutions. Since none of these Pareto-optimal solutions can be identified as better than any others without further consideration, the goal is to find as many Pareto-optimal solutions as possible and include preference information to choose one of them as the final classifier.

Evolutionary Algorithm

The main steps of our algorithm are based on the well-known Strength Pareto Evolutionary Algorithm 2 (SPEA2). This algorithm was designed by Zitzler, Laumanns and Thiele (2001). It is a Pareto Front based multiobjective evolutionary algorithm that introduces some interesting concepts, such as an external elitist

Figure 4. Example of recombination process



set of non-dominated solutions, a fitness assignment schema which takes into account how many individuals each individual dominates and is dominated by, a nearest neighbour density estimation technique and a truncation method that guarantees the preservation of boundary solutions. The general outline of SPEA2 algorithm is shown in Figure 5.

FUTURE TRENDS

During these years, significant research efforts have been dedicated to MI learning and many approaches have been proposed to tackle MI problems. Although some very good results have been reported, the study of MI learning still requires topics which should be addressed. First, more datasets would have to be avail-

Figure 5. Main steps of MOG3P-MI algorithm

Algorithm MOG3P-MI

BEGIN
Generate initial population of rules, P_0 and empty archive (external set) A_0. Set t = 0.

DO
Calculate fitness values of individuals in P_t and A_t.
A_{t+1} = non-dominated individuals in P_t and A_t.
IF (size of A_{t+1} > N)
Reduce A_{t+1}.
ELSE IF (size of A_{t+1} < N)
Fill A_{t+1} ith dominated individuals in P_t and A_t.
END-IF

Fill mating pool by binary tournament selection with replacement on A_{t+1}.
Apply recombination and mutation operators to selected population, P_{t+1}.
Set P_{t+1} as resulting population. Set t = t + 1.

UNTIL an acceptable classification rule is found or the specified maximum number of generations has been reached.

END

able for the purpose of evaluation because the lack of information about many of the MI problems tackled limits studies and comparisons with other developed methods. Secondly, studies are needed to establish a general framework for MI methods and applications. Recognizing the essence and the connection between different methods can sometimes inspire new solutions with well-founded theoretical justifications. Thirdly, with respect to our adaptation of the Genetic Programming paradigm, although it has shown excellent results, more optimization of this method is possible: issues such as the stopping criterion, the pruning strategy, the choice of optimal solutions and the introduction of new objectives for further simplification would be interesting issues for future work.

CONCLUSION

The problem of MIL is a learning problem which has drawn the attention of the machine learning community. We describe a new approach to solve MIL problems which introduces the Evolutionary Algorithm in this learning. This algorithm is called MOG3P-MI and it is derived from the traditional G3P method and SPEA2 multiobjective algorithm.

MOG3P-MI generates a simple rule-based classifier that increases generalization ability and includes interpretability and simplicity in the knowledge discovered. Computational experiments (Zafra & Ventura, 2007) show that the multiobjective technique applied to G3P is an interesting algorithm for learning from multiple instance examples, finding rules which maintain a trade-off between sensitivity and specificity and obtaining the best results in terms of accuracy with respect to other existing learning algorithm.

KEY TERMS

Evolutionary Algorithm (EA): They are search and optimization methodologies based on simulation models of natural selection, which begin with a set of potential solutions and then iteratively generate new candidates and select the fittest from this set. It has been successfully applied to numerous problems from different domains, including optimization, automatic programming, machine learning, economics, ecology, studies of evolution and learning, and social systems.

Genetic Programming (GP): An Evolutionary Algorithm that provides a flexible and complete mechanism for different tasks of learning and optimization. Its main characteristic is that it uses expression tree-based representations or functional program interpretation as its computational model.

Grammar Guided Genetic Programming (G3P): An Evolutionary Algorithm that is used for individual representation grammars and formal languages. This general approach has been shown to be effective for some natural language learning problems, and the extension of the approach to procedural information extraction is a topic of current research in the GP community.

Multi-instance Learning (MIL): It is proposed as a variation of supervised learning for problems with incomplete knowledge about labels of training examples. In MIL the labels are only assigned to *bags of instances*. In the binary case, a bag is labeled positive if *at least* one instance in that bag is positive, and the bag is labeled negative if *all* the instances in it are negative. There are no labels for individual instances. The goal of MIL is to classify unseen bags or instances based on the labeled bags as the training data.

Multiobjective Optimization Problem (MOP): The problem consists of simultaneously optimizing vector functions which maintain conflicting objectives subject to some constrained conditions.

Multiobjective Evolutionary Algorithms (MOEAs): A set of Evolutionary Algorithms suitable for solving multiobjective problems. These algorithms are well suited to multiobjective optimization problems because they are fundamentally based on biological processes which are inherently multiobjective. Multiobjective Evolutionary Algorithms are able to find optimal trade-offs in order to get a set of solutions that are optimal in an overall sense.

Strength Pareto Evolutionary Algorithm 2 (SPEA2): It is an elitist Multiobjective Evolutionary Algorithm. It is an improved version of the Strength Pareto Evolutionary Algorithm (SPEA) which incorporates a fine-grained fitness assignment strategy, a density estimation technique, and an enhanced archive truncation method. SPEA2 operates with a population (archive) of fixed size, from which promising candidates are drawn as parents of the next generation. The resulting offspring then compete with the former ones for inclusion in the population.

Supervised Learning: A machine learning technique for creating a model from training data where every training instance is assigned a discrete or real-valued label. The task of the supervised learner is to classify unseen instances based on the labelled instances of training data.

Multilingual Text Mining

Peter A. Chew
Sandia National Laboratories, USA

INTRODUCTION

The principles of text mining are fundamental to technology in everyday use. The world wide web (WWW) has in many senses driven research in text mining, and with the growth of the WWW, applications of text mining (like search engines) have by now become commonplace. In a way that was not true even less than a decade ago, it is taken for granted that the 'needle in the haystack' can quickly be found among large volumes of text. In most cases, however, users still expect search engines to return results in the same language as that of the query, perhaps the language best understood by the user, or the language in which text is most likely to be available.

The distribution of languages on the WWW does not match the distribution of languages spoken in general by the world's population. For example, while English is spoken by under 10% of the world's population (Gordon 2005), it is still predominant on the WWW, accounting for perhaps two-thirds of documents. There are variety of possible reasons for this disparity, including technological inequities between different parts of the world and the fact that the WWW had its genesis in an English-speaking country. Whatever the cause for the dominance of English, the fact that two-thirds of the WWW is in one language is, in all likelihood, a major reason that the concept of *multilingual* text mining is still relatively new. Until recently, there simply has not been a significant and widespread need for multilingual text mining.

A number of recent developments have begun to change the situation, however. Perhaps these developments can be grouped under the general rubric of 'globalization'. They include the increasing adoption, use, and popularization of the WWW in non-English-speaking societies; the trend towards political integration of diverse linguistic communities (highly evident, for example, in the European Union); and a growing interest in understanding social, technological and political developments in other parts of the world. All these developments contribute to a greater demand for multilingual text processing – essentially, methods for handling, managing, and comparing documents in multiple languages, some of which may not even be known to the end user.

BACKGROUND

A very general and widely-used model for text mining is the vector space model; for a detailed introduction, the reader should consult an information retrieval textbook such as Baeza-Yates & Ribeiro-Neto (1999). Essentially, all variants of the vector space model are based on the insight that documents (or, more generally, chunks of text) can also be thought of as vectors (or columns of a matrix) in which the rows correspond to terms that occur in those documents. The vectors/matrices can be populated by numerical values corresponding to the frequencies of occurrence of particular terms in particular documents, or, more commonly, to *weighted* frequencies. A variety of weighting schemes are employed; an overview of some of these is given in Dumais (1991). A common practice, before processing, is to eliminate rows in the vectors/matrices corresponding to 'stopwords' (Luhn, 1957) – in other words, to ignore from consideration any terms which are considered to be so common that they contribute little to discriminating between documents. At its heart, the vector space model effectively makes the assumption that the meaning of text is an aggregation of the meaning of all the words in the text, and that meaning can be represented in a multidimensional 'concept space'. Two documents which are similar in meaning will contain many of the same terms, and hence have similar vectors. Furthermore, 'similarity' can be quantified using this model; the similarity of two documents in the vector space is the cosine between the vectors for the documents. Document vectors in the vector space model can also be used for supervised predictive mining; an example is in Pang et al. (2002), where document vectors are used to classify movie reviews into 'positive' versus 'negative'.

A variant on the vector space model commonly used in text mining is Latent Semantic Analysis (LSA) (Deerwester et al., 1990). This approach takes advantage of the higher-order structure in the association of terms with documents by applying singular value decomposition (SVD) to the initial term-by-document matrix. SVD is a method in multilinear algebra for decomposition of a matrix into its principal components, and is used to find the best lower-rank approximation to the original matrix. In text mining, SVD can be used to '[represent] both terms and documents as vectors in a space of choosable dimensionality' (Deerwester et al., 1990: 395). The principal contribution of LSA is that it deals with the inherently noisy characteristics of text by mapping terms to more nebulous 'concepts' without abandoning statistical principles to do so; a thesaurus is not required to find terms of similar meaning, as terms of similar meaning should in theory be identifiable by the statistics of their distributions. When applied to practical text mining problems, the results of LSA analyses have often been shown to be as good as, or better than, simpler vector space approaches (Deerwester et al., 1990). Perhaps the most significant advantage of LSA, however, is that the representation of documents is generally much more economical than under approaches in which each term corresponds to the 'dimension' of a vector. In typical real-world text mining problems, document sets may contain thousands of distinct terms, meaning that, with simple vector-space approaches, document vectors must contain thousands of entries (although the vectors are usually sparse). With LSA, on the other hand, documents are often represented by vectors containing on the order of 200-300 values. When it comes to computing cosines between vectors or training predictive data mining models, for example, this can save a significant amount of computational horsepower.

MAIN FOCUS

The basic problem of multilingual text mining (also known as cross-language information retrieval) is that of representing text from different languages in a single, coherent conceptual space. If this can be achieved, then, at least in theory, the groundwork is laid for solving problems such as the following:

- Computation of the similarity of documents in different languages
- Prediction of other variables (such as positive or negative sentiment) from the text, regardless of the text's language
- Clustering of documents in multiple languages by topic, regardless of the documents' languages

From a multilingual perspective, the vector space model in general has many practical features which recommend it. First, the process of tokenization – computing which terms occur in which documents – is very general, from a linguistic point of view. While linguistically the concept of the 'word' may carry different connotations from language to language, it is computationally straightforward to define the 'term' (which at least in English often corresponds to the word) in a way which can easily be applied to virtually all languages. The task is made easier by the fact that a computational infrastructure for this already exists: both Unicode, itself a product of the 'globalization' of computing, and regular expressions, facilitate tokenization in multiple languages. Essentially, we can say that a term is any portion of text bounded at its left and right edges by 'non-word' characters (the latter being pre-defined in the regular expressions framework for virtually all Unicode code pages). Thus, Unicode allows this definition to be applied equally for languages in Roman and non-Roman script; for languages with left-to-right or right-to-left script; and so on. Of the major languages of the WWW, Chinese is perhaps the only one that presents a challenge to the general definition, as 'non-word' characters often occur only at sentence boundaries in Chinese. Yet this is by no means an insurmountable problem; while Chinese characters do not exactly correspond to English words, a reasonable approach with Chinese, representing only a minor deviation from the general rule proposed above, would be to treat each *character* as a term, since Chinese characters in general each have a meaning of their own.

The simplest vector space model, in which the rows of the vectors and matrices correspond one-to-one to distinct terms, is inappropriate for multilingual text mining, however. The reason for this is that there is usually comparatively little overlap between languages with respect to the terms that occur in those languages. Even where it exists, some of the overlap is attributable to 'faux amis' – words which are homographic across languages but have different meanings, such as

English ‘coin’ and French ‘coin’ (corner). For pairs of languages written in mutually exclusive scripts, such as English and Russian, the respective sets of terms are completely disjoint by definition. Thus, an approach to cross-language text comparison which treats terms as features is more or less doomed from the start.

A more promising vector-space approach to multilingual text mining is offered by LSA. In this approach, described in Berry et al. (1994), Young (1994), and Dumais et al. (1997), the initial term-by-document matrix is formed from a parallel corpus. The list of indexed terms, then, will contain all distinct terms from *any* of the parallel languages, while each ‘document’ will be a parallel text chunk consisting of the *concatenation* of the text in all the parallel languages. The effect of this is that terms which are synonymous but from different languages (translations of one another) will tend to co-occur in the same documents. The SVD is computed for the term-by-document matrix, just as if the matrix had been formed from documents of just one language. Since SVD takes into account the statistics of term co-occurrence, terms and documents which are translations of one another will generally be represented within the vector space by vectors with a high similarity to one another. Under this method, even documents which are not in a parallel corpus can be compared to one another. Moreover, the approach is extensible: it can be applied to large numbers of languages at once, not just pairs of languages, as long as all languages are represented in the parallel corpus used to train LSA. Using parallel translations of the Bible (Resnik, 1999; Biola University, 2007) as training data, Chew & Abdelali (2007) show that the method can be extended to dozens of languages at once. Including large numbers of languages in the training data not only allows documents in all those languages to be mapped within a single cross-language semantic space; it also results in an improved characterization of that semantic space, since including more parallel languages measurably increases precision in cross-language retrieval. Increasingly, as parallel text becomes more available on-line, new possibilities are opened up for this type of analysis.

However, even multilingual LSA suffers from certain drawbacks. Essentially, these all stem from the fact that there is no simple set of correspondences between terms in one language and terms in another. For example, English ‘in’ might sometimes be translated into French as ‘en’, sometimes as ‘dans’, sometimes (together with following ‘the’) as ‘au’ or ‘aux’, and so on. Conversely, French ‘aux’ can be translated back into English as ‘in the’, ‘at the’, or ‘to the’, depending on the context. Furthermore, as can be seen from these examples, one term in French may correspond to two terms in English, meaning the word-alignment is not always one-to-one. Depending on how closely related two languages are, these effects may be more extreme. For example, Russian, unlike English, preserves a nominal case system in which the ending of a noun is determined by its function in the sentence. Some examples are given in Table 1.

In Russian, therefore, the word-endings take on many of the same functions that are fulfilled in English by prepositions. Within a model in which terms are strings of text bounded by non-word characters, the consequence of this is that Russian packs more information into each term than English. A further consequence is that Russian requires fewer terms overall to express the same meaning as English, which can be confirmed by inspection of any parallel English-Russian text. The problem of lack of simple term-to-term correspondences cannot simply be solved by removing stopwords (such as English ‘to’, ‘of’ and ‘the’ in the above example), because one must still deal with the fact that ‘собака’, ‘собаку’, ‘собаки’ and ‘собаке’ are distinct terms all corresponding to ‘dog’.

For LSA, one reason this presents a problem is that languages will not receive equal weighting in the decomposition of parallel text. If, for example, parallel English-Russian text consistently contains more English terms than Russian ones, simply because Russian requires fewer terms to convey the same meaning,

Table 1. Example term correspondences between English and Russian

‘dog’ (subject of sentence)	собака
‘dog’ (object of sentence)	собаку
‘of the dog’	собаки
‘to the dog’	собаке

English terms will tend to be overweighted in the decomposition.

An alternative to LSA which goes some way towards remedying this is PARAFAC2 (Harshman, 1972). In multilingual text mining, PARAFAC2 is a close cousin to LSA, and is also within the general family of techniques that operate within the vector-space model. PARAFAC2 assumes that the parallel corpus is represented as a three-way array instead of as a single term-by-document matrix (Chew et al., 2007). Each slice of the array corresponds to the term-by-document matrix for a single language. A separate LSA-like decomposition is performed for each slice with the constraint that the 'document-by-concept matrix' output by the decomposition (the so-called V matrix) is constant across all languages. This allows each language some autonomy in contributing to the overall decomposition, and providing a principled statistical method allowing for the fact that some languages use more terms than others. It has been demonstrated empirically that PARAFAC2 results in an improved characterization of the documents within a semantic space, compared to LSA (Chew et al., 2007); this is measured by increased precision in the results of cross-language information retrieval tests from, for example, 0.268 to 0.415. Nonetheless, the results do still vary depending on the language pair; generally, for morphologically complex languages like Russian where terms are more content-rich, results are not as good. In this respect, PARAFAC2 still has some of the same weaknesses as LSA.

FUTURE TRENDS

As the volume and diversity of on-line multilingual content increases, multilingual text mining can be expected to receive growing attention from users and the research community. To some extent, this is already becoming evident through the existence of specialist groups such as the Cross-Language Evaluation Forum (CLEF) (see for example Peters, 2001), which has explored issues surrounding cross-language information retrieval since the turn of the millennium. Interest in multilingual text mining can also be expected to grow as the processes of globalization make users increasingly aware of text resources available elsewhere around the world.

It is frequently observed that the lack of more multilingual resources (such as parallel corpora, particularly for minority languages) is an impediment to multilingual text mining. It is certainly true that recent successes in multilingual natural language processing have come from data-driven approaches such as Statistical Machine Translation (SMT) (Koehn et al. 2003, Chiang 2005). Indeed, the whole field of machine translation has undergone a revival in recent years precisely because training data is becoming more available; an additional factor is the increased availability of computing power necessary to train SMT or similar algorithms on large amounts of data. Furthermore, it is generally the case that more training data equates to improved results for methods such as SMT. Thus, to the extent that multilingual corpora are *not* available, it would be true that multilingual text mining has been held back. However, as observed in this article, and evidenced by an increasing number of workshops devoted to the issue of multilingual resources, examples being the Workshop on Multilingual Language Resources and Interoperability (Association for Computational Linguistics, 2006) and the Workshop on Cross-Lingual Information Access to be held in 2008, the problem of lack of data is in the process of being addressed. If the availability of data is not already a solved problem, it soon may be; and attention will increasingly need to be focused on the next issue at hand, which is the improvement of algorithms for processing that data.

CONCLUSION

This article has surveyed the state of the art in multilingual text mining, from an introduction to the vector space model, to techniques such as Latent Semantic Analysis and PARAFAC2. While significant strides have been made in the field, by no means all the problems of multilingual text mining have been solved. In particular, a challenge is to find a model which is more able to handle text in morphologically complex languages than existing models. One of the factors which has contributed to progress in other related fields, such as machine translation, is an expansion of textual data available for training statistical models. There is good reason to hope that these same factors, together with improved algorithms for analysis of (or decomposition of) the data will lead to new breakthroughs in the field of multilingual text mining.

KEY TERMS

Information Retrieval: The science of searching for information in documents or for documents themselves, for example through efficient indexing of the documents.

Latent Semantic Analysis (LSA): Also known as Latent Semantic Indexing, LSA is a statistically-based natural language processing technique for analyzing relationships between documents and their constituent terms by computing the *n* most important 'concepts' expressed in the text (where *n* is determined by the analyst).

PARAFAC2: An abbreviation for Parallel Factor Analysis 2, PARAFAC2 is a model for decomposition of multi-way arrays. It is a variant of PARAFAC1 (or simply PARAFAC) which can be used for decomposition of tensors, with the difference that, under PARAFAC2, strict trilinearity is not required.

Stopwords: Terms filtered out prior to processing of text. Typically, stopwords are hand-picked according to the judgement of the analyst; they are the terms considered to have low intrinsic meaning because of their widespread distribution.

Terms: The units of which text is composed. Often, 'term' is synonymous with 'word'.

Text Mining: The automated extraction of useful information from unstructured text data.

Tokenization: The process of breaking a document or chunk of text into its constituent terms.

Vector Space Model: An algebraic approach to the representation of documents or text chunks. Documents are represented as vectors of identifiers, such as index terms.

Multiple Criteria Optimization in Data Mining

INTRODUCTION

Multiple criteria optimization seeks to simultaneously optimize two or more objective functions under a set of constraints. It has a great variety of applications, ranging from financial management, energy planning, sustainable development, to aircraft design. Data mining is aim at extracting hidden and useful knowledge from large databases. Major contributors of data mining include machine learning, statistics, pattern recognition, algorithms, and database technology (Fayyad, Piatetsky-Shapiro, & Smyth, 1996). In recent years, the multiple criteria optimization research community has actively involved in the field of data mining (See, for example: Yu 1985; Bhattacharyya 2000; Francisci & Collard, 2003; Kou, Liu, Peng, Shi, Wise, & Xu, 2003; Freitas 2004; Shi, Peng, Kou, & Chen, 2005; Kou, Peng, Shi, Wise, & Xu, 2005; Kou, Peng, Shi, & Chen, 2006; Shi, Peng, Kou, & Chen, 2007).

Many data mining tasks, such as classification, prediction, clustering, and model selection, can be formulated as multi-criteria optimization problems. Depending upon the nature of problems and the characteristics of datasets, different multi-criteria models can be built. Utilizing methodologies and approaches from mathematical programming, multiple criteria optimization is able to provide effective solutions to large-scale data mining problems. An additional advantage of multi-criteria programming is that it assumes no deterministic relationships between variables (Hand & Henley, 1997).

BACKGROUND

The goal of data mining is to identify hidden, interesting, and useful structures from large databases (Fayyad & Uthurusamy, 2002). Methods and techniques from multiple disciplines, such as machine learning, statistics, pattern recognition, and database technology, have been applied extensively in data mining to extract patterns from data. Recently, the multi-criteria or multi-objective optimization-based methods have been proposed as another option for data mining tasks. For instance, Bhattacharyya proposed a multi-objective model for direct marketing (2000); Francisci and Collard addressed the interestingness measure of dependency rules by formulating the scenario as a multi-criteria problem (2003); and Kou, Peng, Shi, and Chen built a multi-criteria convex quadratic programming model for credit portfolio management (2006).

If a data mining task can be modeled as optimization problems with multiple objective functions, it can be cast into the multi-criteria optimization framework. Many data mining functionalities, such as classification, prediction, and interestingness measure, can be formulated as multi-criteria optimization problems. For example, in multi-criteria optimization context, the classification problem can be stated as one of simultaneously minimizing misclassified points and maximizing correctly classified points. The established methodologies and procedures for solving multi-criteria optimization problems and incorporating the results into the business decision process by the discipline of multi-criteria decision making (MCDM) can be applied to these data mining tasks.

MAIN FOCUS

Currently, the main focuses of multiple criteria optimization in data mining include: model construction, algorithm design, and results interpretation and application.

Model Construction

Model construction refers to the process of establishing mathematical models for multi-criteria data mining problems, which exist in many data mining tasks. For example, in network intrusion detection, the goal is to build classifiers that can achieve not only high classification accuracy, but also low false alarm rate. Although multiple objectives can be modeled separately, they normally can not provide optimal solutions to the overall problem (Fonseca & Fleming, 1995). Furthermore, a model may perform well on one objective, but poorly on other objectives. In this kind of scenario, multiple criteria optimization can be used to build models that can optimize two or more objectives simultaneously and find solutions to satisfy users' preferences.

Algorithm Design

Algorithm design is a set of steps that takes raw data as input and generates solutions as output. Specifically, algorithm design normally includes data preparation, optimization approach, and model assessment.

1. **Data preparation:** Raw data are selected and cleaned according to the requirements of data mining tasks. In addition, data need to be formatted into appropriate forms. Since multiple criteria optimization models can handle only numeric inputs, categorical attributes need to be transformed into numeric types.
2. **Optimization approach:** There are three main approaches to multiple criteria optimization (Freitas, 2004): (i) convert multiple objectives into a single-criterion problem using weight vectors; (ii) prioritize objectives and concentrate on objectives with high priorities, which is called the lexicographical approach; (iii) find a set of non-dominated solutions and allow business users to pick their desired solutions, which is also known as the Pareto approach. Each approach has its advantages and disadvantages. The first approach, reformatting multi-criteria as a single-objective problem, is by far the most popular one in data mining field due to its simplicity and efficiency.
3. **Model assessment:** Results of models, such as accuracy and generality, are assessed according to predefined criteria.

Results Interpretation and Application

Depending on application domains and user preferences, results should be interpreted differently. Take health insurance fraud detection as an example. Multiple criteria optimization can provide class labels and probability scores. Health insurance companies need to process large volumes of records and have limited resources to manually investigate potential fraud records (Peng et al., 2007). In this case, class labels alone, which distinguish normal records from fraud records, are not as useful as the combination of class labels and probability scores that can rank potential fraud records. Data miners should discuss with business users to determine which forms of results can better satisfy business objectives (Chapman, Clinton, Khabaza, Reinartz, & Wirth, 1999).

FUTURE TRENDS

The application of multiple criteria optimization techniques can be expanded to more data mining tasks. So far classification task is the most studied problem in the data mining literature. Multiple criteria optimization could be applied to many other data mining issues, such as data preprocessing, clustering, model selection, and outlier detection (Mangasarian, 1996). Another direction is to examine the applicability of the lexicographical and Pareto approaches in large scale data mining problems.

CONCLUSION

Many data mining tasks involve simultaneously satisfy two or more objectives and thus multiple criteria optimization is appropriate for these tasks in nature. The main components of multiple criteria optimization in data mining include model construction, algorithm design, and results interpretation and application. Model construction builds multi-criteria models; algorithm

design takes raw data and generates optimization solutions; optimization solutions are interpreted and implemented according to end users' preferences. Compare with popular data mining techniques, such as machines learning and statistics, multiple criteria optimization is not well studied. Much more work is needed to broaden the applicability of multiple criteria optimization in important data mining problems.

KEY TERMS

Multi-Criteria Decision Making: the study of methods and procedures by which concerns about multiple conflicting criteria can be formally incorporated into the management planning process (International Society on MCDM).

Multi-Criteria Optimization: In mathematics, optimization/mathematical programming is concerned with the problems/processes in finding the maxima and minima of objectives/functions, subject to constraints/sets. Linear programming (LP) and nonlinear programming (NLP) are two sub-areas of optimization.

Linear Programming: Linear programming (LP) problems are optimization problems with linear objective function and linear constraints.

Nonlinear Programming: Nonlinear programming problems are optimization problems with nonlinear function in the objective function, constraints or both of them.

Multiple Hypothesis Testing for Data Mining

Sach Mukherjee
University of Oxford, UK

INTRODUCTION

A number of important problems in data mining can be usefully addressed within the framework of statistical hypothesis testing. However, while the conventional treatment of statistical significance deals with error probabilities at the level of a single variable, practical data mining tasks tend to involve thousands, if not millions, of variables. This Chapter looks at some of the issues that arise in the application of hypothesis tests to multi-variable data mining problems, and describes two computationally efficient procedures by which these issues can be addressed.

BACKGROUND

Many problems in commercial and scientific data mining involve selecting objects of interest from large datasets on the basis of numerical relevance scores ("object selection"). This Section looks briefly at the role played by hypothesis tests in problems of this kind. We start by examining the relationship between relevance scores, statistical errors and the testing of hypotheses in the context of two illustrative data mining tasks. Readers familiar with conventional hypothesis testing may wish to progress directly to the main part of the Chapter.

As a topical example, consider the differential analysis of gene microarray data (Piatetsky-Shapiro & Tamayo, 2004; Cui & Churchill, 2003). The data consist of expression levels (roughly speaking, levels of activity) for each of thousands of genes across two or more conditions (such as healthy and diseased). The data mining task is to find a set of genes which are differentially expressed between the conditions, and therefore likely to be relevant to the disease or biological process under investigation. A suitably defined mathematical function (the t-statistic is a canonical choice) is used to assign a "relevance score" to each gene and a subset of genes selected on the basis of the scores. Here, the objects being selected are genes.

As a second example, consider the mining of sales records. The aim might be, for instance, to focus marketing efforts on a subset of customers, based on some property of their buying behavior. A suitably defined function would be used to score each customer by relevance, on the basis of his or her records. A set of customers with high relevance scores would then be selected as targets for marketing activity. In this example, the objects are customers.

Clearly, both tasks are similar; each can be thought of as comprising the assignment of a suitably defined relevance score to each object and the subsequent selection of a set of objects on the basis of the scores. The selection of objects thus requires the imposition of a threshold or cut-off on the relevance score, such that objects scoring higher than the threshold are returned as relevant. Consider the microarray example described above. Suppose the function used to rank genes is simply the difference between mean expression levels in the two classes. Then the question of setting a threshold amounts to asking how large a difference is sufficient to consider a gene relevant. Suppose we decide that a difference in means exceeding x is 'large enough': we would then consider each gene in turn, and select it as "relevant" if its relevance score equals or exceeds x. Now, an important point is that the data are random variables, so that if measurements were collected again from the same biological system, the actual values obtained for each gene might differ from those in the particular dataset being analyzed. As a consequence of this variability, there will be a real possibility of obtaining scores in excess of x from genes which are in fact *not* relevant.

In general terms, high scores which are simply due to chance (rather than the underlying relevance of the object) lead to the selection of irrelevant objects; errors of this kind are called false positives (or Type I errors). Conversely, a truly relevant object may have an unusually low score, leading to its omission from the final set of results. Errors of this kind are called false negatives (or Type II errors). Both types of error are associated with identifiable costs: false positives lead to wasted

resources, and false negatives to missed opportunities. For example, in the market research context, false positives may lead to marketing material being targeted at the wrong customers; false negatives may lead to the omission of the "right" customers from the marketing campaign. Clearly, the rates of each kind of error are related to the threshold imposed on the relevance score: an excessively strict threshold will minimize false positives but produce many false negatives, while an overly lenient threshold will have the opposite effect. Setting an *appropriate* threshold is therefore vital to controlling errors and associated costs.

Statistical hypothesis testing can be thought of as a framework within which the setting of thresholds can be addressed in a principled manner. The basic idea is to specify an acceptable false positive rate (i.e. an acceptable probability of Type I error) and then use probability theory to determine the precise threshold which corresponds to that specified error rate. A general discussion of hypothesis tests at an introductory level can be found in textbooks of statistics such as DeGroot and Schervish (2002), or Moore and McCabe (2002); the standard advanced reference on the topic is Lehmann (1997).

Now, let us assume for the moment that we have only one object to consider. The hypothesis that the object is irrelevant is called the null hypothesis (and denoted by H_0), and the hypothesis that it is relevant is called the alternative hypothesis (H_1). The aim of the hypothesis test is to make a decision regarding the relevance of the object, that is, a decision as to which hypothesis should be accepted. Suppose the relevance score for the object under consideration is t. A decision regarding the relevance of the object is then made as follows:

1. Specify an acceptable level of Type I error p^*.
2. Use the sampling distribution of the relevance score under the null hypothesis to compute a threshold score corresponding to p^*. Let this threshold score be denoted by c.
3. If $t \geq c$, reject the null hypothesis and regard the object as relevant. If $t < c$, regard the object as irrelevant.

The specified error level p^* is called the significance level of the test and the corresponding threshold c the critical value.

Hypothesis testing can alternatively be thought of as a procedure by which relevance scores are converted into corresponding error probabilities. The null sampling distribution can be used to compute the probability p of making a Type I error if the threshold is set at exactly t, i.e. just low enough to select the given object. This then allows us to assert that the probability of obtaining a false positive if the given object is to be selected is at least p. This latter probability of Type I error is called a P-value. In contrast to relevance scores, P-values, being probabilities, have a clear interpretation. For instance, if we found that an object had a t-statistic value of 3 (say), it would be hard to tell whether the object should be regarded as relevant or not. However, if we found the corresponding P-value was 0.001, we would know that if the threshold were set just low enough to include the object, the false positive rate would be 1 in 1000, a fact that is far easier to interpret.

MAIN THRUST

We have seen that in the case of a single variable, relevance scores obtained from test statistics can be easily converted into error probabilities called P-values. However, practical data mining tasks, such as mining microarrays or consumer records, tend to be on a very large scale, with thousands, even millions of objects under consideration. Under these conditions of multiplicity, the conventional P-value described above no longer corresponds to the probability of obtaining a false positive.

An example will clarify this point. Consider once again the microarray analysis scenario, and assume that a suitable relevance scoring function has been chosen. Now, suppose we wish to set a threshold corresponding to a false positive rate of 0.05. Let the relevance score whose P-value is 0.05 be denoted by t_{05}. Then, in the case of a single variable/gene, if we were to set the threshold at t_{05}, the probability of obtaining a false positive would be 0.05. However, in the multi-gene setting, it is *each* of the thousands of genes under study that is effectively subjected to a hypothesis test with the specified error probability of 0.05. Thus, the chance of obtaining a false positive is no longer 0.05, but much higher. For instance, if each of 10000 genes were statistically independent, $(0.05 \times 10000) = 500$ genes would be mistakenly selected on average! In

effect, the very threshold which implied a false positive rate of 0.05 for a single gene now leaves us with hundreds of false positives.

Multiple hypothesis testing procedures address the issue of multiplicity in hypothesis tests and provide a way of setting appropriate thresholds in multi-variable problems. The remainder of this Section describes two well-known multiple testing methods (the Bonferroni and False Discovery Rate methods), and discusses their advantages and disadvantages.

Table 1 summarizes the numbers of objects in various categories, and will prove useful in clarifying some of the concepts presented below. The total number of objects under consideration is m, of which m_1 are relevant and m_0 are irrelevant. A total of S objects are selected, of which S_1 are true positives and S_0 are false positives. We follow the convention that variables relating to irrelevant objects have the subscript "0" (to signify the null hypothesis) and those relating to relevant objects the subscript "1" (for the alternative hypothesis). Note also that fixed quantities (e.g. the total number of objects) are denoted by lower-case letters, while variable quantities (e.g. the number of objects selected) are denoted by upper-case letters.

The initial stage of a multi-variable analysis follows from our discussion of basic hypothesis testing and is common to the methods discussed below. The data is processed as follows:

1. Score each of the m objects under consideration using a suitably chosen test statistic f. If the data corresponding to object j is denoted by D_j, and the corresponding relevance score by T_j:

   $$T_j = f(D_j)$$

Let the scores so obtained be denoted by T_1, T_2,…T_m.

Table 1. Summary table for multiple testing, following Benjamini and Hochberg (1995)

	Selected	Not selected	Total
Irrelevant objects	S_0	m_0-S_0	m_0
Relevant objects	S_1	m_1-S_1	m_1
Total	S	m-S	m

2. Convert each score T_j to a corresponding P-value P_j by making use of the relevant null sampling distribution

   $$T_j \xrightarrow{\text{null sampling distribution}} P_j$$

These P-values are called 'nominal P-values' and represent *per-test* error probabilities. The procedure by which a P-value corresponding to an observed test statistic is computed is not described here, but can be found in any textbook of statistics, such as those mentioned previously. Essentially, the null cumulative distribution function of the test statistic is used to compute the probability of Type I error at threshold T_j.

3. Arrange the P-values obtained in the previous step in ascending order (smaller P-values correspond to objects more likely to be relevant). Let the *ordered* P-values be denoted by:

   $$P_{(1)} \le P_{(2)} \le \cdots \le P_{(m)}$$

Thus, each object has a corresponding P-value. In order to select a subset of objects, it will therefore be sufficient to determine a threshold in terms of nominal P-value.

The Bonferroni Method

This is perhaps the simplest method for correcting P-values. We first specify an acceptable probability of committing at least one Type I error, and then calculate a corresponding threshold in terms of nominal P-value.

Procedure

1. Specify an acceptable probability p^* of at least one Type I error being committed.
2. Recall that $P_{(1)} \le P_{(2)} \le \ldots \le P_{(m)}$ represent the ordered P-values. Find the largest i which satisfies the following inequality: $P_{(i)} \le \frac{p^*}{m}$

   Let the largest i found be denoted k.

3. Select the k objects corresponding to P-values $P_{(1)}$, $P_{(2)}$…$P_{(k)}$ as relevant.

If we assume that all *m* tests are statistically independent, it is easy to show that this simple procedure does indeed guarantee that the probability of obtaining at least one false positive is *p**.

Advantages

- The basic Bonferroni procedure is extremely simple to understand and use.

Disadvantages

- The Bonferroni procedure sets the threshold to meet a specified probability of making *at least one* Type I error. This notion of error is called "Family Wise Error Rate", or FWER, in the statistical literature. FWER is a very strict control of error, and is far too conservative for most practical applications. Using FWER on datasets with large numbers of variables often results in the selection of a *very* small number of objects, or even none at all.
- The assumption of statistical independence between tests is a strong one, and almost never holds in practice.

The FDR Method of Benjamini and Hochberg

An alternative way of thinking about errors in multiple testing is the false discovery rate **(FDR)** (Benjamini & Hochberg, 1995). Looking at Table 1 we can see that of *S* objects selected, S_0 are false positives. FDR is simply the average proportion of false positives among the objects seleced:

$$FDR \equiv E\left[\frac{S_0}{S}\right]$$

Where, E[] denotes expectation. The Benjamini and Hochberg method allows us to compute a threshold corresponding to a specified FDR.

Procedure

1. Specify an acceptable FDR q*
2. Find the largest *i* which satisfies the following inequaity:

$$P_{(i)} \leq \frac{i}{m} \times q^*$$

Let the largest *i* found be denoted *k*.

(3) Select the *k* objects corresponding to P-values $P_{(1)}, P_{(2)} \ldots P_{(k)}$ as relevant.

Under the assumption that the *m* tests are statistically independent, it can be shown that this procedure leads to a selection of objects such that the FDR is indeed *q**.

Advantages

- The FDR concept is far less conservative than the Bonferroni method described above.
- Specifying an acceptable proportion *q** of false positives is an intuitively appealing way of controlling the error rate in object selection.
- The FDR method tells us in advance that a certain proportion of results are likely to be false positives. As a consequence, it becomes possible to plan for the associated costs.

Disadvantages

- Again, the assumption of statistically independent tests rarely holds.

FUTURE TRENDS

A great deal of recent work in statistics, machine learning and data mining has focused on various aspects of multiple testing in the context of object selection. Some important areas of active research which were not discussed in detail are briefly described below.

Robust FDR Methods

The FDR procedure outlined above, while simple and computationally efficient, makes several strong assumptions, and while better than Bonferroni is still often too conservative for practical problems (Storey & Tibshirani, 2003). The recently introduced "q-value" (Storey, 2003) is a more sophisticated approach to FDR correction and provides a very robust methodol-

ogy for multiple testing. The q-value method makes use of the fact that P-values are uniformly distributed under the null hypothesis to accurately estimate the FDR associated with a particular threshold. Estimated FDR is then used to set an appropriate threshold. The q-value approach is an excellent choice in many multivariable settings.

Resampling Based Methods

In recent years a number of resampling based methods have been proposed for multiple testing (see e.g. Westfall & Young, 1993). These methods make use of computationally intensive procedures such as the bootstrap (Efron, 1982; Davison & Hinckley, 1997) to perform non-parametric P-value corrections. Resampling methods are extremely powerful and make fewer strong assumptions than methods based on classical statistics, but in many data mining applications the computational burden of resampling may be prohibitive.

Machine Learning of Relevance Functions

The methods described in this chapter allowed us to determine threshold relevance scores, but very little attention was paid to the important issue of choosing an appropriate relevance scoring function. Recent research in bioinformatics (Broberg, 2003; Mukherjee, 2004a) has shown that the effectiveness of a scoring function can be very sensitive to the statistical model underlying the data, in ways which can be difficult to address by conventional means. When fully labeled data (i.e. datasets with objects flagged as relevant/irrelevant) are available, canonical supervised algorithms (see e.g. Hastie, Tibshirani, & Friedman , 2001) can be used to learn effective relevance functions. However, in many cases - microarray data being one example - fully labeled data is hard to obtain. Recent work in machine learning (Mukherjee, 2004b) has addressed the problem of learning relevance functions in an unsupervised setting by exploiting a probabilistic notion of stability; this approach turns out to be remarkably effective in settings where underlying statistical models are poorly understood and labeled data unavailable.

CONCLUSION

An increasing number of problems in industrial and scientific data analysis involve multiple testing, and there has consequently been an explosion of interest in the topic in recent years. This Chapter has discussed a selection of important concepts and methods in multiple testing; for further reading we recommend Benjamini and Hochberg (1995) and Dudoit, Shaffer, & Boldrick, (2003).

KEY TERMS

Alternative Hypothesis: The hypothesis that an object is relevant. In general terms, the alternative hypothesis refers to the set of events that is the complement of the null hypothesis.

False Discovery Rate (FDR): The expected proportion of false positives among the objects selected as relevant.

False Negative: The error committed when a truly relevant object is not selected. More generally, a false negative occurs when the null hypothesis is erroneously accepted. Also called Type II error.

False Positive: The error committed when an object is selected as relevant when it is in fact irrelevant. More generally, a false positive occurs when the null hypothesis is erroneously rejected. Also called Type I error.

Gene Microarray Data: Measurements of mRNA abundances derived from biochemical devices called microarrays. These are essentially measures of gene activity.

Hypothesis Test: A formal statistical procedure by which an interesting hypothesis (the alternative hypothesis) is accepted or rejected on the basis of data.

Multiple Hypothesis Test: A formal statistical procedure used to account for the effects of multiplicity in a hypothesis test.

Null Hypothesis: The hypothesis that an object is irrelevant. In general terms, it is the hypothesis we wish to falsify on the basis of data.

P-Value: The P-value for an object is the probability of obtaining a false positive if the threshold is set just high enough to include the object among the set selected as relevant. More generally, it is the false positive rate corresponding to an observed test statistic.

Random Variable: A variable characterized by random behavior in assuming its different possible values.

Sampling Distribution: The distribution of values obtained by applying a function to random data.

Test Statistic: A relevance scoring function used in a hypothesis test. Classical test statistics (such as the t-statistic) have null sampling distributions which are known *a priori*. However, under certain circumstances null sampling distributions for arbitrary functions can be obtained by computational means.

Music Information Retrieval

Alicja A. Wieczorkowska
Polish-Japanese Institute of Information Technology, Poland

INTRODUCTION

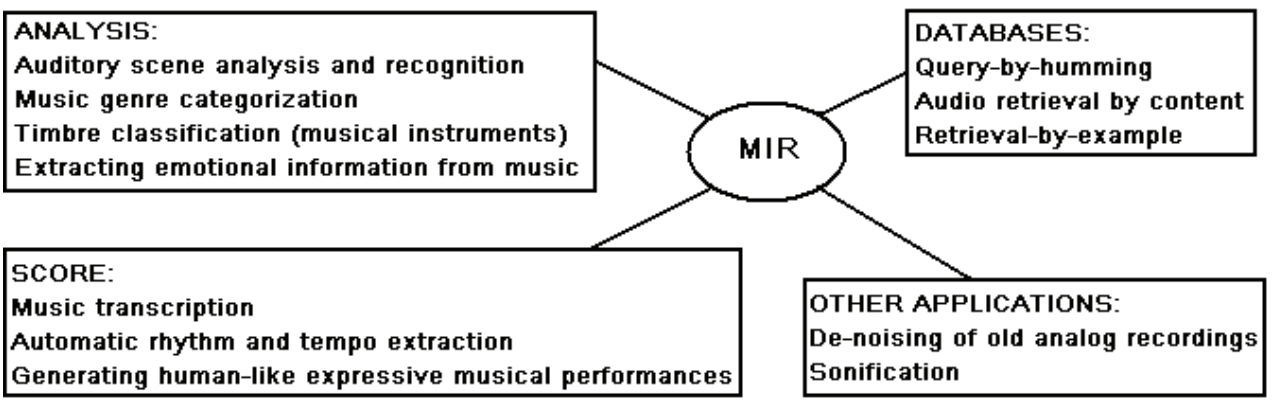
Music information retrieval (MIR) is a multi-disciplinary research on retrieving information from music, see Fig. 1. This research involves scientists from traditional, music and digital libraries, information science, computer science, law, business, engineering, musicology, cognitive psychology and education (Downie, 2001).

BACKGROUND

Huge amount of audio resources, including music data, is becoming available in various forms, both analog and digital. Notes, CDs, and digital resources of the World Wide Web are constantly growing in amount, but the value of music information depends on how easy it can be found, retrieved, accessed, filtered and managed. MIR consists in quick and efficient searching for various types of audio data of interest to the user, and filtering them in order to receive only the data items which satisfy the user's preferences (Fingerhut, 1997), (International Organization for Standardization, 2003), (Wieczorkowska & Ras, 2003). MIR applications include retrieval of music pieces from huge audio databases, and automatic production of music score on the basis of the presented input. The MIR topics are interrelated, since similar techniques can be applied for various purposes, e.g., source separation is applied in auditory scene analysis, music transcription, and even for restoring (de-noising) of all recordings. Generally, the research within MIR domain is focused on: harmonic structure analysis, note extraction, melody and rhythm tracking, timbre and instrument recognition, classification of type of the signal (speech, music, pitched vs. non-pitched), etc.

The research basically uses digital audio recordings, where sound waveform is digitally stored as a sequence of discrete samples representing the sound intensity at given time instant, and MIDI files, storing information on parameters of electronically synthesized sounds (voice, note on, note off, pitch bend etc.). Sound analysis and data mining tools are used to extract information from music files, in order to provide the data that meet user's needs (Wieczorkowska & Ras, 2001).

Figure 1. Topics of MIR



MAIN THRUST OF THE CHAPTER

Various types of music data are investigated in MIR research. Basic techniques of digital sound analysis come from speech processing, focused on automatic speech recognition and speaker identification (Foote, 1999). The obtained sound descriptors can be applied to facilitate content-based searching of music databases.

The issue of representation of music and multimedia information in a form that allows interpretation of the information's meaning is addressed by MPEG-7 standard, named Multimedia Content Description Interface. MPEG-7 provides a rich set of standardized tools to describe multimedia content through metadata, i.e. data about data, and music information description has been also taken into account in this standard (International Organization for Standardization, 2003).

The following topics are investigated within MIR domain:

- Auditory scene analysis and recognition (Rosenthal & Okuno, 1998), which focuses on various aspects of music, like timbre description, sound harmonicity, spatial origin, source separation, etc. (Bregman, 1990), based on signal processing techniques. Timbre is defined subjectively as this feature of sound that distinguishes two sounds of the same pitch, loudness and duration. Therefore, subjective listening tests are often performed in this research. One of the main topics of computational auditory scene analysis is automatic separation of individual sound sources from a mixture. It is difficult with mixtures of harmonic instrument sounds, where spectra overlap. However, assuming time-frequency smoothness of the signal, sound separation can be performed, and when sound changes in time are observed, onset, offset, amplitude and frequency modulation have similar shapes for all frequencies in the spectrum, thus a de-mixing matrix can be estimated for them (Virtanen, 2003), (Viste & Evangelista, 2003). Audio source separation techniques can also be used to source localization for auditory scene analysis. These techniques, like independent component analysis (ICA), originate from speech recognition in cocktail party environment, where many sound sources are present. ICA is used for finding underlying components from multidimensional statistical data, and it looks for components that are statistically independent (Vincent, Rodet, Röbel, Févotte, Carpentier, Gribonval, Benaroya, & Bimbot, 2003). Also, computational auditory scene recognition may aim at classifying auditory scenes into predefined classes, using audio information only. Examples of auditory scenes are various outside and inside environments, like streets, restaurants, offices, homes, cars etc. Statistical and nearest neighbor algorithms can be applied for this purpose. In the nearest neighbor algorithm the class (type of auditory scene in this case) is assigned on the basis of the distance of the investigated sample to the nearest sample, for which the class membership is known. Various acoustic features, based on Fourier spectral analysis (i.e. mathematic transform, decomposing the signal into frequency components), can be applied to parameterize the auditory scene for classification purposes. Effectiveness of this research approaches 70% correctness for about 20 auditory scenes (Peltonen, Tuomi, Klapuri, Huopaniemi, & Sorsa, 2002).
- Music genre categorization is aimed at automatic classification of music into various genres. This can be especially useful for large audio collections, if they are not manually labelled (Guaus & Herrera, 2006).
- Audio retrieval-by-example for orchestral music aims at searching for acoustic similarity in an audio collection, based on analysis of the audio signal. Given an example audio document, other documents in a collection can be ranked by similarity on the basis of long-term structure, specifically the variation of soft and louder passages, determined from envelope of audio energy versus time in one or more frequency bands (Foote, 2000). This research is a branch of audio retrieval by content. Audio query-by-example search can be also performed within a single document, when searching for sounds similar to the selected sound event. Such a system for content-based audio retrieval can be based on a self-organizing feature map, i.e. a special kind of a neural network, designed by analogy with a simplified model of the neural connections in the brain, and trained to find relationships in the data. Perceptual similarity can be assessed on the basis of spectral evolution, in order to find sounds of similar timbre (Spevak

& Polfreman, 2001). Neural networks are also used in other forms in audio information retrieval systems. For instance, time-delayed neural networks, i.e. neural nets with time delay inputs, are applied, since they perform well in speech recognition applications (Meier, Stiefelhagen, Yang, & Waibel, 2000). One of applications of audio retrieval-by-example is searching for the piece in a huge database of music pieces, with the use of so called audio fingerprinting – technology that allows piece identification. Given a short passage transmitted for instance via car phone, the piece is extracted, and, what is most important, also is extracted the information on the performer and title, linked to this piece in the database. In this way, the user may identify the piece of music with very high accuracy (95%), only on the basis of a small recorded (possibly noisy) passage.

- Transcription of music, defined as to writing down the musical notation for the sounds that constitute the investigated piece of music. Onset detection based on incoming energy in frequency bands, and multi-pitch estimation based on spectral analysis may be used as the main elements of an automatic music transcription system. The errors in such system may contain additional inserted notes, omissions, or erroneous transcriptions (Klapuri, Virtanen, Eronen, & Seppänen, 2001). Pitch tracking, i.e. estimation of pitch of note events in a melody or a piece of music, is often performed in many MIR systems. For polyphonic music, polyphonic pitch-tracking and timbre separation in digital audio is performed, with such applications as score-following and de-noising of old analog recordings. Wavelet analysis can be applied for this purpose, since it decomposes the signal into time-frequency space, and then musical notes can be extracted from the result of this decomposition (Popovic, Coifman, & Berger, 1995). Simultaneous polyphonic pitch and tempo tracking, aiming at automatic inferring a musical notation that lists the pitch and the time limits of each note, is a basis of the automatic music transcription. A musical performance can be modeled for these purposes using dynamic Bayesian networks, i.e. directed graphical models of stochastic processes (Cemgil, Kappen, & Barber, 2003). It is assumed that the observations may be generated by a hidden process that cannot be directly experimentally observed, and dynamic Bayesian networks represent the hidden and observed states in terms of state variables, which can have complex interdependencies. Dynamic Bayesian networks generalize hidden Markov models, which have one hidden node and one observed node per observation time.
- Automatic characterizing of rhythm and tempo of music and audio, revealing tempo and the relative strength of particular beats, is a branch of research on automatic music transcription. Since highly structured or repetitive music has strong beat spectrum peaks at the repetition times, it allows tempo estimation and distinguishing between different kinds of rhythms at the same tempo. The tempo can be estimated using beat spectral peak criterion (the lag of the highest peak exceeding assumed time threshold), accurately to within 1% in the analysis window (Foote & Uchihashi, 2001).
- Automatic classification of musical instrument sounds, aiming at accurate identification of musical instruments playing in a given recording, based on various sound analysis and data mining techniques (Herrera, Amatriain, Batlle, & Serra, 2000), (Wieczorkowska, 2001), (Eronen, 2001), (Aniola & Lukasik, 2007). This research is mainly focused on monophonic sounds, and sound mixes are usually addressed in the research on separation of sound sources (Kostek, Dziubiński, & Dalka, 2005). In most cases, sounds of instruments of definite pitch have been investigated, but recently also research on percussion is undertaken. Various analysis methods are used to parameterize sounds for instrument classification purposes, including time-domain description, Fourier and wavelet analysis. Classifiers range from statistic and probabilistic methods, through learning by example, to artificial intelligence methods. Effectiveness of this research ranges from about 70% accuracy for instrument identification, to more than 90% for instruments family (i.e. strings, winds etc.), approaching 100% for discriminating impulsive and sustained sounds, thus even exceeding human performance. Such instrument sound classification can be included in automatic music transcription systems.
- Query-by-humming systems, which search melodic databases using sung queries (Adams, Bartsch, & Wakefield, 2003). This topic rep-

resents audio retrieval by contents. Melody is usually coarsely quantized with respect to pitch and duration, assuming moderate singing abilities of users. Music retrieval system takes such an aural query (a motif, or a theme) as input, and searches the database for the piece this query comes from. Markov models, based on Markov chains, can be used for modeling musical performances. Markov chain is a stochastic process for which the parameter is discrete time values. In Markov sequence of events the probability of future states depends on the present state; in this case, states represent pitch (or set of pitches) and duration (Birmingham, Dannenberg, Wakefield, Bartsch, Bykowski, Mazzoni, Meek, Mellody, & Rand, 2001). Query-by-humming is one of more popular topics within MIR domain.

- Generating human-like expressive musical performances, with appropriately adjusted dynamics (i.e. loudness), rubato (variation in notes' length), vibrato (changes of pitch) etc. (Mantaras & Arcos, 2002).
- Extracting emotional information from music - estimating what mood is envoked by a given piece of music (tenderness, sadness, joy, calmness etc.). Also, if the musical content can be changed, the mood of the piece can be changed too, thus creating a different version of this piece. This research can be also applied for psychological, or even medical purposes (Wieczorkowska, Synak, & Raś, 2006), (Koelsch, Fritz, Cramon, Müller, & Friederici, 2006).
- Sonification, in which utilities for intuitive auditory display (i.e. in audible form) are provided through a graphical user interface (Ben-Tal, Berger, Cook, Daniels, Scavone, & Cook, 2002).

The topics mentioned above interrelate and sometimes partially overlap. For instance, auditory scene analysis and recognition take into account broad range of recordings, containing numerous acoustic elements to identify and analyze. Query by humming requires automatic transcription of music, since the input audio samples must be first transformed into the form based on musical notation, describing basic melodic features of the query. Audio retrieval by example and automatic classification of musical instrument sounds are both branches of retrieval by content. Transcription of music requires pitch tracking, and also automatic characterizing of rhythm and tempo. Pitch tracking is needed in many areas, including music transcription, query by humming, and even automatic classification of musical instrument sounds, since pitch is one of the features characterizing instrumental sound. Sonification and generating human-like expressive musical performances are both related to sound synthesis, needed to create auditory display or emotional performance. All these topics are focused on broad domain of music and its aspects.

Results of MIR research are not always easily measurable, since they are usually validated via subjective tests. Other topics, like transcription of music, may produce errors of various importance (wrong pitch, length, omission etc.), and comparison of the obtained transcript with the original score can be measured in many ways, depending on the considered criteria. The easiest estimation and comparison of results can be performed in case of recognition of singular sound events or files. In case of query by example, very high recognition rate has been already obtained (95% of correct piece identification via audio fingerprinting), reaching commercial level.

The research on MIR is gaining an increasing interest from the scientific community, and investigation of further issues in this domain can be expected.

FUTURE TRENDS

Multimedia databases and library collections need efficient tools for content based search. Therefore, we can expect intensification of research effort on MIR, which may aid searching music data. Especially, tools for query-by-example and query-by-humming are needed, tools for automatic music transcription, and also for extracting or changing emotions in music, so these areas should be broadly investigated in the nearest future.

CONCLUSION

MIR has a broad range of research and applications, including audio retrieval by content, automatic music transcription etc. Results of this research help users in finding the audio data they need, even if the users itself are not experienced musicians. Constantly growing, huge audio resources evoke demand for efficient

tools to deal with this data, therefore MIR becomes a dynamically developing field of research.

KEY TERMS

Digital Audio: Digital representation of sound waveform, recorded as a sequence of discrete samples, representing the intensity of the sound pressure wave at given time instant. Sampling frequency describes the number of samples recorded in each second, and bit resolution describes the number of bits used to represent the quantized (i.e. integer) value of each sample.

Fourier Analysis: Mathematical procedure for spectral analysis, based on Fourier transform that decomposes a signal into sine waves, representing frequencies present in the spectrum.

Information Retrieval: The actions, methods and procedures for recovering stored data to provide information on a given subject.

Metadata: Data about data, i.e. information about the data.

MIDI: Musical Instrument Digital Interface. MIDI is a common set of hardware connectors and digital codes, used to interface electronic musical instruments and other electronic devices. MIDI controls actions such as note events, pitch bends, etc. while the sound is generated by the instrument itself.

Music Information Retrieval: Multi-disciplinary research on retrieving information from music.

Pitch Tracking: Estimation of pitch of note events in a melody or a piece of music.

Sound: A physical disturbance in the medium through which it is propagated. Fluctuation may change routinely and such a periodic sound is perceived as having pitch. The audible frequency range is from about 20 Hz (hertz, i.e. cycles per second) to about 20 kHz. Harmonic sound wave consists of frequencies being integer multiples of the first component (fundamental frequency), corresponding to the pitch. The distribution of frequency components is called spectrum. Spectrum and its changes in time can be analyzed using mathematical transforms, such as Fourier or wavelet transform.

Wavelet Analysis: Mathematical procedure for time-frequency analysis, based on wavelet transform that decomposes a signal into shifted and scaled versions of the original function called wavelet.

Neural Networks and Graph Transformations

Ingrid Fischer
University of Konstanz, Germany

INTRODUCTION

As the beginning of the area of artificial neural networks the introduction of the artificial neuron by McCulloch and Pitts is considered. They were inspired by the biological neuron. Since then many new networks or new algorithms for neural networks have been invented with the result. In most textbooks on (artificial) neural networks there is no general definition on what a neural net is but rather an example based introduction leading from the biological model to some artificial successors. Perhaps the most promising approach to define a neural network is to see it as a network of many simple processors ("units"), each possibly having a small amount of local memory. The units are connected by communication channels ("connections") that usually carry numeric (as opposed to symbolic) data called the weight of the connection. The units operate only on their local data and on the inputs they receive via the connections. It is typical of neural networks, that they have great potential for parallelism, since the computations of the components are largely independent of each other. Typical application areas are:

- Capturing associations or discovering regularities within a set of patterns;
- Any application where the number of variables or diversity of the data is very great;
- Any application where the relationships between variables are vaguely understood; or,
- Any application where the relationships are difficult to describe adequately with conventional approaches.

Neural networks are not programmed but can be trained in different ways. In supervised learning, examples are presented to an initialized net. From the input and the output of these examples, the neural net learns. There are as many learning algorithms as there are types of neural nets. Also learning is motivated physiologically. When an example is presented to a neural network it cannot recalculate, several different steps are possible: the neuron's data is changed, the connection's weight is changed or new connections and/or neurons are inserted. Introductory books into neural networks are (Graupe, 2007; Colen, Kuehn & Sollich, 2005).

There are many advantages and limitations to neural network analysis and to discuss this subject properly one must look at each individual type of network. Nevertheless there is one specific limitation of neural networks potential users should be aware of. Neural networks are more or less, depending on the different types, the ultimate "black boxes". The final result of the learning process is a trained network that provides no equations or coefficients defining a relationship beyond its own internal mathematics.

Graphs are widely used concepts within computer science, in nearly every field graphs serve as a tool for visualization, summarization of dependencies, explanation of connections, etc. Famous examples are all kinds of different nets and graphs as e.g. semantic nets, petri nets, flow charts, interaction diagrams or neural networks, the focus of this chapter. Invented 35 years ago, graph transformations have been constantly expanding. Wherever graphs are used, graph transformations are also applied (Rozenberg, 1997; Ehrig, Engels, Kreowski, and Rozenberg, 1999; Ehrig, Kreowski, Montanari, and Rozenberg, 1999; Ehrig, Ehrig, Prange & Taentzer, 2006).

Graph transformations are a very promising method for modeling and programming neural networks. The graph part is automatically given as the name "neural network" already indicates. Having graph transformations as methodology, it is easy to model algorithms on this graph structure. Structure preserving and structure changing algorithms can be modeled equally well. This is not the case for the widely used matrices programmed mostly in *C* or *C++*. In these approaches modeling structure change becomes more difficult.

This directly leads to a second advantage. Graph transformations have proven useful for visualizing

the network and its algorithms. Most modern neural network simulators have some kind of visualization tool. Graph transformations offer a basis for this visualization as the algorithms are already implemented in visual rules.

When having a formal methodology at hand, it is also possible to use it for proving properties of nets and algorithms. Especially in this area, earlier results for graph transformation systems can be used. Three possibilities are especially promising: first it is interesting whether an algorithm is terminating. Though this question is not decidable in the general case, the formal methods of graph rewriting and general rewriting offer some chances to prove termination for neural network algorithms. The same holds for the question whether the result produced by an algorithm is useful, whether the learning of a neural network was successful. Then it helps proving whether two algorithms are equivalent. Finally possible parallelism in algorithms can be detected and described based on results for graph transformation systems.

BACKGROUND

A Short Introduction to Graph Transformations

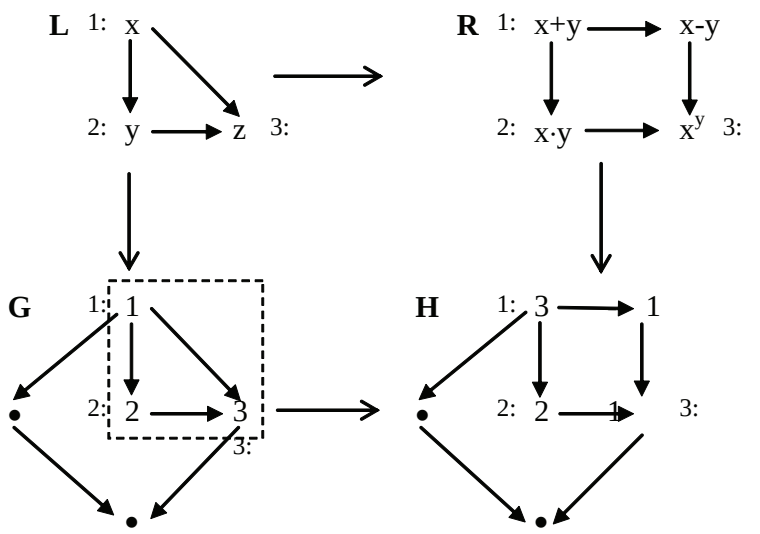
Despite the different approaches to handle graph transformations, there are some properties all approaches have in common. When transforming a graph *G* somehow, it is necessary to specify what part of the graph, what subgraph *L*, has to be exchanged. For this subgraph, a new graph *R* must be inserted. When applying such a rule to a graph *G* three steps are necessary:

- Choose an occurrence of *L* in *G*.
- Delete *L* from *G*.
- Insert *R* into the remainder of *G*.

In Figure 1 a sample application of a graph transformation rule is shown. The left hand side *L* consists of three nodes *(1:, 2:, 3:)* and three edges. This graph is embedded into a graph *G*. Numbers is *G* indicate how the nodes of *L* are matched. The embedding of edges is straightforward. In the next step *L* is deleted from *G* and *R* is inserted. If *L* is simply deleted from *G*, hanging edges remain. All edges ending/starting at *1:,2:,3:* are missing one node after deletion. With the help of numbers *1:,2:,3:* in the right hand side *R*, it is indicated how these hanging edges are attached to *R* inserted in *G/L*. The resulting graph is *H*.

Simple graphs are not enough for modeling real world applications. Among the different extensions two are of special interest. First graphs and graph rules can be labeled. When *G* is labeled with numbers, *L* is labeled with variables and *R* is labeled with terms over *L*'s variables. This way, calculations can be modeled. Taking our example and extending *G* with numbers *1,2,3*, the left hand side *L* with variables *x,y,z* and the

Figure 1. The application of a graph rewrite rule L → R to a graph G



right hand side with terms $x+y$, $x-y$, $x \cdot y$, x^y is shown in Figure 1. When L is embedded in G, the variables are set to the numbers of the corresponding nodes. The nodes in H are labeled with the result of the terms in R when the variable settings resulting from the embedding of L in G are used.

Also application conditions can be added restricting the application of a rule. For example the existence of a certain subgraph A in G can be allowed or forbidden. A rule can only be applied if A can be found resp. not found in G. Additionally label based application conditions are possible. Above rule could be extended by asking for $x < y$. Only in this case the rule would be applied.

Combining Neural Networks and Graph Transformations

Various proposals exist, how graph transformations and neural networks can be combined having different goals in mind. Several ideas originate from evolutionary computing (De Jong & Pollack, 2001; Curran & O'Riodan, 2002; Siddiqi & Lucas, 1998), others stem from electrical engineering as (Wan & Beaufays, 1998). The approach of (Fischer, 2000) has its roots in graph transformations itself. Despite these sources only three really different ideas can be found:

- In most of the papers (De Jong, and Pollack, 2001; Curran, and O'Riodan, 2002; Siddiqi, and Lucas 1998) some basic graph operators like *insert-node*, *delete-node*, *change-attribute*, etc. are used. This set of operators differs in the approaches. Additionally to these operators some kind of application condition exists stating which rule has to be applied when on which nodes or edges. These application conditions can be directed acyclic graphs giving the sequence of the rule applications. It can also be tree-based, where newly created nodes are handed to different paths in the tree. The main application area of these approaches is to grow neural networks from just one node. In this field also other grammar-based approaches can be found as (Cantu-Paz, and Kamath, 2002) where matrices are rewritten or (Browse, Hussain, and Smili,e 1999) taking attributed grammars. In (Tsakonas, and Dounias, 2002) feedforward neural networks are grown with the help of a grammar in Backus-Naur-Form.
- In (Wan, and Beaufays, 1998) signal flow graphs known from electrical engineering are used to model the information flow through the net. With the help of rewrite rules, the elements can be reversed, so that the signal flow is going in the opposite direction as before. This way gradient descent based training methods as backpropagation, a famous training algorithm (Rojas, 2000), can be derived. A disadvantage of this method is that no topology changing algorithms can be modeled.
- In (Fischer, 2000; Sona 2002) arbitrary (neural) nets are modeled as graphs and transformed by arbitrary transformation rules. Because this is the most general approach it will be explained in detail in the following sections.

MAIN THRUST OF THE CHAPTER

In the remainder of this paper one special sort of neural network, the so-called probabilistic neural networks together with training algorithms are explained in detail.

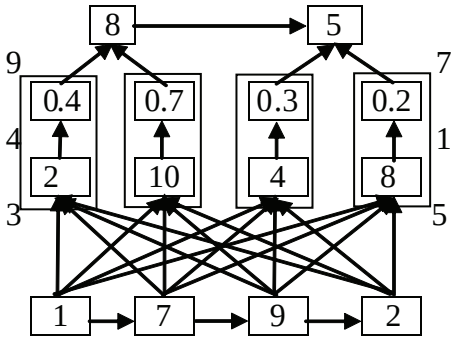
Probabilistic Neural Networks

The main purpose of a probabilistic neural network is to sort patterns into classes. It always has three layers, an input layer, a hidden layer and an output layer. The input neurons are connected to each neuron in the hidden layer. The neurons of the hidden layer are connected to one output neuron each. Hidden neurons are modeled with two nodes, as they have an input value and do some calculations on it resulting in an output value. Neurons and connections are labeled with values resp. weights. In Figure 2 a probabilistic neural network is shown.

Calculations in Probabilistic Neural Networks

First input is presented to the input neurons. The next step is to calculate the input value of the hidden neurons. The main purpose of the hidden neurons is to represent examples of classes. Each neuron represents one example. This example forms the weights from the input neurons to this special hidden neuron. When an input is presented to the net, each neuron in the hidden

Figure 2. A probabilistic neural network seen as graph



Note: Please note that not all edges are labeled due to space reasons

layer computes the probability, that it is the example it models. Therefore first the Euclidean distance between the activation of the input neurons and the weight of the connection to hidden layer's neuron is computed. The result coming via the connections is summed up to within a hidden neuron. This is the distance, the current input has from the example modeled by the neuron. If the exact example is inserted into the net, the result is *0*. In Figure 3 this calculation is shown in detail. The given graph transformation rule can be applied to the net shown in Figure 2. The labels *i* are variables modeling the input values of the input neurons, *w* models the weights of the connections. In the right hand side *R* a formula is given to calculate the input activation.

Then a Gaussian function is used to calculate the probability, that the inserted pattern is the example pattern of the neuron. The radius σ of the Gaussian function has to be chosen during the training of the net or it has to be adapted by the user. The result is the output activation of the neuron.

The main purpose of the connection between hidden and output layer is to sum up the activations of the hidden layer's neurons for one class. These values are multiplied with a weight associated to the corresponding connection. The output neuron with the heighest activation represents the class of the input pattern.

Training Neural Networks

For the probabilistic neural networks, different methods are used. The classical training method is the following: The complete net is built up by inserting one hidden neuron for each training pattern. As weights of the connections from the input neuron to the hidden neuron representing this example, the training pattern itself is taken. The connections from the hidden layer to the output layer are weighted with *1/m* if there are *m* training patterns for one class. σ, the radius of the Gaussian function used, is usually simply set to the average distance between centers of Gaussians modeling training patterns.

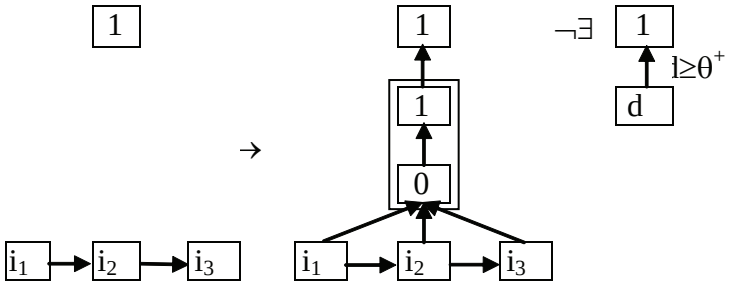
A more sophisticated training method called *Dynamic Decay Adjustment*. The algorithm also starts with no neuron in the hidden layer. If a pattern is presented to the net, first the activation of all existing hidden neurons is calculated. If there is a neuron whose activation is equal or higher to a given threshold θ^+, this neuron covers the input pattern. If this is not the case a new hidden neuron is inserted into the net as shown in Figure 4. With the help of this algorithm fewer hidden neurons are inserted.

FUTURE TRENDS

The area of graph grammars and graph transformation systems several programming environments, especially *AGG* and *Progress* (Ehrig, Engels, Kreowski, and Rozenberg, 1999) have been developed. They can be used to obtain new implementations of neural network algorithms, especially of algorithms, that change the net's topology.

Figure 3. Calculating the input activation of a neuron

Figure 4. A new neuron is inserted into a net (this example is taken from Dynamic Decay Adjustment)



Pruning means the deletion of neurons and connections between neurons in already trained neural networks to minimize their size. Several mechanisms exist, that mainly differ in the evaluation function determining the neurons/connections to be deleted. It is an interesting idea to model pruning with graph transformation rules.

A factor graph is a bipartite graph that expresses how a global function of many variables factors into a product of local functions. It subsumes other graphical means of artificial intelligence as Bayesian networks or Markov random fields. It would be worth checking whether graph transformation systems are helpful in formulating algorithms for these soft computing approaches. Also for more biological applications the use of graph transformation is interesting.

CONCLUSION

Modeling neural networks as graphs and algorithms on neural networks as graph transformations is an easy to use and straightforward method. It has several advantages. First, the structure of neural nets is supported. When modeling the net topology and topology changing algorithms, graph transformation systems can present their full power. This might be of special interest for educational purposes where it's useful to visualize step-by-step what algorithms do. Finally the theoretical background of graph transformation and rewriting systems offers several possibilities for proving termination, equivalence etc. of algorithms.

KEY TERMS

Confluence: A rewrite system is confluent, if no matter in which order rules are applied, they lead to the same result.

Graph: A graph consists of vertices and edges. Each edge is connected to a source node and a target node. Vertices and edges can be labeled with numbers and symbols.

Graph Production: Similar to productions in general Chomsky grammars, a graph production consists of a left hand side and a right hand side. The left hand side is embedded in a host graph. Then it is removed and in the resulting hole the right hand side of the graph production is inserted. To specify how this right hand side is attached into this hole, how edges are connected to the new nodes, some additional information is necessary. Different approaches exist how to handle this problem.

Graph Rewriting: The application of a graph production to a graph is also called graph rewriting.

Neuron: The smallest processing unit in a neural network.

Neural Networks: Learning systems, designed by analogy with a simplified model of the neural connections in the brain, which can be trained to find nonlinear relationships in data. Several neurons are connected to form the neural networks.

Probabilistic Neural Network: One of the many different kinds of neural networks with the application area to classify input data into different classes.

Rewrite System: A rewrite system consists of a set of configurations and a relation $x \rightarrow y$ denoting that the configuration x follows the configuration y with the help of a rule application.

Termination: A rewrite system terminates if it has no infinite chain.

Weight: Connections between neurons of neural networks have a weight. This weight can be changed during the training of the net.

New Opportunities in Marketing Data Mining

Victor S.Y. Lo
Fidelity Investments, USA

INTRODUCTION

Data mining has been widely applied in many areas over the past two decades. In marketing, many firms collect large amount of customer data to understand their needs and predict their future behavior. This chapter discusses some of the key data mining problems in marketing and provides solutions and research opportunities.

BACKGROUND

Analytics and data mining are becoming more important than ever in business applications, as described by Davenport and Harris (2007) and Baker (2006). Marketing analytics have two major areas: market research and database marketing. The former addresses strategic marketing decisions through survey data analysis and the latter handles campaign decisions through analysis of behavioral and demographic data. Due to the limited sample size of a survey, market research is normally not considered data mining. This chapter will focus on database marketing where data mining is used extensively by large corporations and consulting firms to maximize marketing return on investment.

The simplest tool is RFM where historical purchase recency (R), frequency (F), and monetary (M) value are used for targeting. Other tools include profiling by pre-selected variables to understand customer behavior, segmentation to group customers with similar characteristics, and association rules to explore purchase relationships among products, see Rud (2001); Berry and Linoff(2000). More advanced marketing involves predictive modeling to improve targeting and maximize returns. For examples, marketing-mix analysis has been around for three decades to optimize advertising dollars, see Dekimpe and Hanssens (2000); attrition modeling is used to identify customers at risk of attrition, see Rud (2001); and long-term value is used to prioritize marketing and services, see Peppers and Rogers (1997,1999).

To improve 1:1 marketing campaigns (e.g. direct mails, outbound), response modeling to identify likely responders is now a standard practice in larger corporations. As summarized in Figure 1, a previous campaign provides data on the 'dependent variable' (responded or not), which is merged with individual characteristics. A response model is developed to predict the response rate given the characteristics. The model is then used to score the population to predict response rates for all individuals. Finally, the best list of individuals will be targeted in the next campaign in order to maximize effectiveness and minimize expense.

Response modeling can be applied in the following activities via any marketing channel, see Rud (2001); Berry and Linoff (1997):

1. **Acquisition:** Which prospects are most likely to become customers.
2. **Development:** Which customers are mostly likely to purchase additional products (cross-selling) or add monetary value (up-selling).
3. **Retention:** Which customers are most retainable; this can be relationship or value retention.

MAIN FOCUS

In this chapter, we describe highly important problems that are infrequently mentioned in academic literature but frequently faced by marketing analysts. These problems are embedded in various components of the campaign process, from campaign design to response modeling to campaign optimization, see Figure 2. Each problem will be described in the Problem-Solution-Opportunity format.

CAMPAIGN DESIGN

The design of a marketing campaign is the starting point of a campaign process. It often does not receive enough attention in data mining. A poorly designed campaign

Figure 1. Response modeling process

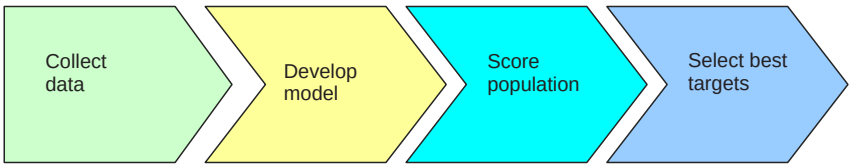

Figure 2. Database marketing campaign process

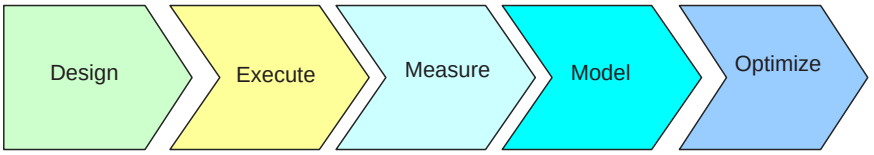

could make learning infeasible while a scientifically designed one can maximize learning opportunities.

The design process includes activities such as sample size determination for treatment and control groups (both have to be sufficiently large such that measurement and modeling, when required, are feasible), sampling methods (pure or stratified random sampling), and cell design structure (testing various offers and also by age, income, or other variables). We will focus on the latter here.

Problem 1: Classical designs often test one variable at a time. For example, in a cell phone direct mail campaign, we may test a few price levels of the phone. After launching the campaign and the price level that led to the highest revenue is uncovered, another campaign can be launched to test monthly fee and a third campaign will test the mail message, etc. A more efficient way is to structure the cell design such that all these variables are testable in one campaign. Consider an example, a credit card company would like to determine the best combination of treatments for each prospect, and the treatment attributes and attribute levels are summarized in Table 1 (channel is incorporated as an attribute). The number of all possible combinations = $4^4 x 2^2 = 1024$ cells, which is not practical to test.

Solution 1: To reduce the number of cells, a fractional factorial design can be applied (full factorial refers to the design that includes all possible combinations), see Montgomery (1991) and Almquist and Wyner (2001). Two types of fractional factorial are: 1) orthogonal design where all attributes are made orthogonal (uncorrelated) with each other; and 2) optimal design where criterion related to the covariance matrix of parameter estimates is optimized, see Kuhfeld (1997,2004) for the applications of SAS PROC FACTEX and PROC OPTEX in market research (Kuhfeld's market research applications are applicable to database marketing).

For the credit card problem above, an orthogonal fractional factorial design using PROC FACTEX in SAS with estimable main effects, all two-way interaction effects, and quadratic effects on quantitative variables generates a design of 256 cells, which may still be considered large. An optimal design using PROC OPTEX with the same estimable effects generates a design of 37 cells only, see Table 2.

Fractional factorial design has been used in credit card acquisition but is not widely used in other industries for marketing. Two reasons are: (1) lack of experimental design knowledge and experience; (2) business process

Table 1. Example of design attributes and attribute levels

Attribute	Attribute level
APR	5.9% (0), 7.9% (1), 10.9% (2), 12.9% (3)
Credit limit	$2,000 (0), $5,000 (1), $7,000 (2), $10,000 (3)
Color	Platinum (0), Titanium (1), Ruby (2), Diamond (3)
Rebate	None (0), 0.5% (1), 1% (2), 1.5% (3)
Brand	SuperCard (0), AdvantagePlus (1)
Channel	Direct mail (0), Email (1)

Note: numbers in parentheses are coded levels.

requirement—tight coordination with list selection and creative design professionals is required. See Holland (2005) for further applications.

Opportunity 1: Mayer and Sarkissien (2003) proposed using individual characteristics as attributes in an optimal design, where individuals are chosen "optimally." Using both individual characteristics and treatment attributes as design attributes is theoretically compelling. This approach can be evaluated and compared with other techniques such as stratified random sampling. Additionally, if many variables (say, hundreds) are used in the design, constructing an optimal design may be very computationally intensive due to the large design matrix and thus may require a unique optimization technique to solve.

RESPONSE MODELING

Problem 2: As stated in Introduction, response modeling uses data from a previous marketing campaign to identify likely responders given individual characteristics, e.g. Berry and Linoff (1997,2000). Treatment and control groups were set up in the campaign for measurement. The methodology typically uses treatment data to identify characteristics of customers who are likely to respond. In other words, for individual $i \in W$,

$$P(Y_i = 1 | X_i; \text{treatment}) = f(X_i) \quad (1)$$

where W = set of all individuals in the campaign, Y_i = dependent variable (responded or not), and X_i is a set of individual characteristics. For examples, f(.) is a logistic function in logistic regression, Hosmer and

Table 3. Campaign measurement of model effectiveness (response rates)—illustrative

	Treatment (e.g. mail)	Control (e.g. no-mail)	Incremental (treatment minus control)
Model	1%	0.8%	0.2%
Random	0.5%	0.3%	0.2%

Lemeshow (1989); a step function in decision trees, Zhang and Singer (1999); and a nonlinear function in neural network, Haykin (1999).

A problem can arise when we apply model (1) to the next campaign. Depending on the industry and product, the model can select individuals who are likely to respond regardless of the marketing campaign. The results of the new campaign may show equal or similar (treatment minus control) performance in model and random cells, see e.g. Table 3.

Solution 2: The key issue is that fitting model (1) and applying the model to find the 'best' individuals is inappropriate. The correct way is to find those who are most positively influenced by the campaign. It requires us to predict "lift" := $P(Y_i = 1| X_i$; treatment) - $P(Y_i = 1| X_i$; control) for each i and then select those with the highest values of estimated lift. Alternative solutions to this problem are:

1. Fitting two separate treatment and control models: This is relatively straightforward except that estimated lift can be sensitive to statistically insignificant differences in parameters of the treatment and control models;
2. Using dummy variable and interaction effects: Lo (2002) proposed the following independent variables: X_i, T_i, and X_i*T_i where $T_i = 1$ if i is in the treatment group and = 0 otherwise, and modeling the response rate using a logistic regression:

$$P_i = \frac{\exp(\alpha + \beta' X_i + \gamma T_i + \delta' X_i T_i)}{1 + \exp(\alpha + \beta' X_i + \gamma T_i + \delta' X_i T_i)} \qquad (2)$$

where α, β, γ, δ, are parameters to be estimated. In equation (2), α denotes the intercept, β is a vector of parameters measuring the main effects of the independent variables, γ denotes the main treatment effect, and δ measures additional effects of the independent variables due to treatment. To predict the lift:

$$P_i \mid treatment - P_i \mid control = \frac{\exp(\alpha+\gamma+\beta' X_i+\delta' X_i)}{1+\exp(\alpha+\gamma+\beta' X_i+\delta' X_i)} - \frac{\exp(\alpha+\beta' X_i)}{1+\exp(\alpha+\beta' X_i)} \qquad (3)$$

That is, the parameter estimates from model (2) can be used in equation (3) to predict the lift for each i in a new data set. Individuals with high positive predicted lift values will be selected for next campaign. Similar technique of using a dummy variable and interactions can be applied in other supervised learning algorithms such as neural network. See Lo (2002) for a detailed description of the methodology.

3. Decision tree approach: To maximize lift, the only commercial software known is Quadstone that uses a decision tree such that each split at every parent node is processed to maximize the difference between lift (treatment—control response rates) in left and right children nodes, see Radcliffe and Surry (1999) and Radcliffe (2007).

Opportunity 2: (1) Alternative modeling methods for this lift-based problem should exist and readers are encouraged to uncover them. (2) As in typical data mining, the number of potential predictors is large. Variable reduction techniques are available for standard problems (i.e. finding the best subset associated with the dependent variable) but a unique one for the lift-based problem is needed (i.e. finding the best subset associated with the lift).

Problem 3: An extension of Problem 2 is when multiple treatments/channels are present. Data can be obtained from an experimentally designed campaign where multiple treatment attributes were tested, e.g. Solution 1. Question: how to incorporate treatment attributes and individual characteristics in the same response model?

Solution 3: An extension of equation (2) is to incorporate both treatment attributes and individual characteristics in the same lift-based response model:

$$P_i = \frac{\exp(\eta_i)}{1+\exp(\eta_i)}$$

where $\eta_i = \alpha + \beta' X_i + \gamma T_i + \delta' X_i T_i + \lambda' Z_i + \theta' Z_i X_i$,

Z_i *is the vector of treatment attributes,*

and λ *and* θ *are additional parameters* ($Z_i = 0$ *if* $T_i = 0$).

In practice, equation (4) can have many variables including many interaction effects and thus multi-collinearity may be a concern. Developing two separate treatment and control models may be more practical.

Opportunity 3: Similar to Opportunity 2, there should be alternative methods to handle multiple treatment response modeling.

OPTIMIZATION

Marketing optimization refers to delivering the best treatment combination to the right people so as to optimize certain criterion subject to constraints. It is a natural step after campaign design and response modeling, especially when multiple treatment combinations were tested in the previous campaign(s), and response model score for each treatment combination and each individual is available, see Problem 3.

Problem 4: The main issue is that the number of decision variables = number of individuals in the targets (n) times number of treatment (& channel) combinations (m). For example, in an acquisition campaign where the target population has n=30 MM prospect individuals and the number of treatment combinations is m=100. Then the number of decision variables is nxm=3 billions. Consider the following binary integer programming problem, see e.g. Cornuejols and Tutuncu (2007):

$$\begin{aligned}
&\textit{Maximize } \pi = \sum_i \sum_j \pi_{ij} x_{ij} \\
&\textit{subject to}: \\
&\sum_i x_{ij} \le \max.\ \#\textit{individuals receiving treatment combination } j, \\
&\sum_i \sum_j c_{ij} x_{ij} \le \exp\textit{ense budget, plus other relevant constra}\text{int s}, \\
&x_{ij} = 0 \textit{ or } 1, \\
&\textit{where } \pi_{ij} = \textit{inc.value received by sending treatment comb. } j \textit{ to individual } i, \\
&\qquad c_{ij} = \cos t \textit{ of sending treatment comb. } j \textit{ to individual } i.
\end{aligned} \tag{5}$$

In model (5), π_{ij} is linked to the predicted incremental response rate of individual i and treatment combination j. For example, if π_{ij} is the predicted incremental response rate (i.e. lift), the objective function is to maximize the total number of incremental responders; if π_{ij} is incremental revenue, it may be a constant times the incremental response rate. Similar forms of model (5) appear in Storey and Cohen (2002) and Ansari and Mela (2003) except that we are maximizing *incremental* value or responders here. In the literature, similar formulations for *aggregate-level* marketing optimization such as Stapleton et al. (2003) and Larochelle and Sanso (2000) are common but not for *individual-level* optimization.

Solution 4: One way to address such a problem is through heuristics which do not guarantee global optimum. For example, to reduce the size of the problem, one may group the individuals in the target population into clusters and then apply linear programming to solve at the cluster level. This is exactly the first stage outlined in Storey and Cohen (2002). The second stage of their approach is to optimize at the individual level for each of the optimal clusters obtained from the first stage. SAS has implemented this methodology in their new software known as Marketing Optimization. One may also consider MarketSwitch at www.marketswitch.com where the problem is solved with exact solution through a mathematical transformation, see Leach (2001).

Opportunity 4: (1) Simulation and empirical studies can be used to compare existing heuristics to global optimization. (2) General heuristics such as simulated annealing, genetic algorithms, and tabu search can be attempted, e.g. Goldberg (1989) and Michalewicz and Fogel (2002).

Problem 5: Predictive models never produce exact results. Random variation of predicted response rates can be estimated in various ways. For example, in the holdout sample, the modeler can compute the standard deviation of lift by decile. More advanced methods such as bootstrapping can also be applied to assess variability, e.g. Efron and Tibshirani (1998). Then how should the variability be accounted for in optimization?

Solution 5: A simple way is to perform sensitivity analysis of response rates on optimization. The downside is that if the variability is high and/or the number

of treatment combinations is large, the large number of possibilities will make it difficult. An alternative is to solve the stochastic version of the optimization problem, using stochastic programming, see Wallace and Ziemba (2005). Solving such a large stochastic programming problem typically relies on Monte Carlo simulation method and can easily become a large project.

Opportunity 5: The two alternatives in Solution 5 may not be practical for large optimization problems. It is thus an opportunity for researchers to develop a practical solution. One may consider using robust optimization which incorporates the tradeoff between optimal solution and conservatism in linear programming, see Fabozzi et al (2007).

FUTURE TRENDS

1. Experimental design is expected to be more utilized to maximize learning.
2. More marketers are now aware of the lift problem in response modeling (see Solution 2) and alternative methods will be developed to address the problem.
3. Optimization can be performed across campaigns, channels, customer segments, and business initiatives so that a more "global" optimal solution is achieved. This requires not only data and response models but also coordination and cultural shift.

CONCLUSION

Several problems with suggested solutions and opportunities for research have been described. While they are not frequently mentioned in academic literature, they are highly valuable and commonly faced by marketing analysts. The solutions involve multiple areas including data mining, statistics, operations research, database marketing, and marketing science. Researchers and practitioners are encouraged to evaluate current solutions and develop new methodologies.

KEY TERMS

Campaign Design: The art and science of designing a marketing campaign including cell structure, sampling, and sizing.

Control Group: Individuals who look alike those in the treatment group but are not contacted.

Database Marketing: A branch of marketing that applies database technology and analytics to understand customer behavior and improve effectiveness in marketing campaigns.

Fractional Factorial: A subset of the full factorial design, i.e. subset of all possible combinations.

Marketing Optimization: Delivering the best treatments to the right individuals.

Response Modeling: Predicting response given individual characteristics using data from a previous campaign.

Treatment Group: Individuals who are contacted (e.g. mailed) in a campaign.

Non-Linear Dimensionality Reduction Techniques

Dilip Kumar Pratihar
Indian Institute of Technology, Kharagpur, India

INTRODUCTION

Most of the complex real-world systems involve more than three dimensions and it may be difficult to model these higher dimensional data related to their input-output relationships, mathematically. Moreover, the mathematical modeling may become computationally expensive for the said systems. A human being can visualize only up to three dimensions (3-D). So, any system involving more than 3-D cannot be visualized. To overcome this difficulty, higher dimensional data are generally mapped into either 2-D or 3-D, for visualization and ease of modeling. Dimensionality reduction techniques are nothing but the mapping methods, with the help of which the higher dimensional data can be mapped into the lower dimension after ensuring a reasonable accuracy. It is to be noted that the precision of modeling depends on the said accuracy in mapping. Thus, it is worthy to study the dimensionality reduction techniques.

BACKGROUND

A number of dimensionality reduction techniques are available in the literature; those are classified into two groups, namely linear and non-linear methods (Siedlecki, Seidlecka & Sklansky, 1988; Konig, 2000; Pratihar, Hayashida & Takagi, 2001). In linear methods, each of the lower dimensional components is considered as a linear combination of the higher dimensional components. These methods include principal component analysis (Jolliffe, 1986; Jackson, 1991), projection pursuit mapping (Crawford & Fall, 1990), factor analysis (Mardia, Kent & Bibby, 1995), independent component analysis (Cardoso, 1999), and others. On the other hand, there are some non-linear mapping methods in use, in which the relationships among the lower dimensional and higher dimensional components are non-linear in nature. The non-linear methods are further classified into two sub-groups, namely distance preserving and topology preserving techniques. Distance preserving techniques include Sammon's non-linear mapping (NLM) (Sammon, 1969), VISOR algorithm (Konig, Bulmahn & Glessner, 1994), triangulation method (Konig, 2000), and others, whereas the techniques like self-organizing map (SOM) (Kohonen, 1995), topology preserving mapping of sample sets (Konig, 2000) are known as the topology preserving tools. Two other dimensionality reduction techniques, namely locally linear embedding (LLE) (Roweis & Saul, 2000) and Isomap (Tenenbaum, de Silva & Langford, 2000) proposed in 2000, have also gained the popularity. Dimensionality reduction problem has also been solved using an optimization tool like genetic algorithm (GA) (Raymer, Punch, Goodman, Kuhn & Jain, 2000). In this connection, it is important to mention that more recently, the author of this chapter along with one of his students have proposed a GA-like approach for dimensionality reduction (Dutta & Pratihar, 2006). Another dimensionality reduction technique, namely HyperMap has been proposed by An, Yu, Ratanamahatana & Phoebe Chen (2007), in which the limitation of Euclidean space has been overcome by representing an axis as a line, a plane or a hyperplane. Moreover, an interactive technique has been developed to vary the weights associated with each hyperaxis for ease of visualization. The present chapter deals with some of the non-linear dimensionality reduction techniques (also known as mapping methods). It is important to mention that a particular mapping method may differ from others in terms of accuracy in mapping, visualization capability and computational complexity. An ideal dimensionality reduction technique is one, which can carry out the mapping from a higher dimensional space to a lower dimensional space accurately at a low computational cost and at the same time, can also provide with the widely distributed mapped data suitable for visualization.

MAIN FOCUS

In this section, the principles of some of the non-linear dimensionality reduction techniques have been explained.

Sammon's Nonlinear Mapping (NLM)

It is a distance preserving technique of mapping. Here, the error in mapping from a higher dimensional space to a lower dimensional space/plane is minimized using a gradient descent method (Sammon, 1969).

Let us consider N points in an L-dimensional (L>3) space represented by X_i, where i = 1,2,3,....,N. The aim is to map these N-points from L-dimensional space to 2-D plane or 3-D space. Let us also suppose that the mapped data in 2-D plane or 3-D space are represented by Y_i, where i = 1,2,....,N. The scheme is shown in Figure 1.

The N points in L-dimensional space are indicated as follows:

$$X_1 = \begin{bmatrix} x_{11} \\ x_{12} \\ . \\ . \\ x_{1L} \end{bmatrix}, X_2 = \begin{bmatrix} x_{21} \\ x_{22} \\ . \\ . \\ x_{2L} \end{bmatrix}, \ldots\ldots, X_N = \begin{bmatrix} x_{N1} \\ x_{N2} \\ . \\ . \\ x_{NL} \end{bmatrix}.$$

Similarly, the N-points in 2-D plane or 3-D space can be expressed like the following.

$$Y_1 = \begin{bmatrix} y_{11} \\ . \\ . \\ . \\ y_{1D} \end{bmatrix}, Y_2 = \begin{bmatrix} y_{21} \\ . \\ . \\ . \\ y_{2D} \end{bmatrix}, \ldots\ldots\ldots, Y_N = \begin{bmatrix} y_{N1} \\ . \\ . \\ . \\ y_{ND} \end{bmatrix},$$

where D indicates the dimension of the lower dimensional space.

This technique consists of the following steps:

- Initially, generate N points in 2-D plane at random, corresponding to N points in L-D space.
- Determine the mapping error as follows: Let d_{ij}^* be the Euclidean distance between two points X_i and X_j in L-dimensional space and d_{ij} represents the Euclidean distance between the corresponding two mapped points Y_i and Y_j, in 2-D plane. For an error-free mapping, the following condition has to be satisfied:

  $$d_{ij}^* = d_{ij}.$$

However, the mapping may not be error-free and the mapping error in m^{th} iteration E(m) can be determined mathematically as follows:

$$E(m) = \frac{1}{C} \sum_{i=1}^{N} \sum_{j=1(i<j)}^{N} \frac{[d_{ij}^* - d_{ij}(m)]^2}{d_{ij}^*}$$

where $C = \sum_{i=1}^{N} \sum_{j=1(i<j)}^{N} d_{ij}^*$ and

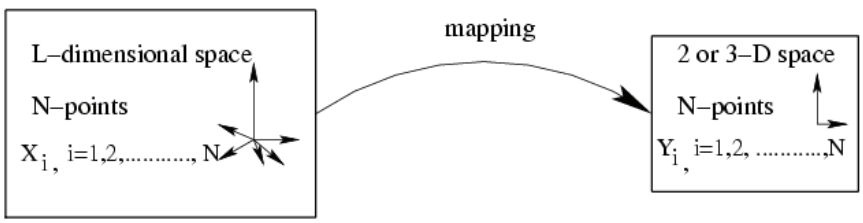
$$d_{ij}(m) = \sqrt{\sum_{k=1}^{D} [y_{ik}(m) - y_{jk}(m)]^2}.$$

- The aforementioned mapping error can be minimized using the steepest descent method, in which the search follows a rule given as:

  $$y_{pq}(m+1) = y_{pq}(m) - (MF)\Delta_{pq}(m),$$

  where $y_{pq}(m)$ and $y_{pq}(m+1)$ represent the $q-th$ dimension of point p in 2-D at $m-th$ and $(m+1)-th$ iterations, respectively, MF is a magic factor representing the step length and it varies in the range of 0.0 to 1.0, and:

Figure 1. Mapping from L-dimensional space to 2-D plane or 3-D space using NLM (Dutta & Pratihar, 2006).



$$\Delta_{pq}(m) = \frac{\partial E(m)/\partial y_{pq}(m)}{\left|\partial^2 E(m)/\partial y_{pq}^2(m)\right|}.$$

It is to be noted that the search direction of the algorithm is indicated by Δ_{pq}. It is also important to mention that the search direction has been chosen so, as the rate of change of a function is found to be the maximum along its gradient direction.

The terms $\partial E/\partial y_{pq}$ and $\partial^2 E/\partial y_{pq}^2$ can be expressed as follows (refer to Box 1.).

In this method, the error in mapping is minimized using the principle of a steepest descent method. As the gradient of a function is its local property, there is a chance of the solutions of this method for being trapped into the local minima.

VISOR Algorithm

It is a mapping technique, which uses a geometrical method for data projection by preserving the distance information (Konig, Bulmahn & Glessner, 1994). Its principle is explained in Figure 2.

Let us suppose that N points of L-dimensional space are to be mapped to a 2-D plane as accurately as possible.

Figure 2 shows the scheme of VISOR algorithm, which consists of the following steps:

- Locate the pivot-vectors - V_1, V_2, V_3 in L-dimensional space, which provide a convex enclosure to the remaining data points. The following approach is adopted for the said purpose:

1. Compute centroid M of all the data points N in L-dimensional space by calculating the dimension-wise average values.
2. Identify the pivot-vector V_1 (that is, a point out of all N points) such that the Euclidean distance between V_1 and M follows the condition given as:

   $d(V_1,M) = \max^{N}_{i=1}(d(v_i,M)$.

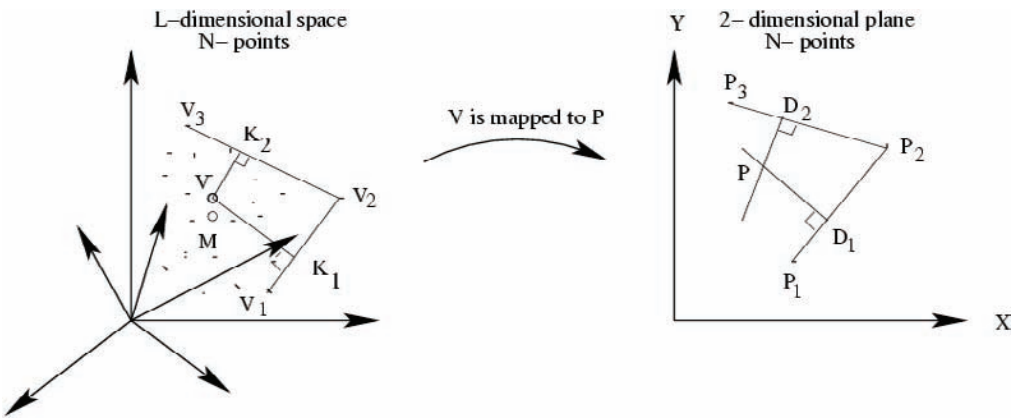
3. Determine the second pivot-vector V_2 (that is, another point out of the remaining $(N-1)$ points) such that the Euclidean distance between V_2 and V_1 is obtained as follows:

Box 1.

$$\frac{\partial E}{\partial y_{pq}} = \frac{-2}{C}\sum_{j=1, j\neq p}^{N}\left[\frac{d^*_{pj} - d_{pj}}{d_{pj} d^*_{pj}}\right](y_{pq} - y_{jq}),$$

$$\frac{\partial^2 E}{\partial y_{pq}^2} = \frac{-2}{C}\sum_{j=1, j\neq p}^{N}\frac{1}{d^*_{pj} d_{pj}}\left[(d^*_{pj} - d_{pj}) - \frac{(y_{pq} - y_{jq})^2}{d_{pj}}\left(1 + \frac{d^*_{pj} - d_{pj}}{d_{pj}}\right)\right]$$

Figure 2. VISOR algorithm (Dutta & Pratihar, 2006)



$d(V_2,V_1) = \max^{N-1}_{i=1}(d(v_i,V_1)$.

4. Locate the pivot-vector V_3 (that is, another point out of the remaining $(N-2)$ points) such that the Euclidean distance between V_3 and V_2 and that between V_3 and V_1 follow the conditions:

   $d(V_3,V_2) = \max^{N-2}_{i=1}(d(v_i,V_2)$ and
   $d(V_3,V_1) = \max^{N-2}_{i=1}(d(v_i,V_1)$.

- Obtain the pivot-vectors - P_1,P_2,P_3 in 2-D plane corresponding to the vectors V_1,V_2,V_3, respectively, by considering their Euclidean distances from the origin of coordinate systems and that between themselves.
- Map the remaining (N-3) points as follows:

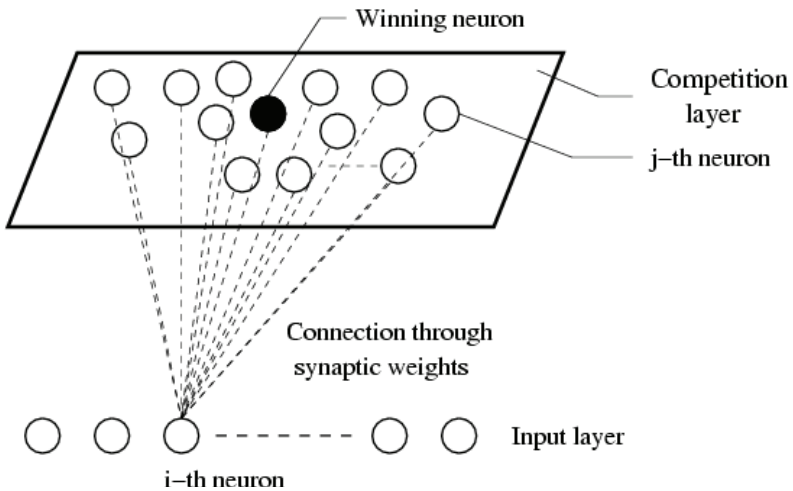
1. Let us suppose that a particular point V of L-dimensional space (refer to Figure 2) is to be mapped to a corresponding point in 2-D plane. The straight lines V_1V_2 and V_2V_3 are considered first and then two perpendicular lines are drawn from the point V to them. Thus, the points K_1 and K_2 are obtained on the lines V_1V_2 and V_2V_3, respectively.
2. In 2-D, locate D_1 on the line P_1P_2 such that D_1 divides the line P_1P_2 in the same proportion as K_1 has divided the line V_1V_2 (in L–dimensional space). Similarly, the point D_2 is obtained on the line P_2P_3.
3. The perpendiculars are drawn at the points D_1 and D_2 to the lines P_1P_2 and P_2P_3, respectively and they intersect at the point P. Thus, the point V in L-dimensional space is mapped to a corresponding point P in 2 – D plane.

As the algorithm uses simple geometrical rules, it is easy to understand and implement.

Self-Organizing Map (SOM)

It is a topology preserving dimensionality reduction technique proposed by Kohonen (Kohonen, 1995). It produces self-organizing feature maps similar to those present in our brain. It works based on unsupervised and competitive learning. Figure 3 shows the schematic diagram of a self-organizing map. It consists of two layers, namely input and competition layers. The input layer contains multivariate data, which are to be mapped to a lower dimensional space. The competition layer contains a number of neurons equal to that of the data points present in the input layer. Each multivariate data present in the input layer is connected to all the neurons of the competition layer through some synaptic weights. The neurons in the competition layer undergo three basic operations, such as competition, cooperation and updating, in stages. In the competition stage, neurons in the competition layer compete among themselves to be identified as a winner, which has the best match with the input unit. In the cooperation stage, a neighborhood surrounding the winning neuron is identified, which contains neurons similar to the winning one. The winning neuron along with its

Figure 3. A schematic diagram representing self-organizing map (Dutta & Pratihar, 2006).



neighbors is updated in the third stage. All these stages are explained as follows.

1. **Competition:** Let us assume that there are *L* - dimensional *N* points (neurons) in the input layer. Thus, a particular input neuron *i* can be expressed as follows:

   $X_i = [x_{i1}, x_{i2}, ..., x_{iL}]^T$, where $i = 1,2,...,N$.

   Let us also consider that the synaptic weight vector between input neuron *i* and neuron j lying in the competition layer is denoted by:

   $W^i_j = [w^i_{j1}, w^i_{j2}, ..., w^i_{jL}]^T$, where $j = 1,2,....,N$.

   The number of neurons lying in the competition layer is assumed to be equal to that of the input layer. To identify the best match for the input data *i*, we need to find the neuron lying in the competition layer, which has the smallest Euclidean distance with it. Let us represent the neuron lying in the competition layer that has the best match with the input vector X_i by n. Thus, Euclidean distance between n and X_i can be expressed as follows:

   $n(X_i)$ = Minimum of $\sqrt{(X_i - W^i_j)^2}$,
   where $j = 1,2,...,N$.

2. **Cooperation:** The winning neuron decides its topological neighborhood (expressed with the help of a neighborhood function) of excited neurons and they will cooperate with each other. Due to this cooperation, their synaptic weights will be updated. For cooperation, the neighborhood function is assumed to follow a Gaussian distribution as:

$$h_{j,n(x_i)}(t) = \exp\left(-\frac{d^2_{j,n(X_i)}}{2\sigma^2_t}\right)$$

   where iteration number $t = 0,1,2,...$ and $d_{j,n(X_i)}$ represents the lateral distance between the winning neuron n and the excited neuron j, σ_t indicates the value of standard deviation at t^{th} iteration, which is expressed as $\sigma_t = \sigma_0 \exp(-(t/\tau))$, where σ_0 is the initial value of standard deviation and τ indicates the pre-defined number of maximum iterations. Thus, the topological neighborhood is assumed to shrink with the number of iterations. It indicates that the algorithm initially starts with a wide neighborhood for cooperation and the size of neighborhood is decreased iteratively. As the iteration proceeds, the algorithm becomes more selective in choosing the neighborhood for cooperation. Thus, the winning neuron and its neighbors help each other to improve their situations.

- **Updating:** The synaptic weights of the winning neuron and all the excited neurons lying in its neighborhood are updated by following the rule:

$$W^i_j(t+1) = W^i_j(t) + \eta(t) h_{j,n(X_i)}(t)[X_i - W^i_j(t)],$$

  where $\eta(t)$ is the learning rate lying between 0.0 and 1.0.
  The aforementioned method is followed to identify a winning neuron lying on the competition layer corresponding to each of the input data points. The winning neurons are then displayed in the lower dimension for visualization. As it is a topology-preserving tool, the neighbourhood information of the higher dimensional data will remain intact in the lower dimension.

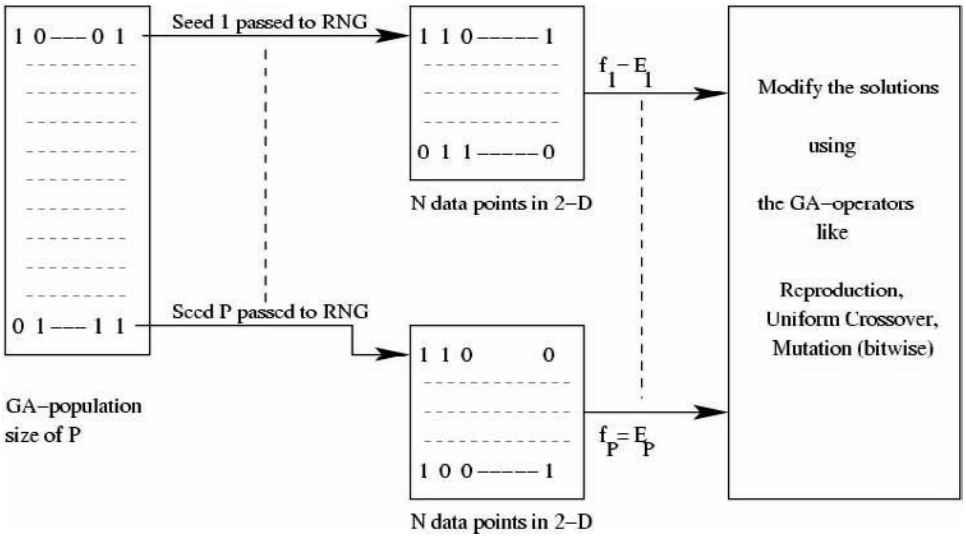
Genetic Algorithm-Like Technique

Genetic algorithm (GA) is a non-traditional tool of optimization, in which different operators of natural genetics have been modeled artificially and the principle of natural selection has been followed (Holland, 1975; Goldberg, 1989). A GA-like technique has been proposed by Dutta & Pratihar, to map data from a higher dimensional space to a lower dimensional space after preserving the distance information (Dutta & Pratihar, 2006).

The technique consists of the following steps (refer to Figure 4):

- Generate a set of N random data points lying on the surface of a higher dimensional function after considering the values of the input variables within their respective ranges. Determine the Euclidean distance values d^*_{ij} s for different combinations of two points - *i* and *j*.

Figure 4. A schematic diagram of the GA-like dimensionality reduction technique (Dutta & Pratihar, 2006)



- Create an initial population of solutions of size *P*, at random. Some bits (consisting of 1 and/or 0) are assigned to represent each solution. The decoded value of each binary string (solution) will be used as a seed for another Random Number Generator (RNG). Thus, the initial population of solutions will contain P seed values. Using a particular seed value, N data points are generated in 2-D lying within the range of the variables, at random. The Euclidean distance between the points *i* and *j* is then calculated, in 2-D. Thus, the GA-like approach carries out its search in a wider space compared to where the conventional GA does.
- Determine the error in mapping E_p (for p^{th} solution) using the expression:

$$E_p = \frac{1}{C}\sum_{i=1}^{N}\sum_{j=1(i<j)}^{N}\frac{[d_{ij}^{*} - d_{ij}]^2}{d_{ij}^{*}}$$

The symbols carry the same meaning as they have in Sammon's NLM.

- The fitness of p^{th} solution of the population is made equal to E_p, that is to be minimized. The fitness values for all the solutions of the population are calculated by following the same procedure.
- Modify the population of solutions using the operators, namely tournament selection, uniform crossover and bit-wise mutation. Tournament selection is a special type of reproduction scheme, in which a number of solutions (depending on the pre-defined tournament size) are taken from the population at random and the best one is selected and kept in the mating pool. Uniform crossover is a modified multi-point crossover, where the participating parents are checked at each bit position with a probability of 0.5, whether there will be a swapping of their bits.
- Continue the process until the termination criterion (say, maximum number of generations or desired accuracy in the solution) is reached. As it is a population-based search and optimization technique, the chance of its solutions for being trapped into the local minima is less.

Comparisons

An attempt has been made to compare the performances of the aforementioned mapping tools on different test functions, in terms of accuracy in mapping, visibility of the mapped data and computational complexity (Dutta & Pratihar, 2006). In this chapter, the results of comparison for a particular test function, say Schaffer's F1 have been shown. Two hundred points are generated at random, which are lying on the surface of the said test function. It is mathematically expressed as:

$$y = 0.5 + \frac{Sin^2\sqrt{\sum_{i=1}^{4} x_i^2} - 0.5}{1.0 + 0.001\left(\sum_{i=1}^{4} x_i^2\right)^2}$$

Figure 5. Results of mapping on Schaffer's F1 function using the approaches – (a) Sammon's NLM, (b) VISOR algorithm, (c) SOM and (d) GA-like approach (Dutta & Pratihar, 2006).

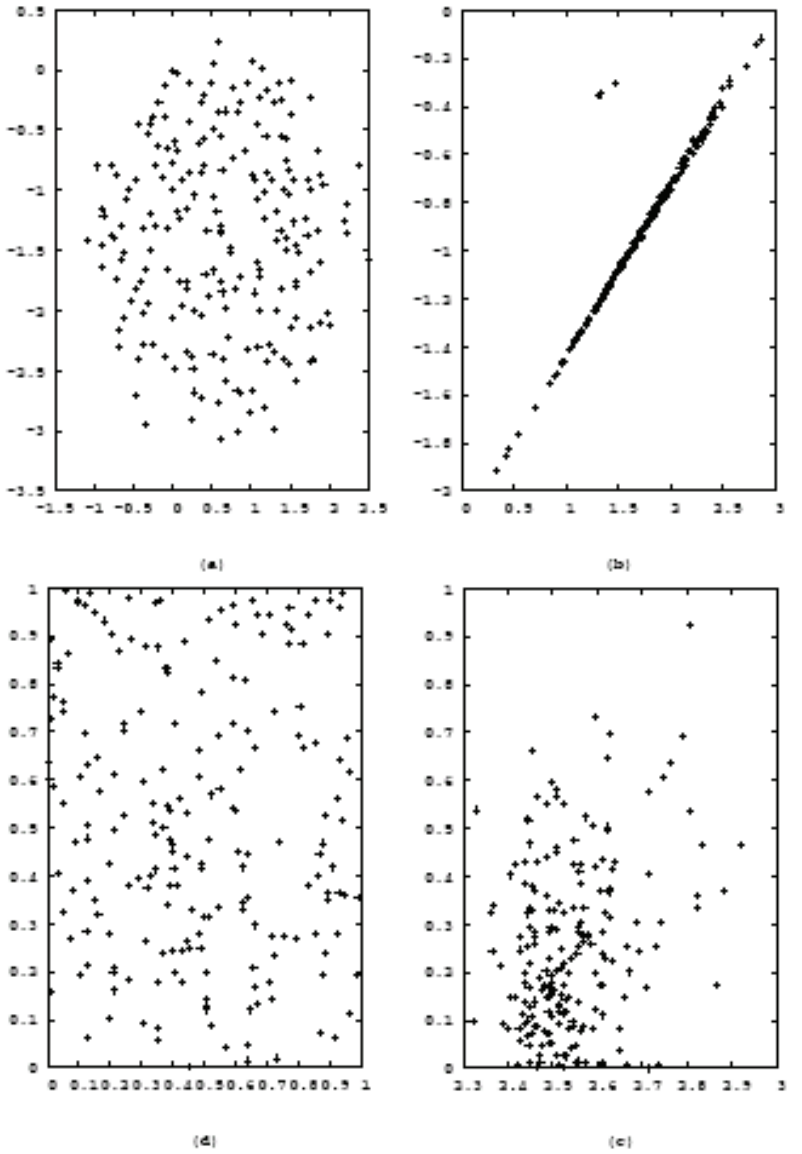


Figure 5 shows the mapped data for the said function in 2-D obtained using the aforementioned four mapping methods. The GA-like approach is found to outperform other approaches in terms of accuracy in mapping, ease of visibility of the mapped data but at the cost of computational complexity. The VISOR algorithm is seen to be the fastest of all but it has been defeated by other algorithms with respect to accuracy in mapping and visibility.

FUTURE TRENDS

An ideal dimensionality reduction technique should be able to map the higher dimensional data to a lower dimension accurately at a low computational cost and at the same time, the mapped data will be well distributed to ensure a better visibility. However, developing an algorithm that can satisfy all the aforementioned requirements in the optimal sense is the main aim of this field of research. Moreover, the mapping techniques could be integrated with other algorithms of data

analysis, such as an optimization tool, a data miner, and others, to have better understanding of their working principle. For example, in order to investigate the topological information of the function to be optimized using a GA, a mapping tool may be clubbed with it for visualization.

CONCLUSION

The present chapter explains the principles of four nonlinear dimensionality reduction techniques. Out of them, the GA-like approach is found to be the best of all in terms of accuracy in mapping and ease of visualization of the mapped data, whereas the VISOR algorithm is seen to be the worst. The GA-like approach and VISOR algorithm are found to be the slowest and fastest of all the aforementioned techniques, respectively. The SOM can also provide with a reasonably well mapping in terms of accuracy and nature of distribution of the mapped data. The performances of the dimensionality reduction techniques are seen to be data dependent.

KEY TERMS

Dimensionality Reduction: Mapping of higher dimensional data to a lower dimension for ease of visualization and modeling.

Distance Preserving: It is a property, in which the Euclidean distance between two higher dimensional points is kept the same with that between the two corresponding points in lower dimension.

Genetic Algorithm: It is a population-based search and optimization tool, which works based on the mechanics of natural genetics and Darwin's principle of natural selection.

Linear Mapping: It is a mapping, where each of the lower dimensional components of the data set is considered as a linear combination of the higher dimensional components.

Non-linear Mapping: It is a mapping, where each of the lower dimensional components is considered as a non-linear combination of the higher dimensional components.

Self-Organizing Map (SOM): A neural network consisting of input and competition layers that can map the higher dimensional data onto a lower dimension through unsupervised learning.

Steepest Descent Method: It is a gradient-based traditional tool of optimization.

Topology Preserving: It is a property, in which the topological information of a point with its neighborhood in a higher dimensional space will remain unaltered in the lower dimensional space.

Unsupervised Learning: It is a process of learning that takes place through a self-organizing process in the absence of a teacher (that is, the target output).

Visualization: Graphical presentation of data in either 2-D or 3-D for ease of understanding.

A Novel Approach on Negative Association Rules

Ioannis N. Kouris
University of Patras, Greece

INTRODUCTION

Research in association rules mining has initially concentrated in solving the obvious problem of finding positive association rules; that is rules among items that exist in the stored transactions. It was only several years after that the possibility of finding also negative association rules became especially appealing and was investigated. Nevertheless researchers based their assumptions regarding negative association rules on the absence of items from transactions. This assumption though besides being dubious, since it equated the absence of an item with a conflict or negative effect on the rest items, it also brought out a series of computational problems with the amount of possible patterns that had to be examined and analyzed. In this work we give an overview of the works having engaged with the subject until now and present a novel view for the definition of negative influence among items.

BACKGROUND

Association rule mining is still probably the prominent method for knowledge discovery in databases (KDD), among all other methods such as classification, clustering, sequential pattern discovery etc. The discovery of association relationships among items in a huge database has been known to be useful in various sectors such as telecommunications, banking, transport and particularly in retail. Also it has been applied to various data sets such as census data, text documents, transactional data, medical images and lately biological data. In fact any data type that is collected and constitutes a large database of "baskets", each containing multiple "items" can fit this model. The prototypical application of association rules mining and probably until today the most extensively studied and popular one is the analysis of supermarket sales or basket data; hence the problem of finding association rules is often referred to as the "market-basket" problem. In this problem, we are given a set of items and a large collection of transactions which are subsets (baskets) of these items. The objective is to find relationships correlating various items within those baskets. More formally the specific task can be stated as follows:

Let $I=\{i_1, i_2,\ldots,i_n\}$ be a set of items and D be a database organized in multiple transactions T where each transaction $\mathbf{T}\in\mathbf{D}$ is a set of items such that $\mathbf{T}\subseteq\mathbf{I}$. An association rule is an implication of the form $X\rightarrow Y$, where $\mathbf{X, Y}\subseteq\mathbf{I}$ and $\mathbf{X}\cap\mathbf{Y}=\varnothing$, and expresses the possibility that whenever we find a transaction that contains all items in X, then this transaction is likely to also contain all items in Y. Consequently X is called the body of the rule and Y the head. The validity and reliability of association rules is expressed usually by means of support and confidence, succored by other measures such as for example implication, lift etc. An example of such a rule is {cell_phone, hands_free➔case (sup=70%, conf=90%)}, which means that 90% of the customers that buy a cell phone and a hands free device buy a cell phone case as well, whereas 70% of all our customers buy all these three things together.

The task of finding association rules was first formulated by Agrawal, Imielinski and Swami (1993). Since then there have been a series of works trying to improve various aspects such as the efficiency of Apriori based algorithms, implementation of new measures for finding strong – alternative rules, application of association rules framework into other domains etc. (for more details interested reader is referred to the work of Tan, Steinbach & Kumar, 2005).

On the other hand negative association rules have been initially either neglected or considered unimportant. It was not only but after several years since the first introduction of association rules that the problem of negative association rules was brought up. Also despite the fact that the existence and significance of

negative association rules has been recognized for quite some time, comparably a very small percentage of researchers have engaged with it.

MAIN FOCUS

Positive association rules take into consideration only the items that remained and finally appear in the stored transactions. Negative association rules on the other hand, at least as they have been traditionally defined in the literature up to now, take into consideration also the items that do not appear in a transaction. For example a positive association rule would consider all transactions containing pasta and cheese and would generate from them all corresponding association rules (i.e. **pasta → cheese**). An approach dealing with negative association rules on the other hand would also consider rules such as: those that buy pasta buy also cheese but not refreshments (**pasta → cheese** $\wedge \neg$ **refreshment**), or those that buy pasta but not bread buy also cheese (**pasta** $\wedge \neg$ **Bread → cheese**). The measures used for determining the strength of a correlation and for pruning the insignificant ones are again the support and confidence metrics.

A so called generalized negative association rule can include various negated and positive items (i.e. items existing and items absent from transactions) either in its antecedent or in its consequent. An example of such a rule would be: $\mathbf{A} \wedge \neg \mathbf{C} \wedge \neg \mathbf{F} \wedge \mathbf{W} \rightarrow \mathbf{B} \wedge \neg \mathbf{D}$ (i.e. people that buy items A and W but not C and F are likely to buy B but not D). However the obvious insurmountable obstacle created by such a contemplation is the number of possible itemsets that would have to be generated and counted as well as the number of rules created, since apart from the existing items we would have to consider all possible absent items and their combinations. Most approaches thus far have made various assumptions in order to come to approximate solutions, working on subsets of the problem of generalized association rules. For example considering rules where the entire consequent or antecedent could be a conjunction of similar items (i.e. negated or non-negated), considering negative rules only in the infrequent items, considering rules only between two items etc.. Nevertheless the absence of an item from a transaction does not necessarily imply direct negative correlation between items, but could be attributed to various other factors.

Previous Works on Negative Association Rules

To our knowledge Brin, Motwani & Silverstein (1997) were the first that have introduced and addressed the existence of negative relationships between items, by using a chi-squared test for correlations derived from statistics. In the specific work though there were mined negative associations only between two items. Subsequently Savasere, Omiecinski & Navathe (1998) and Yuan, Buckles, Yuan & Zhang (2002) have proposed two similar approaches, which tried to discover strong negative associations depending heavily on domain knowledge and predefined taxonomies. In the same context was the work of Daly & Taniar (2004), who organized items hierarchically following an ancestor – descendant scheme in order to avoid considering all negative items when no additional knowledge would be extracted from lower levels. As an example if customers do not buy refreshments after having bought pasta then we need not examine each and every kind of refreshment. Another work was that of Wu, Zhang & Zhang (2002), which used in addition to the support and confidence measure, a measure for more efficient pruning of the frequent itemsets generated called mininterest. Thiruvady & Webb (2004) proposed an extension of GRD - Generalized Rule Discovery algorithm (Webb, 2000) for mining negative rules. The proposed algorithm did not require the use of any minimum support threshold, but rather the specification of some interestingness measure along with a constraint upon the number of rules that would be finally generated. Finally Antonie & Zaiane (2004) proposed an algorithm for finding generalized association rules, where the entire antecedent or consequent consists of similar items (i.e. only negative or only positive items), thus generating only a subset of negative rules that they refer to as confined negative association rules. In their work they used in addition to the minimum support and minimum confidence measures, the correlation threshold as a third parameter. In the same context can also be considered to some extent works dealing with unexpected patterns (also known as surprising patterns), where the negative items can be thought as such patterns (e.g. Liu, Lu, Feng & Hussain, 1999; Hwang, Ho & Tang, 1999; Hussain, Liu, Suzuki & Lu, 2000; Suzuki & Shimura,

1996; Suzuki, 1997; Padmanabhan & Tuzhilin, 2000; Padmanabhan & Tuzhilin, 1998). Last but not least is the most recent work of Arunasalam, Chawla & Sun (2005) that propose an efficient algorithm for mining both positive and negative patterns in large spatial databases (i.e. databases where objects are characterized by some spatial attributes like location or coordinates).

A NEW APPROACH TO NEGATIVE ITEMSETS

As noted above the equation of the absence of an item from a transaction with a negative influence on the rest items is a highly questionable assumption. The fact that for example beers might never appear together with milk or cereals could possibly mean that these two items present some kind of conflict or negative influence to one another but this is not always the case not even the norm. Practically this kind of behavior could be attributed to various other factors such as (just to name a few for the case of retail data):

- **Complementary products:** Products or items in general that can be consumed or used in place of one another in at least some of their possible uses. Classic examples of substitute goods include margarine instead of butter, or natural gas instead of petroleum.
- **Replacement products:** Products or items where one gradually replaces another one. For example the case where cassettes were replaced by cd's, thus they were never found together in a basket.
- **Mere luck or coincidence** ought to various other factors such as for example due to the placement of products within a store far apart.

Finally the current definition of negative association rules is not only dubious but also creates large computational problems, since the addition of negative items could render the specific task NP – hard.

Our proposal on negative items is based on a far more sound and palpable behavior, similar to that of positive association rules. More specifically instead of considering rules stemming from itemsets where the absence of an item implies a negative relationship we consider itemsets where the conflict between items is recorded in the form of a removal. For example suppose that a customer has already put in his basket pasta, cheese and some refreshment. Normally we would expect the specific customer to keep his basket unchanged until the end or at least to put some more products in it. Nevertheless it could happen that the specific customer now decides to buy beers, but also to remove the refreshment from his basket. Then this is some clear indication that there is some kind of conflict or negative relation between these products, which finally triggered the removal of the refreshment. As one can easily understand this is a completely different contemplation than regarding the absence of an item as an indication of negative relation because in the case of the removal we are dealing with a specific conscious act. This contemplation though raises three main questions that have to be answered. First how are we going to store the actual removal of items? Secondly how are we going to quantify it? And thirdly how are we going to use it?

The answer to the first question is quite trivial. All existing systems and applications do not store the actual removal of an item, but only the cases where it entered and finally remained in a transaction. For example in the case of a retail shop they store for every transaction a unique transaction identifier (noted as TID), the date and sometimes even the exact time of the purchase and finally the unique ids (in the form of bar codes) of the items purchased. Removed items are not taken into consideration in any way, although they contain valuable knowledge that is unfortunately neglected by current approaches and systems. Recording these items though is a simple task that could be implemented even with the existing systems practically with minimum modifications. Of course depending on the application we might have to store not only the order, but the exact time, their physical relevant distance and many other factors.

As far as the quantification of the removal of an item is considered things are a little more complicated. The most obvious and probably naïve approach would be to consider all items preceding the item that was removed as having an equal negative effect on the removed item. More accurate would be to consider the effect that the preceding items have on the removed one as diminishing according to their relevant distance in the transaction (i.e. the item chosen right before the removal having the greatest negative influence). Another possible solution would be to consider as the determinant factor and consequently the only one having a negative

effect on the removed item the one that was purchased last. This is justified also by the fact that the removed item was remaining in the transaction along with all the rest items, and was most probably removed by the choice of the last one.

The removed items could be viewed as separate items from the ones that remained in the transaction (i.e. item A is a different item than item –A) or there could be used a formula for combining the removals and the actual appearances. These are yet a few variations of how one could quantify the removal of an item from transactions or records in general. It remains up to the user and the desired outcome to propose and use a specific variation that better suits specific needs.

Last but not least is the actual use of these patterns. This task is also application specific. For example if we are operating in a retail firm, where the profits generated is the determinant factor, then we would have to examine if the item proposed thus possibly triggering the removal of another one has more net profits than the removed one as well as if it triggers the choice of more other items.

FUTURE TRENDS

The contemplation proposed above has to be followed by the design and implementation of efficient procedures and algorithms for mining negative association rules. Such algorithms might spring from existing ones, although we believe that some completely new solutions would have to be implemented. Another very important parameter neglected in current works in association rules mining is the exact order of items within transactions. The fact that some items are purchased together gains more interest and applicability if we stored and used their exact order of appearances coupled with parameters such as time between purchases, time to complete a purchase etc. This parameter is yet more important if combined with items being removed from transactions. Of course taking into consideration the order of items within transactions adds a lot to complexity, and requires carefully planned approaches.

CONCLUSION

In this chapter we attempted to give a brief but thorough review of all works done thus far in the field of finding negative relationships among items, or had some close relevance to the specific task. Consequently we described the functioning of current approaches, argued about their effectiveness exposing several of their biggest drawbacks that make them less effective. We concluded with a presentation of our view of the problem of finding negative itemsets and relationships among them, possible problems caused by our contemplation as well as some solutions to these problems.

KEY TERMS

Association Rules: An implication of the form $X \rightarrow Y$ where X and Y are itemsets. An association rule expresses the possibility that whenever we find a transaction that contains all items in *X*, then this transaction is likely to also contain all items in *Y*.

Confidence: A rule X→Y is said to have confidence c%, if c% of the records (transactions) in a database that contain X contain also Y.

Data Mining: Analysis of data in a database using tools which look for trends or anomalies without knowledge of the meaning of the data. The nontrivial extraction of implicit, previously unknown, and potentially useful information from data. The science of extracting useful information from large data sets or databases.

Itemsets: A collection or a combination of positive or negative items in a database.

Negative Itemsets: Traditionally as negative itemsets were considered those absent from transactions. An alternative contemplation is those itemsets having entered and later have being removed from a transaction.

Positive Association Rules: Rules that value and take into consideration only the items that remain finally in a transaction.

Support: A rule X→Y is said to have support s%, if c% of all the records (transactions) in a database contain both itemsets X and Y.

INTRODUCTION

The most commonly used protection mechanisms today are based on either what a person possesses (e.g. an ID card) or what the person remembers (like passwords and PIN numbers). However, there is always a risk of passwords being cracked by unauthenticated users and ID cards being stolen, in addition to shortcomings like forgotten passwords and lost ID cards (Huang & Yan, 1997). To avoid such inconveniences, one may opt for the new methodology of Biometrics, which though expensive will be almost infallible as it uses some unique physiological and/or behavioral (Huang & Yan, 1997) characteristics possessed by an individual for identity verification. Examples include signature, iris, face, and fingerprint recognition based systems.

The most widespread and legally accepted biometric among the ones mentioned, especially in the monetary transactions related identity verification areas is carried out through handwritten signatures, which belong to behavioral biometrics (Huang & Yan,1997). This technique, referred to as signature verification, can be classified into two broad categories - online and off-line. While online deals with both static (for example: number of black pixels, length and height of the signature) and dynamic features (such as acceleration and velocity of signing, pen tilt, pressure applied) for verification, the latter extracts and utilizes only the static features (Ramesh and Murty, 1999). Consequently, online is much more efficient in terms of accuracy of detection as well as time than off-line. But, since online methods are quite expensive to implement, and also because many other applications still require the use of off-line verification methods, the latter, though less effective, is still used in many institutions.

BACKGROUND

Starting from banks, signature verification is used in many other financial exchanges, where an organization's main concern is not only to give quality services to its customers, but also to protect their accounts from being illegally manipulated by forgers.

Forgeries can be classified into four types—random, simple, skilled and traced (Ammar, Fukumura & Yoshida, 1988; Drouhard, Sabourin, & Godbout, 1996). Generally online signature verification methods display a higher accuracy rate (closer to 99%) than off-line methods (90-95%) in case of all the forgeries. This is because, in off-line verification methods, the forger has to copy only the shape (Jain & Griess, 2000) of the signature. On the other hand, in case of online verification methods, since the hardware used captures the dynamic features of the signature as well, the forger has to not only copy the shape of the signature, but also the temporal characteristics (pen tilt, pressure applied, velocity of signing etc.) of the person whose signature is to be forged. In addition, he has to simultaneously hide his own inherent style of writing the signature, thus making it extremely difficult to deceive the device in case of online signature verification.

Despite greater accuracy, online signature recognition is not encountered generally in many parts of the world compared to off-line signature recognition, because it cannot be used everywhere, especially where signatures have to be written in ink, e.g. on cheques, where only off-line methods will work. Moreover, it requires some extra and special hardware (e.g. pressure sensitive signature pads in online methods vs. optical scanners in off-line methods), which are not only expensive but also have a fixed and short life span.

MAIN THRUST

In general, all the current off-line signature verification systems can be divided into the following submodules:

- Data Acquisition
- Preprocessing and Noise Removal
- Feature Extraction and Parameter Calculations
- Learning and Verification (or Identification)

Data Acquisition

Off-line signatures do not consider the time related aspects of the signature such as velocity, acceleration and pressure. Therefore, they are often termed as "static" signatures, and are captured from the source (i.e. paper) using a camera or a high resolution scanner, in comparison to online signatures (in which data is captured using a digitizer or an instrumented pen generating signals) (Tappert, Suen, & Wakahara, 1990; Wessels & Omlin, 2000), which do consider the time related or dynamic aspects besides the static features.

Preprocessing

The preprocessing techniques that are generally performed in off-line signature verification methods comprise of noise removal, smoothening, space standardization and normalization, thinning or skeletonization, converting a gray scale image to a binary image, extraction of the high pressure region images, etc.

- **Noise Removal:** Signature images, like any other image may contain noises like extra dots or pixels (Ismail & Gad, 2000), which originally do not belong to the signature, but get included in the image because of possible hardware problems or the presence of background noises like dirt. To recognize the signature correctly, these noise elements have to be removed from the background in order to get the accurate feature matrices in the feature extraction phase. A number of filters have been used as preprocessors (Ismail & Gad, 2000) by researchers to obtain the noise free image. Examples include the mean filter, median filter,

Figure 1. Modular structure of an offline verification system

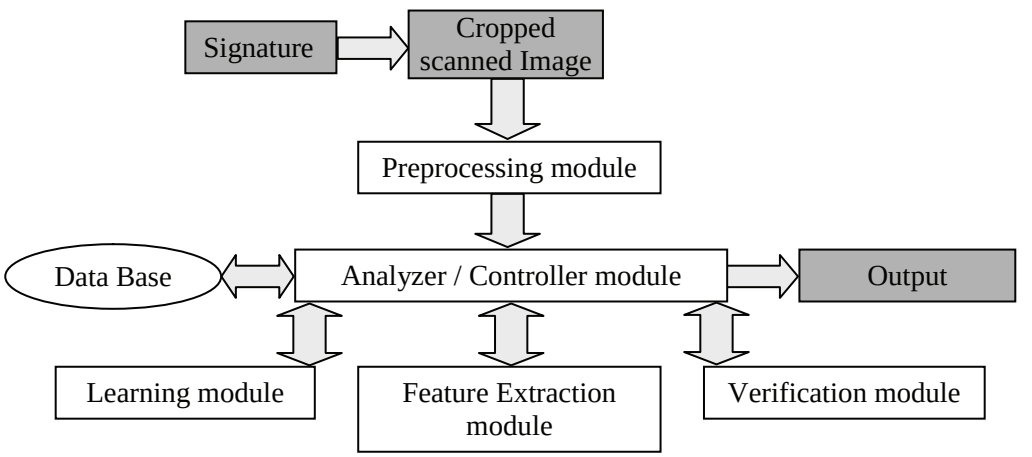

Figure 2. Noise removal using median filter

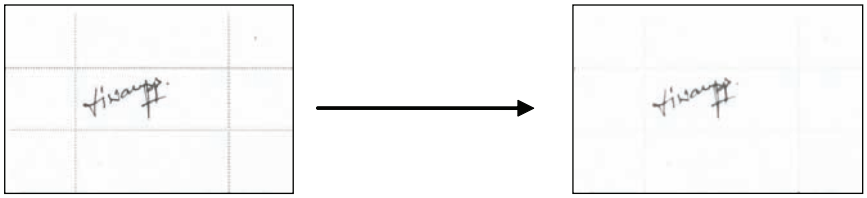

(a) Gray scale *(b) Noise free*

filter based on merging overlapped run lengths in one rectangle (Ismail & Gad, 2000) etc. Among all the filtering techniques mentioned above, average and median filtering are considered to be standard noise reduction and isolated peak noise removal techniques(Huang & Yan, 1997). However, median filter is preferred more because of its ability to remove noises without blurring the edges of the signature instance unlike the mean filter.

- **Space Standardization and Normalization:** In Space standardization, the distance between the horizontal components of the same signature is standardized, by removing blank columns, so that it does not interfere with the calculation of global and local features of the signature image (Baltzakis & Papamarkos, 2001; Qi & Hunt, 1994). In normalization, the signature image is scaled to a standard size which is the average size of all training samples, keeping the width to height ratio constant (Baltzakis & Papamarkos, 2001; Ismail & Gad, 2000; Ramesh & Murty, 1999).
- **Extracting the Binary Image from Grayscale Image:** Using the Otsu's method a threshold is calculated to obtain a binary version of the grayscale image (Ammar, Fukumura, & Yoshida, 1988; Ismail & Gad, 2000; Qi & Hunt, 1994). The algorithm is as follows:

$$S(x,y) = \begin{cases} 1 & R(x,y) > threshold, \\ 0 & R(x,y) < threshold, \end{cases}$$

where S(x,y) is the binary image and R(x,y) is the grayscale image.

- **Smoothening:** The noise-removed image may have small connected components or small gaps, which may need to be filled up. It is done using a binary mask obtained by thresholding followed by morphological operations (which include both erosion and dilation) (Huang & Yan, 1997; Ismail & Gad, 2000; Ramesh & Murty, 1999).
- **Extracting the High Pressure Region Image:** Ammar et al. (Ammar, M., Fukumura, T., & Yoshida Y., 1986) have used the high pressure region as one of the prominent features for detecting skilled forgeries. It is the area of the image where the writer gives special emphasis reflected in terms of higher ink density (more specifically, higher gray level intensities than the threshold chosen). The threshold is obtained as follows:

$$Th_{HPR} = I_{min} + 0.75(I_{max} - I_{min}),$$

Figure 3. Converting grayscale image into binary image

(a) Grayscale *(b) High pressure region*

Figure 5. Extraction of thinned image

(a) Binary *(b) Thinned*

where I_{min} and I_{max} are the minimum and maximum grayscale intensity values.

- Thinning or Skeletonization: This process is carried out to obtain a single pixel thick image from the binary signature image. Different researchers have used various algorithms for this purpose (Ammar, Fukumura, & Yoshida, 1988; Baltzakis & Papamarkos, 2001; Huang & Yan, 1997; Ismail & Gad, 2000).

Feature Extraction

Most of the features can be classified in two categories - global and local features.

- **Global Features:** Ismail and Gad (2000) have described global features as characteristics, which identify or describe the signature as a whole. They are less responsive to small distortions and hence are less sensitive to noise as well. Examples include width and height of individual signature components, width to height ratio, total area of black pixels in the binary and high pressure region (HPR) images, horizontal and vertical projections of signature images, baseline, baseline shift, relative position of global baseline and centre of gravity with respect to width of the signature, number of cross and edge points, circularity, central line, corner curve and corner line features, slant, run lengths of each scan of the components of the signature, kurtosis (horizontal and vertical), skewness, relative kurtosis, relative skewness, relative horizontal and vertical projection measures, envelopes, individual stroke segments. (Ammar, Fukumura, & Yoshida, 1990; Bajaj & Chaudhury, 1997; Baltzakis & Papamarkos, 2001, Fang, et al., 2003, Huang & Yan, 1997; Ismail & Gad, 2000; Qi & Hunt, 1994, Ramesh & Murty, 1999; Yacoubi, Bortolozzi, Justino, & Sabourin, 2000; Xiao & Leedham, 2002)
- **Local Features:** Local features are confined to a limited portion of the signature, which is obtained by dividing the signature image into grids or treating each individual signature component as a separate entity (Ismail & Gad, 2000). In contrast to global features, they are responsive to small distortions like dirt, but are not influenced by other regions of the signature. Hence, though extraction of local features requires more computations, they are much more precise. Many of the global features have their local counterparts as well. Examples of local features include width and height of individual signature components, local gradients such as area of black pixels in high pressure region and binary images, horizontal and vertical projections, number of cross and edge points, slant, relative position of baseline, pixel distribution, envelopes etc. of individual grids or components. (Ammar, Fukumura, & Yoshida, 1990; Bajaj & Chaudhury, 1997; Baltzakis & Papamarkos, 2001; Huang & Yan, 1997; Ismail & Gad, 2000; Qi & Hunt, 1994; Ramesh & Murty, 1999; Yacoubi, Bortolozzi, Justino, & Sabourin, 2000)

Learning and Verification

The next stage after feature extraction involves learning. Though learning is not mentioned separately for verification as a separate sub module, it is the most vital part of the verification system in order to verify the authenticity of the signature. Usually five to forty features are passed in as a feature matrix/vector to train the system. In the training phase, 3-3000 signature instances are used. These signature instances include either the genuine or both genuine and forged signatures depending on the method. All the methods extract features in a manner such that the signature cannot be constructed back from them in the reverse order but have sufficient data to capture the features required for verification. These features are stored in various formats depending upon the system. It could be either in the form of feature values, weights of the neural network, conditional probability values of a belief (Bayesian) network or as a covariance matrix (Fang et al., 2003). Later, when a sample signature is to be tested, its feature matrix/vector is calculated, and is passed into the verification sub module of the system, which identifies the signature to be either authentic or unauthentic. So,

Table 1. Summary of some prominent offline papers

Author	Mode of Verification	Database	Feature Extraction	Results
Ammar, Fukumara and Yoshida (1988)	Statistical method-- Euclidian distance and threshold	10 genuine signatures per person from 20 people	Global baseline, upper and lower extensions, slant features, local features (e.g. local slants) and pressure feature	90% verification rate
Huang and Yan (1997)	Neural network Based-- Multilayer perceptron based neural networks trained and used	A total of 3528 signatures (including genuine and forged)	Signature outline, core feature, ink distribution, high pressure region, directional frontiers feature, area of feature pixels in core, outline, high pressure region, directional frontiers, coarse, and in fine ink	99.5 % for random forgery and 90 % for targeted forgeries
Ramesh and Murty (1999)	Genetic Algorithms used for obtaining genetically optimized weights for weighted feature vector	650 signatures, 20 genuine and 23 forged signatures from 15 people	Global geometric features: Aspect ratio, width without blanks, slant angle, vertical center of gravity (COG) etc. Moment Based features: horizontal and vertical projection images, kurtosis measures(horizontal and vertical) Envelope Based: extracting the lower and upper envelopes and Wavelet Based features	90 % under genuine, 98 % under random forgery and 70-80 % under skilled forgery case
Ismail and Gad (2000)	Fuzzy concepts	220 genuine and 110 forged samples	Central line features, corner line features, central circle features, corner curve features, critical points features	95% recognition rate and 98% verification rate
Yacoubi, Bortolozzi, Justino and Sabourin (2000)	Hidden Markov Model	4000 signatures from 100 people (40 people for 1st and 60 for 2nd database	Caliber, proportion, behavior guideline, base behavior, spacing	Average Error(%) :0.48 on 1st database, and 0.88 on the 2nd database
Fang, Leung, Tang, Tse, Kwok, and Wong (2003)	Non-linear dynamic time warping applied to horizontal and vertical projections. Elastic bunch graph matching to individual stroke segments	1320 genuine signatures from 55 authors and 1320 forgeries from 12 authors	Horizontal and Vertical projections for non linear dynamic time warping method. Skeletonized image with approximation of the skeleton by short lines for elastic bunch graph matching algorithm	Best result of 18.1% average error rate (average of FAR and FRR) for first method. The Average error rate was 23.4% in case of the second method

unless the system is trained properly, chances, though less, are that it may recognize an authentic signature to be unauthentic (false rejection), and in certain other cases, recognize the unauthentic signature to be authentic (false acceptance). So, one has to be extremely cautious at this stage of the system. There are various methods for off-line verification systems that are in use today. Some of them include:

- Statistical methods (Ammar, M., Fukumura, T., & Yoshida Y., 1988; Ismail & Gad, 2000)
- Neural network based approach (Bajaj & Chaudhury, 1997; Baltzakis & Papamarkos, 2001; Drouhard, Sabourin, & Godbout, 1996; Huang & Yan, 1997)
- Genetic algorithms for calculating weights (Ramesh & Murty, 1999)
- Hidden Markov Model (HMM) based methods (Yacoubi, Bortolozzi, Justino, & Sabourin, 2000)
- Bayesian networks (Xiao & Leedham, 2002)
- Nonliinear dynamic time warping (in spatial domain) and Elastic bunch graph matching (Fang et al., 2003)

The problem of signature verification is that of dividing a space into two different sets of genuine and forged signatures. Both online and off-line approaches use features to do this, but, the problem with this approach is that even two signatures by the same person may not be the same. The feature set must thus have sufficient interpersonal variability so that we can classify the input signature as genuine or forgery. In addition, it must also have a low intrapersonal variability so that an authentic signature is accepted. Solving this problem using fuzzy sets and neural networks has also been tried. Another problem is that an increase in the dimensionality i.e. using more features does not necessarily minimize(s) the error rate. Thus, one has to be cautious while choosing the appropriate/optimal feature set.

FUTURE TRENDS

Most of the presently used off-line verification methods claim a success rate of more than 95% for random forgeries and above 90% in case of skilled forgeries. Although, a 95% verification rate seems high enough, it can be noticed that, even if the accuracy rate is as high as 99 %, when we scale it to the size of a million, even a 1% error rate turns out to be a significant number. It is therefore necessary to increase this accuracy rate as much as possible.

CONCLUSION

Performance of signature verification systems is measured from their *false rejection rate* (FRR or type I error) (Huang & Yan, 1997) and *false acceptance rate* (FAR or type II error) (Huang & Yan, 1997) curves. Average error rate, which is the mean of the FRR and FAR values, is also used at times. Instead of using the FAR and FRR values, many researchers quote the "100 - average rate" values as the performance result. Values for various approaches have been mentioned in the table above. It is very difficult to compare the values of these error rates, as there is no standard database either for off-line or for online signature verification methods.

Although online verification methods are gaining popularity day by day because of higher accuracy rates, off-line signature verification methods are still considered to be indispensable, since they are easy to use and have a wide range of applicability. Efforts must thus be made to improve its efficiency to as close as that of online verification methods.

KEY TERMS

O

Area of Black Pixels: It is the total number of black pixels in the binary image.

Biometric Authentication: The identification of individuals using their physiological and behavioral characteristics.

Centre of Gravity: The centre of gravity of the image is calculated as per the following equation:

$$X = \sum_{y=1}^{m} (y.P_h[y]) / \sum_{y=1}^{m} P_h[y], \text{ and}$$

$$Y = \sum_{x=1}^{n} (x.P_v[x]) / \sum_{x=1}^{n} P_v[x],$$

where X, Y are the x and y coordinates of the centre of gravity of the image, and P_h and P_v are the horizontal and vertical projections respectively.

Cross and Edge Points: A cross point is an image pixel in the thinned image having at least three eight neighbors, while an edge point has just one eight neighbor in the thinned image.

Envelopes: Envelopes are calculated as upper and lower envelopes above and below the global baseline. These are the connected pixels which form the external points of the signature obtained by sampling the signature at regular intervals.

Global Baseline: It is the median value of pixel distribution along the vertical projection.

Horizontal and Vertical Projections: Horizontal projection is the projection of the binary image along the horizontal axis. Similarly, vertical projection is the projection of the binary image along the vertical axis. They can be calculated as follows:

$$P_h[y] = \sum_{x=1}^{n} \text{black.pixel}(x, y),$$

$$P_v[x] = \sum_{y=1}^{m} \text{black.pixel}(x, y),$$

where m = width of the image and n = height of the image.

Moment Measures: Skewness and kurtosis are moment measures calculated using the horizontal and vertical projections and co-ordinates of centre of gravity of the signature.

Slant: Either it is defined as the angle at which the image has maximum horizontal projection value on rotation or it is calculated using the total number of positive, negative, horizontally or vertically slanted pixels.

INTRODUCTION

The problem of efficiently *visualizing multidimensional data sets* produced by scientific and statistical tasks/processes is becoming increasingly challenging, and is attracting the attention of a wide multidisciplinary community of researchers and practitioners. Basically, this problem consists in visualizing multidimensional data sets by capturing the *dimensionality* of data, which is the most difficult aspect to be considered. Human analysts interacting with high-dimensional data often experience disorientation and cognitive overload. Analysis of high- dimensional data is a challenge encountered in a wide set of real-life applications such as (*i*) biological databases storing massive gene and protein data sets, (*ii*) real-time monitoring systems accumulating data sets produced by multiple, multi-rate streaming sources, (*iii*) advanced *Business Intelligence* (BI) systems collecting business data for decision making purposes etc.

Traditional DBMS front-end tools, which are usually tuple-bag-oriented, are completely inadequate to fulfill the requirements posed by an interactive exploration of high-dimensional data sets due to two major reasons: (*i*) DBMS implement the OLTP paradigm, which is optimized for transaction processing and deliberately neglects the dimensionality of data; (*ii*) DBMS operators are very poor and offer nothing beyond the capability of conventional SQL statements, what makes such tools very inefficient with respect to the goal of visualizing and, above all, interacting with multidimensional data sets embedding a large number of dimensions.

Despite the above-highlighted practical relevance of the problem of visualizing multidimensional data sets, the literature in this field is rather scarce, due to the fact that, for many years, this problem has been of relevance for life science research communities only, and interaction of the latter with the computer science research community has been insufficient. Following the enormous growth of scientific disciplines like *Bio-Informatics*, this problem has then become a fundamental field in the computer science academic as well as industrial research. At the same time, a number of proposals dealing with the multidimensional data visualization problem appeared in literature, with the amenity of stimulating novel and exciting application fields such as the visualization of *Data Mining* results generated by challenging techniques like clustering and association rule discovery.

The above-mentioned issues are meant to facilitate understanding of the high relevance and attractiveness of the problem of visualizing multidimensional data sets at present and in the future, with challenging research findings accompanied by significant spin-offs in the *Information Technology* (IT) industrial field.

A possible solution to tackle this problem is represented by well-known OLAP techniques (Codd et al., 1993; Chaudhuri & Dayal, 1997; Gray et al., 1997), focused on obtaining very efficient representations of multidimensional data sets, called *data cubes*, thus leading to the research field which is known in literature under the terms *OLAP Visualization* and *Visual OLAP*, which, in the remaining part of the article, are used interchangeably.

Starting from these considerations, in this article we provide an overview of OLAP visualization techniques with a comparative analysis of their advantages and disadvantages. The outcome and the main contribution of this article are a comprehensive survey of the relevant state-of-the-art literature, and a specification of guidelines for future research in this field.

BACKGROUND

Formally, given a relational data source $\mathcal{R}$, a data cube $\mathcal{L}$ defined on top of R is a tuple $\mathcal{L} = \langle C, J, \mathcal{H}, \mathcal{M} \rangle$, such that: (*i*) C is the data domain of $\mathcal{L}$ containing (OLAP) *data cells* storing *SQL aggregations*, such as those based on SUM, COUNT, AVG etc, computed over tuples in $\mathcal{R}$; (*ii*) J is the set of *functional attributes* (of $\mathcal{R}$) with respect to which $\mathcal{L}$ is defined, also called *dimensions* of $\mathcal{L}$; (*iii*) $\mathcal{H}$ is the set of *hierarchies* related to dimensions of $\mathcal{L}$; (*iv*) $\mathcal{M}$ is the set of *attributes of interest* (of $\mathcal{R}$) for the underlying OLAP analysis, also called *measures* of $\mathcal{L}$. OLAP data cubes can thus be used to effectively visualize multidimensional data sets and also support interactive exploration of such data sets using a wide set of operators (Han & Kamber, 2000), among which we recall: (*i*) *drill-down*, which descends in a dimension hierarchy of the cube by increasing the level of detail of the measure (and decreasing its level of abstraction); (*ii*) *roll-up*, which is a reverse of drill-down used to aggregate the measure to a coarser level of detail (and a finer level of abstraction); (*iii*) *pivot*, which rotates the dimensions of the cube, thus inducting data re-aggregation. Apart the visualization amenities, OLAP also offers very efficient solutions to the related problem of *representing multidimensional data sets* by means of a wide set of alternatives (Han & Kamber, 2000) according to which data cubes are stored in mass memory: (*i*) ROLAP (*Relational OLAP*), which makes use of the storage support provided by conventional RDBMS (i.e., relational tables); (*ii*) MOLAP (*Multidimensional OLAP*), which employs multidimensional arrays equipped with highly-efficient indexing data structures; (*iii*) HOLAP (*Hybrid OLAP*), which combines the two previous alternatives via storing portions of the cube on a relational support, and other portions on an array-oriented support (depending on various parameters such as the query-workload of the cube). Without further details, it is worth noticing that the efficiency of the data representation has a great impact on the effectiveness of data visualization and exploration activities.

Visual OLAP results from the convergence of BI techniques and the achievements in the scientific areas of *Information Visualization* and *Visual Analytics*. Traditional OLAP front-end tools, designed to support reporting and analysis routines primarily, use visualization merely for expressive presentation of the data. In the Visual OLAP approach, however, visualization plays the key role as the method of *interactive query-driven analysis*. A more comprehensive analysis of such a kind includes a variety of tasks such as: examining the data from multiple perspectives, extracting useful information, verifying hypotheses, recognizing trends, revealing patterns, gaining insights, and discovering new knowledge from arbitrarily large and/or complex volumes of multidimensional data. In addition to conventional operations of analytical processing, such as drill-down, roll-up, slice-and-dice, pivoting, and ranking, Visual OLAP supports further interactive data manipulation techniques, such as zooming and panning, filtering, brushing, collapsing etc.

OLAP VISUALIZATION: A SURVEY

First proposals on using visualization for exploring large data sets were not tailored towards OLAP applications, but addressed the generic problem of visual querying of large data sets stored in a database. Early experiences related to multidimensional data visualization can be found in real-life application scenarios, such as those proposed in (Gebhardt et al., 1997), where an intelligent visual interface to multidimensional databases is proposed, as well as in theoretical foundations, such as those stated in (Inselberg, 2001), which discusses and refines general guidelines on the problem of efficiently visualizing and interacting with high-dimensional data. Keim and Kriegel (1994) propose *VisDB*, a visualization system based on an innovative query paradigm. In *VisDB*, users are prompted to specify an initial query. Thereafter, guided by a visual feedback, they dynamically adjust the query, e.g. by using sliders for specifying range predicates on singleton or multiple attributes. Retrieved records are mapped to the pixels of the rectangular display area, colored according to their degree of relevance for the specified set of selection predicates, and positioned according to a grouping or ordering directive.

A traditional interface for analyzing OLAP data is a *pivot table*, or *cross-tab*, which is a multidimensional spreadsheet produced by specifying one or more measures of interest and selecting dimensions to serve as vertical (and, optionally, horizontal) axes for summarizing the measures. The power of this presentation technique comes from its ability in summarizing detailed data along various dimensions, and arranging aggregates computed at different granularity levels into a single

view preserving the "part-of" relationships between the aggregates themselves. Figure 1 exemplifies the idea of "unfolding" a three-dimensional data cube (left side) into a pivot table (right side), with cells of the same granularity marked with matching background color in both representations. However, pivot tables are inefficient for solving non-trivial analytical tasks, such as recognizing patterns, discovering trends, identifying outliers etc (Lee & Ong, 1995; Eick, 2000; Hanrahan et al., 2007). Despite this weakness point, pivot tables still maintain the power of any visualization technique, i.e. saving time and reducing errors in analytical reasoning via utilizing the phenomenal abilities of the human vision system in pattern recognition (Hanrahan et al., 2007).

OLAP interfaces of the current state-of-the-art enhance the pivot table view via providing a set of popular business visualization techniques, such as bar-charts, pie-charts, and time series, as well as more sophisticated visualization layouts such as scatter plots, maps, tree-maps, cartograms, matrices, grids etc, and vendors' proprietary visualizations (e.g., decomposition trees and fractal maps). Some tools go beyond mere visual presentation of data purposes and propose sophisticated approaches inspired by the findings in Information Visualization research. Prominent examples of advanced visual systems are *Advizor* (Eick, 2000) and *Tableau* (Hanrahan et al., 2007). *Advizor* implements a technique that organizes data into three perspectives. A perspective is a set of linked visual components displayed together on the same screen. Each perspective focuses on a particular type of analytical task, such as (*i*) single measure view using a 3D multi-scope layout, (*ii*) multiple measures arranged into a scatter plot, and (*iii*) anchored measures presented using techniques from multidimensional visualization (box plots, parallel coordinates etc). *Tableau* is a commercialized successor of *Polaris*, a visual tool for multidimensional analysis developed by Stanford University (Stolte et al., 2002). *Polaris* inherits the basic idea of the classical pivot table interface that maps aggregates into a grid defined by dimension categories assigned to grid rows and columns. However, *Polaris* uses embedded graphical marks rather than textual numbers in table cells. Types of supported graphics are arranged into a taxonomy, comprising rectangle, circle, glyph, text, Gantt bar, line, polygon, and image layouts.

Back to basic problems, (Russom, 2000) summarizes trends in business visualization software as a progression from rudimentary data visualization to advanced forms, and proposes distinguishing three life-cycle stages of visualization techniques, such as maturing, evolving, and emerging. Within this classification, Visual OLAP clearly fits into the emerging techniques for advanced interaction and visual querying. In the spirit of Visual OLAP, ineffective data presentation is not the only deficiency of conventional OLAP tools. Further problems are cumbersome usability and poor exploratory functionality. Visual OLAP addresses those problems via developing fundamentally new ways of interacting with multidimensional aggregates. A new quality of visual analysis is achieved via unlocking the synergy between the OLAP technology, Information Visualization, and Visual Analytics.

The task of selecting a proper visualization technique for solving a particular problem is by far not trivial as various *visual representations* (also called *metaphors*) may be not only task-dependent, but also domain-de-

pendent. Successful Visual OLAP frameworks need to be based on a comprehensive taxonomy of domains, tasks, and visualizations. The problem of assisting analysts in identifying an appropriate visualization technique for a specific task is an unsolved issue in state-of-the-art OLAP tools. Typically, a user has to find an appropriate solution manually via experimenting with different layout options. To support a large set of diverse visualization techniques and enable dynamic switching from one technique to another, an abstraction layer has to be defined in order to specify the relationships between data and their visual presentation.

Following this approach, the *Tape* model, proposed by Gebhardt et al. (1998), suggests to represent and visualize multidimensional data domains using the metaphors of *tapes* and *tracks*, enhanced with the possibility of defining *hierarchical structures* within a tape.

Maniatis et al. (2003a; 2003b) propose an abstraction layer solution, called *Cube Presentation Model* (CPM), which distinguishes between two layers: a (*i*) *logical layer*, which deals with data modeling and retrieval, and a (*ii*) *presentation layer*, which provides a generic model for representing the data (normally, on a 2D screen). Entities of the presentation layer include points, axes, multi-cubes, slices, tapes, cross-joins, and content functions. Authors demonstrate how CPM constructs can be mapped onto advanced visual layouts at the example of *Table Lens*, a technique based on a cross-tabular paradigm with support for multiple zoomable windows of focus.

A common approach to visualization in OLAP application relies on a set of templates, wizards, widgets, and a selection of visual formats. Hanrahan et al., (2007) argue however that an open set of requirements cannot be addressed by a limited set of techniques, and choose a fundamentally different approach for their visual analysis tool *Tableau*. This novelty is represented by *VizQL*, a *declarative visual query language*. *VizQL* offers high expressiveness via allowing users to create their own visual presentation by means of combining various visual components. Figure 2 illustrates the visualization approach of *Tableau* via showing just a small subset of sophisticated visual presentations created by means of simple *VizQL* statements not relying on any pre-defined template layout.

Designers of *Tableau* deliberately restrict the set of supported visualizations to the popular and proven ones, such as tables, charts, maps, and time series, as doubting general utility of exotic visual metaphors (Hanrahan et al., 2007). Thereby, *Tableau* approach is constrained to generating grids of visual presentations of uniform granularity and limited dimensionality. Other researchers suggest that Visual OLAP should be enriched by extending basic charting techniques or by employing novel and less-known visualization techniques to take full advantage from multidimensional and hierarchical properties of data (Tegarden, 1999;

Figure 2. VizQL at work (Used by permission of Tableau Software, Inc.)

Lee & Ong, 1995; Techapichetvanich & Datta, 2005; Sifer, 2003). Tegarden (1999) formulates the general requirements of *Business Information Visualization* and gives an overview of advanced visual metaphors for multivariate data, such as *Kiviat Diagrams* and *Parallel Coordinates* for visualizing data sets of high dimensionality, as well as 3D techniques, such as *3D scatter-grams*, *3D line graphs*, *floors* and *walls*, and *3D map-based bar-charts*.

An alternative proposal is represented by the DIVE-ON (*Data mining in an Immersed Visual Environment Over a Network*) system, proposed by Ammoura et al. (2001). The main idea of DIVE-ON is furnishing an immersive visual environment where distributed multidimensional data sources are consolidated and presented to users that can interact with such sources by "walking" or "flying" towards them. Thereby, DIVE-ON makes an intelligent usage of the natural human capability of interacting with spatial objects, thus sensitively enhancing the knowledge fruition phase. In its core layer, DIVE-ON exploits the OLAP technology in order to efficiently support the multidimensionality of data. All considering, we can claim that DIVE-ON is one of the most unique experiences in the OLAP visualization research field, with some characteristics that slightly resemble visual entertainment systems.

Another branch of visualization research for OLAP concentrates on developing multi-scale visualization techniques capable of presenting data at different levels of aggregation. Stolte et al. (2003) describe their implementation of multi-scale visualization within the framework of the *Polaris* system. The underlying visual abstraction is that of a zoom graph that supports multiple zooming paths, where zooming actions may be tied to dimensional axes or triggered by different kinds of interaction. Lee and Ong (1995) propose a multidimensional visualization technique that adopts and modifies the *Parallel Coordinates* method for knowledge discovery in OLAP. The main advantage of this technique is its scalability to virtually any number of dimensions. Each dimension is represented by a vertical axis and aggregates are aligned along each axis in form of a bar-chart. The other side of the axis may be used for generating a bar-chart at a higher level of detail. Polygon lines adopted from the original *Parallel Coordinates* technique are used to indicate relationships among aggregates computed along various dimensions (a relationship exists if the underlying sets of fact entries in both aggregates overlap).

Mansmann and Scholl (2007) concentrate on the problem of losing the aggregates computed at preceding query steps while changing the level of detail, and propose using hierarchical layouts to capture the results of multiple decompositions within the same display. Authors introduce a class of multi-scale visual metaphors called *Enhanced Decomposition Tree*. Levels of the visual hierarchy are created via decomposing the aggregates along a specified dimension, and nodes contain the resulting sub-aggregates arranged into an embedded visualization (e.g., a bar-chart). Various hierarchical layouts and embedded chart techniques are considered to account for different analysis tasks.

Sifer (2003) presents a multi-scale visualization technique for OLAP based on coordinated views of dimension hierarchies. Each dimension hierarchy with qualifying fact entries attached as bottom-level nodes is presented using a space-filling nested tree layout. Drilling-down and rolling-up is performed implicitly via zooming within each dimension view. Filtering is realized via (de-)selecting values of interest at any level of dimension hierarchies, resulting either in highlighting the qualifying fact entries in all dimension views (*global context coordination*) or in eliminating the disqualified entries from the display (*result only coordination*).

A similar interactive visualization technique, called the *Hierarchical Dynamic Dimensional Visualization* (HDDV), is proposed in (Techapichetvanich & Datta, 2005). Dimension hierarchies are shown as hierarchically aligned bar-sticks. A bar-stick is partitioned into rectangles that represent portions of the aggregated measure value associated with the respective member of the dimension. Color intensity is used to mark the density of the number of records satisfying a specified range condition. Unlike in (Sifer, 2003), dimension level bars are not explicitly linked to each other, allowing to split the same aggregate along multiple dimensions and, thus, to preserve the execution order of the dis-aggregation task. A technique for finding appropriate representation of multidimensional aggregates, proposed by Choong et al. (2003), may help to improve the analytical quality of any visualization. This technique addresses the problem of ordering aggregates along dimensional axes. By default, the ordering of the measure values is imposed by the lexical ordering of values within dimensions. To make patterns more obvious, the user has to rearrange the ordering manually. The proposed algorithm automates the ordering of measures in a

representation as to best reveal patterns (e.g., trends and similarity) that may be observed in a data set.

More recently, Cuzzocrea et al. (2006; 2007) propose an innovative framework for efficiently supporting OLAP visualization of multidimensional data cubes. This framework has a wide range of applicability in a number of real-life applications, from the visualization of spatio-temporal data (e.g., mobile data) to that of scientific and statistical data. Based on meaningfully handling OLAP hierarchies of the target data cube $\mathcal{L}$, the novelty of the proposed framework consists in computing a *semantics-based partition* of $\mathcal{L}$ that groups OLAP data cells semantically related, thus originating the so-called *semantics-aware buckets*. Thereafter, the resulting partitioned representation is further compressed by means of highly-efficient quad-tree based data structures, what makes the relevant assumption that compressing massive data cubes is a way for efficiently visualizing these data structures. This compressed representation finally originates a novel multidimensional histogram, called *Hierarchy-driven Indexed Quad-Tree Summary* (H-IQTS).

The major benefit of the approach proposed in (Cuzzocrea et al., 2006; Cuzzocrea et al., 2007) is a sensible improvement of visualization and exploration activities on high-dimensional spaces via enabling the user to access and browse sub-partitions of these spaces based on semantics rather than on any other arbitrary partitioning scheme, due to the fact that, during interaction, users are typically interested on specific portions of the overall data domain rather than in the entire domain. On the practical plane, Cuzzocrea et al. (2006; 2007) show that while the compression performance of H-IQTS is comparable with state-of-the-art histogram-based data cube compression techniques, the visualization performance of H-IQTS is several orders of magnitude higher than the one of comparison techniques.

FUTURE TRENDS

OLAP Visualization research is still in its preliminary stage, and a lot of work must be done in this field. A key point for the success of this branch of OLAP research is represented by the relevant range of applicability of Visual OLAP in a plethora of real-life, leading applications such as real-time monitoring of multiple streaming data sources and visualization of results produced by advanced *Knowledge Discovery* tools including clustering, association rule discovery, frequent item set mining, sub-graph mining etc.

Future research directions for OLAP Visualization can be identified in the following three main themes: (*i*) *integration with data warehouse management systems*, which will allow us to complete the overall knowledge generation, processing, and visualization experience over multidimensional data sets; (*ii*) *techniques for visualizing integrated data-cube/data-warehouse schemes*, aiming at studying how to visualize multidimensional data domains obtained from the *integration* of multiple and heterogeneous data sources (i.e., how to furnish the BI and DM analyst with an *integrated, unifying visualization metaphor* over heterogeneous cubes?); (*iii*) *visual query languages for multidimensional databases*, aiming at defining a new paradigm able to support intelligent user interaction with multidimensional data, what also poses challenging theoretical foundations on the designing of a powerful *knowledge extraction language*.

CONCLUSION

Similarly to other fundamental issues in OLAP research, such as data cube indexing and compression, the problem of efficiently visualizing OLAP data is an attractive research topic that demands for innovative models and techniques. At present, there are few initiatives encompassing these issues, and intensive work needs to be carried out in this area.

In the spirit of these considerations, in this article we have provided an overview of OLAP Visualization models, issues and techniques, and also critically highlighted advantages and disadvantages of state-of-the-art approaches, while putting in evidence a number of leading applications of these approaches in modern real-life scenarios.

KEY TERMS

Data Visualization: The use of computer-supported, interactive, visual representations of abstract data to reinforce cognition, hypothesis building and reasoning, building on theory in information design, computer graphics, human-computer interaction and cognitive science.

Multidimensional Cube (Hypercube): A logical structure for fast data analysis based on re-arranging data into a multidimensional array storing numeric facts called measures within array cells, which are indexed by the values drawn from a set of descriptive dimensions.

Multidimensional Visualization: Visualization techniques seeking to efficiently encode more than three dimensions of information simultaneously in a two (three)-dimensional display for multidimensional data analysis purposes.

Online Analytical Processing (OLAP): A methodology for representing, managing and querying massive DW data according to multidimensional and multi-resolution abstractions of them.

Online Transaction Processing (OLTP): A methodology for representing, managing and querying DB data generated by user/application transactions according to flat (e.g., relational) models.

Pivot Table/Cross-Tab: A standard interface for analyzing OLAP data by arranging the specified set of dimensions and measures to obtain the associated totals and subtotals in a two-dimensional (possibly nested) spreadsheet view.

Visual OLAP: An umbrella term encompassing a new generation of end-user tools for interactive ad-hoc exploration of large volumes of multidimensional data via providing a comprehensive framework of advanced visualization techniques for representing retrieved data set, along with a powerful navigation and interaction scheme for specifying, refining, and manipulating subsets of interest.

Online Analytical Processing Systems

INTRODUCTION

Since its origin in the 1970's research and development into databases systems has evolved from simple file storage and processing systems to complex relational databases systems, which have provided a remarkable contribution to the current trends or environments. Databases are now such an integral part of day-to-day life that often people are unaware of their use. For example, purchasing goods from the local supermarket is likely to involve access to a database. In order to retrieve the price of the item, the application program will access the product database. A database is a collection of related data and the database management system (DBMS) is software that manages and controls access to the database (Elmasri & Navathe, 2004).

BACKGROUND

Data Warehouse

A data warehouse is a specialized type of database. More specifically, a data warehouse is a "repository (or archive) of information gathered from multiple sources, stored under a unified schema, at a single site" (Silberschatz, Korth, & Sudarshan, 2002, p. 843). Chaudhuri and Dayal (1997) consider that a data warehouse should be separately maintained from the organization's operational database since the functional and performance requirements of online analytical processing (OLAP) supported by data warehouses are quite different from those of the online transaction processing (OLTP) traditionally supported by the operational database.

OLAP Versus OLTP

Two reasons why traditional OLTP is not suitable for data warehousing are presented: (a) Given that operational databases are finely tuned to support known OLTP workloads, trying to execute complex OLAP queries against the operational databases would result in unacceptable performance. Furthermore, decision support requires data that might be missing from the operational databases; for instance, understanding trends or making predictions requires historical data, whereas operational databases store only current data. (b) Decision support usually requires consolidating data from many heterogeneous sources: these might include external sources such as stock market feeds, in addition to several operational databases. The different sources might contain data of varying quality, or use inconsistent representations, codes and formats, which have to be reconciled.

Traditional Online Transaction Processing (OLTP)

Traditional relational databases have been used primarily to support OLTP systems. The transactions in an OLTP system usually retrieve and update a small

Figure 1. OLTP system

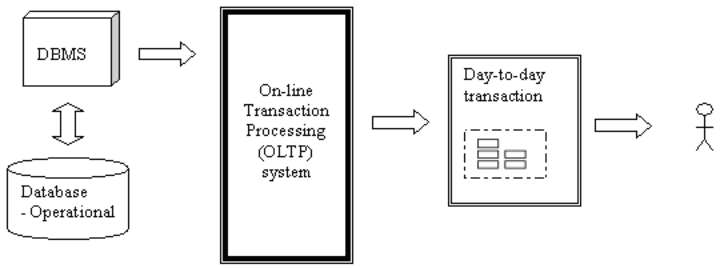

Figure 2. OLAP system

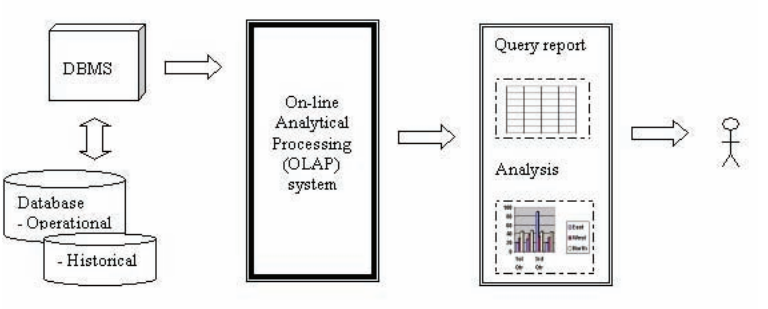

number of records accessed typically on their primary keys. Operational databases tend to be hundreds of megabytes to gigabytes in size and store only current data (Ramakrishnan & Gehrke, 2003).

Figure 1 shows a simple overview of the OLTP system. The operational database is managed by a conventional relational DBMS. OLTP is designed for day-to-day operations. It provides a real-time response. Examples include Internet banking and online shopping.

Online Analytical Processing (OLAP)

OLAP is a term that describes a technology that uses a multi-dimensional view of aggregate data to provide quick access to strategic information for the purposes of advanced analysis (Ramakrishnan & Gehrke, 2003).

OLAP supports queries and data analysis on aggregated databases built in data warehouses. It is a system for collecting, managing, processing and presenting multidimensional data for analysis and management purposes (Figure 2). There are two main implementation methods to support OLAP applications: relational OLAP (ROLAP) and multidimensional OLAP (MOLAP).

ROLAP

Relational online analytical processing (ROLAP) provides OLAP functionality by using relational databases and familiar relational query tools to store and analyse multidimensional data (Ramakrishnan & Gehrke, 2003). Entity Relationship diagrams and normalization techniques are popularly used for database design in OLTP environments. However, the database designs recommended by ER diagrams are inappropriate for decision support systems where efficiency in querying and in loading data (including incremental loads) are crucial. A special schema known as a star schema is used in an OLAP environment for performance reasons (Martyn, 2004). This star schema usually consists of a single fact table and a dimension table for each dimension (Figure 3).

MOLAP

Multidimensional online analytical processing (MOLAP) extends OLAP functionality to multidimensional database management systems (MDBMSs). A MDBMS uses special proprietary techniques to store data in matrix-like n-dimensional arrays (Ramakrishnan & Gehrke, 2003).

The multi-dimensional data cube is implemented by the arrays with the dimensions forming the axes of the cube (Sarawagi, 1997). Therefore, only the data value corresponding to a data cell is stored as direct mapping. MOLAP servers have excellent indexing properties due to the fact that looking for a cell is simple array lookups rather than associative lookups in tables. But unfortunately it provides poor storage utilization, especially when the data set is sparse.

In a multi-dimensional data model, the focal point is on a collection of numeric measures. Each measure depends on a set of dimensions. For instance, the measure attribute is amt as shown in Figure 4. Sales information is being arranged in a three-dimensional array of amt. Figure 4 shows that the array only shows the values for single L# value where L# = L001, which presented as a slice orthogonal to the L# axis.

Cube-By Operator

In decision support database systems, aggregation is a commonly used operation. As previously mentioned, current SQL can be very inefficient. Thus, to effectively support decision support queries in OLAP environment, a new operator, Cube-by was proposed by (Gray, Bosworth, Lyaman, & Pirahesh, 1996). It is an extension of the relational operator Group-by. The Cube-by operator computes Group-by corresponding to all possible combinations of attributes in the Cube-by clause.

In order to see how a data cube is formed, an example is provided in Figure 5. It shows an example of data cube formation through executing the cube statement at the top left of the figure. Figure 5 presents two way of presenting the aggregated data: (a) a data cube, and (b) a 3D data cube in table form.

Figure 6. Two interesting areas of the processing level in OLAP environment

MAIN THRUST

Processing Level in OLAP Systems

The processing level where the execution of the raw data or aggregated data takes place before presenting the result to the user is shown in Figure 6. The user is only interested in the data in the report in a fast response. However, the background of the processing level is needed in order to provide the user with the result of the aggregated data in an effective and efficient way.

The processing level has been broken down into two distinct areas: *back-end processing* and *front-end processing*. Back-end processing basically deals with the raw data, which is stored in either tables (ROLAP) or arrays (MOLAP) and then process it into aggregated data, which is presented to the user. Front-end processing is computing the raw data and managing the pre-computed aggregated data in either in 3D data cube or n-dimensional table.

It is important to mention that front-end processing is similar to back-end processing as it also deals with raw data. It needs to construct or execute the raw data into the data cube and then store the pre-computed aggregated data in either the memory or disk. It is convenient for the user if the pre-computed aggregated data is ready and is stored in the memory whenever the user requests for it.

The difference between the two processing levels is that the front-end has the pre-computed aggregated data in the memory which is ready for the user to use or analyze it at any given time. On the other hand the back-end processing computes the raw data directly whenever there is a request from the user. This is why the front-end processing is considered to present the aggregated data faster or more efficiently than back-end processing. However, it is important to note that back-end processing and front-end processing are basically one whole processing. The reason behind this break down of the two processing levels is because the problem can be clearly seen in back-end processing and front-end processing. In the next section, the problems associated with each areas and the related work in improving the problems will be considered.

Back-End Processing

Back-end processing involves basically dealing with the raw data, which is stored in either tables (ROLAP) or arrays (MOLAP) as shown in Figure 7. The user queries the raw data for decision-making purpose. The raw data is then processed and computed into aggregated data, which will be presented to the user for analyzing. Generally the basic stage: *extracting,* is followed by two sub-stages: *indexing,* and *partitioning* in back-end processing.

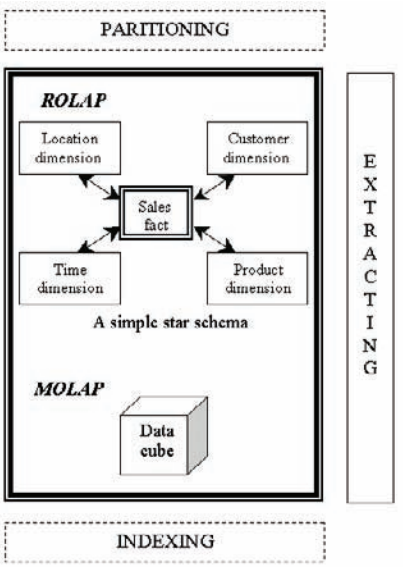
Extracting is the process of querying the raw data either from tables (ROLAP) or arrays (MOLAP) and computing it. The process of extracting is usually time-consuming. Firstly, the database (data warehouse) size is extremely large and secondly the computation time is equally high. However, the user is only interested in a fast response time for providing the resulted data. Another consideration is that the analyst or manager using the data warehouse may have time constraints. There are two sub-stages or fundamental methods of handling the data: (a) indexing and (b) partitioning in order to provide the user with the resulted data in a reasonable time frame.

Indexing has existed in databases for many decades. Its access structures have provided faster access to the base data. For retrieval efficiency, index structures would typically be defined especially in data warehouses or ROLAP where the fact table is very large (Datta, VanderMeer & Ramamritham, 2002). O'Neil and Quass (1997) have suggested a number of important indexing schemes for data warehousing including bitmap index, value-list index, projection index, data index. Data index is similar to projection index but it exploits a positional indexing strategy (Datta, VanderMeer, & Ramamritham, 2002). Interestingly MOLAP servers have better indexing properties than ROLAP servers since they look for a cell using simple array lookups rather than associative lookups in tables.

Partitioning of raw data is more complex and challenging in data warehousing as compared to that of relational and object databases. This is due to the several choices of partitioning of a star schema (Datta, VanderMeer, & Ramamritham, 2002). The data fragmentation concept in the context of distributed databases aims to reduce query execution time and facilitate the parallel execution of queries (Bellatreche, Karlapalem, Mohania, & Schneide, 2000).

In a data warehouse or ROLAP, either the dimension tables or the fact table or even both can be fragmented. Bellatreche et al. (2000) have proposed a methodology for applying the fragmentation techniques in a data warehouse star schema to reduce the total query

Figure 7. Stages in back-end processing



execution cost. The data fragmentation concept in the context of distributed databases aims to reduce query execution time and facilitates the parallel execution of queries.

Front-End Processing

Front-end processing is computing the raw data and managing the pre-computed aggregated data in either in 3D data cube or n-dimensional table. The three basic types of stages that are involved in Front-end processing are shown in Figure 8. They are (i) constructing, (ii) storing and (iii) querying. Constructing is basically the computation process of a data cube by using cube-by operator. Cube-by is an expensive approach, especially when the number of Cube-by attributes and the database size are large.

The difference between constructing and extracting needs to be clearly defined. Constructing in the Front-end processing is similar to the extracting in the Back-end processing as both of them are basically querying the raw data. However, in this case, extracting concentrates on how the fundamental methods can help in handling the raw data in order to provide efficient retrieval. Constructing in the Front-end processing concentrates on the cube-by operator that involves the computation of raw data.

Storing is the process of putting the aggregated data into either the n-dimension table of rows or the n-dimensional arrays or data cube. There are two parts within the storing process. One part is to store temporary raw data in the memory for executing purpose and other part is to store pre-computed aggregated data. Hence, there are two problems related to the storage: (a) insufficient memory space – due to the loaded raw data and also in addition to the incremental loads; (b) poor storage utilization – the array may not fit into memory especially when the data set is sparse.

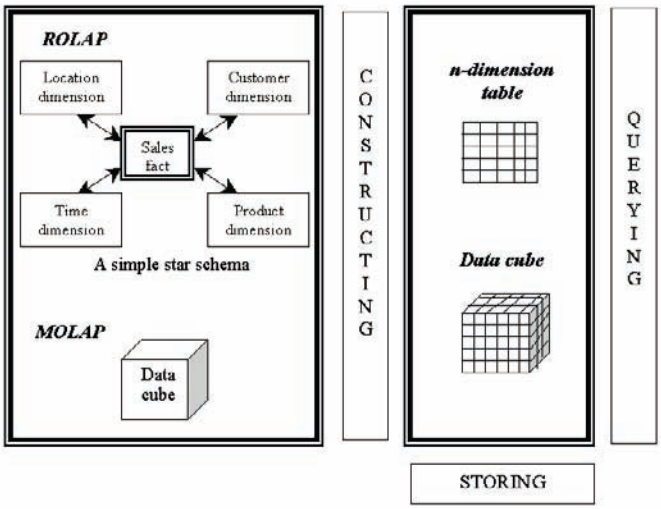
Querying is the process of extracting useful information from the pre-computed data cube or n-dimensional table for decision makers. It is important to take note that Querying is also part of Constructing process. Querying also makes use of cube-by operator that involves the computation of raw data. ROLAP is able to support ad hoc requests and allows unlimited access to dimensions unlike MOLAP only allows limited access to predefined dimensions. Despite the fact that it is able to support ad hoc requests and access to dimensions, certain queries might be difficult to fulfill the need of decision makers and also to reduce the querying execution time when there is n-dimensional query as the time factor is important to decision makers.

To conclude, the three stages and their associated problems in the OLAP environment have been outlined. First, Cube-by is an expensive approach, especially when the number of Cube-by attributes and the database size are large. Second, storage has insufficient memory space – this is due to the loaded data and also in addition to the incremental loads. Third, storage is not properly utilized – the array may not fit into memory especially when the data set is sparse. Fourth, certain queries might be difficult to fulfill the need of decision makers. Fifth, the execution querying time has to be reduced when there is n-dimensional query as the time factor is important to decision makers. However, it is important to consider that there is scope for other possible problems to be identified.

FUTURE TRENDS

Problems have been identified in each of the three stages, which have generated considerable attention from researchers to find solutions. Several researchers have proposed a number of algorithms to solve these cube-by problems. Examples include:

Figure 8. Stages in front-end processing



Constructing

Cube-by operator is an expensive approach, especially when the number of Cube-by attributes and the database size are large.

Fast Computation Algorithms

There are algorithms aimed at fast computation of large sparse data cube (Ross & Srivastava, 1997; Beyer & Ramakrishnon, 1999). Ross and Srivastava (1997) have taken into consideration the fact that real data is frequently sparse. (Ross & Srivastava, 1997) partitioned large relations into small fragments so that there was always enough memory to fit in the fragments of large relation. Whereas, Beyer and Ramakrishnan (1999) proposed the bottom-up method to help reduce the penalty associated with the sorting of many large views.

Parallel Processing System

The assumption of most of the fast computation algorithms is that their algorithms can be applied into the parallel processing system. Dehne, Eavis, Hambrusch, and Rau-Chaplin. (2002) presented a general methodology for the efficient parallelization of exiting data cube construction algorithms. Their paper described two different partitioning strategies, one for top-down and one for bottom-up cube algorithms. They provide a good summary and comparison with other parallel data cube computations (Ng, Wagner, & Yin., 2001; Yu & Lu, 2001). In Ng et al. (2001), the approach considers the parallelization of sort-based data cube construction, whereas Yu and Lu (2001) focuses on the overlap between multiple data cube computations in a sequential setting.

Storing

Two problems related to the storage: (a) insufficient memory space; (b) poor storage utilization.

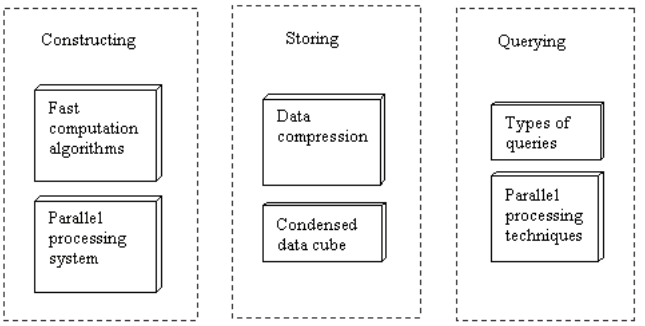
Data Compression

Another technique is related to data compression. Lakshmanan, Pei, and Zhao (2003) have developed a systematic approach to achieve efficacious data cube construction and exploration by semantic summarization and compression.

Condensed Data Cube

Wang, Feng, Lu, and Yu (2002) have proposed a new concept called a condensed data cube. This new approach reduces the size of data cube and hence its computation time. They make use of “single base tuple” compression to generate a “condensed cube” so it is smaller in size.

Figure 9. Working areas in the OLAP system



Querying

It might be difficult for certain queries to fulfill both the need of the decision makers and also the need to reduce the querying execution time when there is n-dimensional query as the time factor is important to decision makers.

Types of Queries

Other work has focused on specialized data structures for fast processing of special types of queries. Lee, Ling and Li (2000) have focused on range-max queries and have proposed hierarchical compact cube to support the range-max queries. The hierarchical structure stores not only the maximum value of all the children sub-cubes, but also stores one of the locations of the maximum values among the children sub-cubes. On the other hand, Tan, Taniar, and Lu (2004) focus on data cube queries in term of SQL and have presented taxonomy of data cube queries. They also provide a comparison with different type queries.

Parallel Processing Techniques

Taniar and Tan (2002) have proposed three parallel techniques to improve the performance of the data cube queries. However, the challenges in this area continue to grow with the cube-by problems.

CONCLUSION

In this overview, the OLAP systems in general have been considered, followed by processing level in the OLAP systems and lastly the related and future work in the OLAP systems. A number of problems and solutions in the OLAP environment have been presented. However, consideration needs to be given to the possibility that other problems maybe identified which in turn will present new challenges for the researchers to address.

INTRODUCTION

Security is one of the major issues in today's world and most of us have to deal with some sort of passwords in our daily lives; but, these passwords have some problems of their own. If one picks an easy-to-remember password, then it is most likely that somebody else may guess it. On the other hand, if one chooses too difficult a password, then he or she may have to write it somewhere (to avoid inconveniences due to forgotten passwords) which may again lead to security breaches. To prevent passwords being hacked, users are usually advised to keep changing their passwords frequently and are also asked not to keep them too trivial at the same time. All these inconveniences led to the birth of the biometric field. The verification of handwritten signature, which is a behavioral biometric, can be classified into off-line and online signature verification methods. Online signature verification, in general, gives a higher verification rate than off-line verification methods, because of its use of both static and dynamic features of the problem space in contrast to off-line which uses only the static features. Despite greater accuracy, online signature recognition is not that prevalent in comparison to other biometrics. The primary reasons are:

- It cannot be used everywhere, especially where signatures have to be written in ink; e.g. on cheques, only off-line methods will work.
- Unlike off-line verification methods, online methods require some extra and special hardware, e.g. electronic tablets, pressure sensitive signature pads, etc. For off-line verification method, on the other hand, we can do the data acquisition with optical scanners.
- The hardware for online are expensive and have a fixed and short life cycle.

In spite of all these inconveniences, the use online methods is on the rise and in the near future, unless a process requires particularly an off-line method to be used, the former will tend to be more and more popular.

BACKGROUND

Online verification methods can have an accuracy rate of as high as 99%. The reason behind is its use of both static and dynamic (or temporal) features, in comparison to the off-line, which uses only the static features (Ramesh & Murty, 1999). The major differences between off-line and online verification methods do not lie with only the feature extraction phases and accuracy rates, but also in the modes of data acquisition, preprocessing and verification/recognition phases, though the basic sequence of tasks in an online verification (or recognition) procedure is exactly the same as that of the off-line. The phases that are involved comprise of:

- Data Acquisition
- Preprocessing and Noise Removal
- Feature Extraction and
- Verification (or Identification)

However, online signatures are much more difficult to forge than off-line signatures (reflected in terms of higher accuracy rate in case of online verification methods), since online methods involve the dynamics of the signature such as the pressure applied while writing, pen tilt, the velocity with which the signature is done etc. In case of off-line, the forger has to copy only the shape (Jain & Griess, 2000) of the signature. On the other hand, in case of online, the hardware used captures the dynamic features of the signature as well. It is extremely difficult to deceive the device in case of dynamic features, since the forger has to not only copy the characteristics of the person whose signature is to be forged, but also at the same time, he has to hide his own inherent style of writing the signature. There are four types of forgeries: random, simple, skilled and traced forgeries (Ammar, Fukumura, & Yoshida, 1988; Drouhard, Sabourin, & Godbout, 1996). In case of online signatures, the system shows almost 100% accuracy for the first two classes of forgeries and 99% in case of the latter. But, again, a forger can also use a compromised signature-capturing device to repeat a previously recorded signature signal. In such extreme cases, even online verification methods may suffer from repetition attacks when the signature-capturing device is not physically secure.

MAIN THRUST

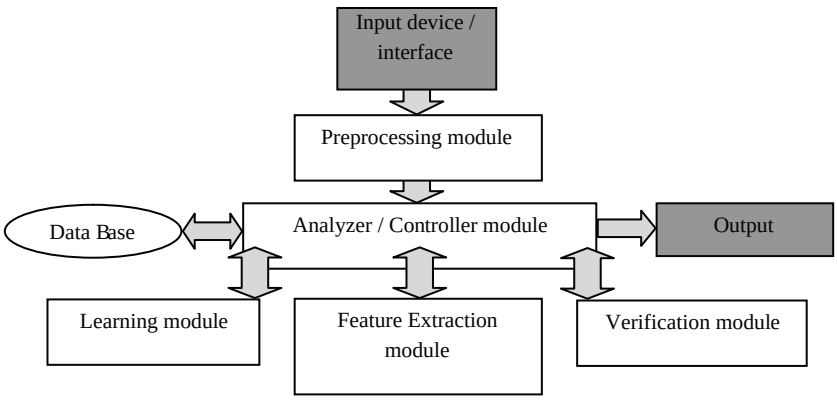
Although the basic sequence of tasks in online signature verification is almost the same as that of off-line methods, the modes differ from each other especially in the ways the data acquisition, preprocessing and feature extraction are carried out. More specifically, the sub-modules of online are much more difficult with respect to off-line (Jain & Griess, 2000). Figure 1 gives a generic structure of an online signature verification system. The online verification system can be classified into the following modules:

- Data Acquisition,
- Preprocessing,
- Feature Extraction,
- Learning and Verification.

Data Acquisition

Data acquisition (of the dynamic features) in online verification methods is generally carried out using special devices called transducers or digitizers (Tappert, Suen, & Wakahara, 1990, Wessels & Omlin, 2000), in contrast to the use of high resolution scanners in case of off-line. The commonly used instruments include the electronic tablets (which consist of a grid to capture the x and y coordinates of the pen tip movements), pressure sensitive tablets, digitizers involving technologies such as acoustic sensing in air medium, surface acoustic waves, triangularization of reflected laser beams, and optical sensing of a light pen to extract information about the number of strokes, velocity of

Figure 1. Modular structure of a generic online verification system



signing, direction of writing, pen tilt, pressure with which the signature is written etc.

Preprocessing

Preprocessing in online is much more difficult than in off-line, because it involves both noise removal (which can be done using hardware or software) (Plamondon & Lorette, 1989) and segmentation in most of the cases. The other preprocessing steps that can be performed are signal amplifying, filtering, conditioning, digitizing, resampling, signal truncation, normalization, etc. However, the most commonly used include:

- **External Segmentation:** Tappert, Suen and Wakahara (1990) define external segmentation as the process by which the characters or words of a signature are isolated before the recognition is carried out.
- **Resampling:** This process is basically done to ensure uniform smoothing to get rid of the redundant information, as well as to preserve the required information for verification by comparing the spatial data of two signatures. According to Jain and Griess (2000), here, the distance between two critical points is measured, and if the total distance exceeds a threshold called the resampling length(which is calculated by dividing the distance by the number of sample points for that segment), then a new point is created by using the gradient between the two points,
- **Noise Reduction:** Noise is nothing but irrelevant data, usually in the form of extra dots or pixels in images (in case of off-line verification methods) (Ismail & Gad, 2000), which do not belong to the signature, but are included in the image (in case of off-line) or in the signal (in case of online), because of possible hardware problems (Tappert, Suen, & Wakahara, 1990) or presence of background noises like dirt or by faulty hand movements (Tappert, Suen, & Wakahara, 1990) while signing.

  The general techniques used are:

  - **Smoothening:** in which a point is averaged with its neighbors. (Tappert, Sue, & Wakahara, 1990)
  - **Filtering:** Online thinning (Tappert, Suen, & Wakahara, 1990) is not the same as off-line thinning (Baltzakis & Papamarkos, 2001), although, both decrease the number of irrelevant dots or points. According to Tappert, Suen and Wakahara (1990), it can be carried out either by forcing a minimum distance between adjacent points or by forcing a minimum change in the direction of the tangent to the drawing for consecutive points.
  - **Wild Point Correction:** This removes noises (points) caused by hardware problems (Tappert, Suen, & Wakahara, 1990).
  - **Dehooking:** Dehooking on the other hand removes hook like features from the signature, which usually occur at the start or end of the signature (Tappert, Suen, & Wakahara, 1990).
  - **Dot Reduction:** The dot size is reduced to single points. (Tappert, Suen, & Wakahara, 1990)

- **Normalization:** Off-line normalization often limits itself to scaling the image to a standard size and/or removing blank columns and rows. In case of online, normalization includes deskewing, baseline drift correction (orienting the signature to horizontal), size normalization and stroke length normalization (Ramesh & Murty, 1999; Tappert, Suen, & Wakahara, 1990; Wessels & Omlin, 2000).

Feature Extraction

Online signature extracts both the static and the dynamic features. Some of the static and dynamic features have been listed below.

- **Static Features:** Although both static and dynamic information are available to the online verification system, in most of the cases, the static information is discarded, as dynamic features are quite rich and they alone give high accuracy rates. Some of the static features used by online method are:

  - Width and height of the signature parts (Ismail & Gad, 2000)
  - Width to height ratio (Ismail & Gad, 2000)

- Number of cross and edge points (Baltzakis & Papamarkos, 2001)
- Run lengths of each scan of the components of the signature (Xiao & Leedham, 2002)
- Kurtosis (horizontal and vertical), skewness, relative kurtosis, relative skewness, relative horizontal and vertical projection measures (Bajaj & Chaudhury, 1997; Ramesh & Murty, 1999)
- **Envelopes:** upper and lower envelope features (Bajaj & Chaudhury, 1997; Ramesh & Murty, 1999)
- **Alphabet Specific Features:** Like presence of ascenders, descenders, cusps, closures, dots etc. (Tappert, Suen, & Wakahara, 1990)

- **Dynamic Features:** Though online methods utilize some of the static features, they give more emphasis to the dynamic features, since these features are more difficult to imitate.

The most widely used dynamic features include:

- **Position ($u_x(t)$ and $u_y(t)$):** e.g. the pen tip position when the tip is in the air, and when it is in the vicinity of the writing surface etc (Jain & Griess, 2000; Plamondon & Lorette, 1989).
- Pressure ($u_p(t)$) (Jain & Griess, 2000; Plamondon & Lorette, 1989)
- **Forces ($u_f(t)$, $u_{fx}(t)$, $u_{fy}(t)$):** Forces are computed from the position and pressure coordinates (Plamondon & Lorette, 1989).
- **Velocity ($u_v(t)$, $u_{vx}(t)$, $u_{vy}(t)$):** It can be derived from position coordinates (Jain & Griess, 2000; Plamondon & Lorette, 1989).
- Absolute and relative speed between two critical points (Jain, Griess, & Connell, 2002)
- **Acceleration ($u_a(t)$, $u_{ax}(t)$, $u_{ay}(t)$):** Acceleration can be derived from velocity or position coordinates. It can also be computed using an accelerometric pen (Jain & Griess, 2000; Plamondon & Lorette, 1989).
- **Parameters:** A number of parameters like number of peaks, starting direction of the signature, number of pen lifts, means and standard deviations, number of maxima and minima for each segment, proportions, signature path length, path tangent angles etc. are also calculated apart from the above mentioned functions to increase the dimensionality (Gupta, 1997; Plamondon & Lorette, 1989; Wessels & Omlin, 2000). Moreover, all these features can be of both global and local in nature.

Verification and Learning

For online, examples of comparison methods include use of:

- Corner Point and Point to Point Matching algorithms (Zhang, Pratikakis, Cornelis, & Nyssen, 2000)
- Similarity measurement on logarithmic spectrum (Lee, Wu, & Jou, 1998)
- Extreme Points Warping (EPW) (Feng & Wah, 2003)
- String Matching and Common threshold (Jain, Griess, & Connell, 2002)
- Split and Merging, (Lee, Wu, & Jou, 1997)
- Histogram classifier with global and local likeliness coefficients (Plamondon & Lorette, 1989)
- Clustering analysis (Lorette, 1984)
- Dynamic programming based methods; matching with Mahalanobis pseudo-distance (Sato & Kogure,1982)
- Hidden Markov Model based methods (McCabe, 2000; Kosmala & Rigoll, 1998)

Table 1 gives a summary of some prominent works in the online signature verification field.

Performance Evaluation

Performance evaluation of the output (which is to accept or reject the signature) is done using false rejection rate (FRR or type I error) and false acceptance rate (FAR or type II error) (Huang & Yan, 1997). The values for error rates of different approaches have been included in the comparison table above. Equal error rate (ERR) which is calculated using FRR and FAR is also used for measuring the accuracy of the systems.

GENERAL PROBLEMS

The feature set in online has to be taken very carefully, since it must have sufficient interpersonal variability

Table 1. Summery of some prominent online papers

Author	Mode Of Verification	Database	Feature Extraction	Results (Error rates)
Wu, Lee and Jou (1997)	Split and merging	200 genuine and 246 forged	coordinates to represent the signature and the velocity	86.5 % accuracy rate for genuine and 97.2 % for forged
Wu, Lee and Jou (1998)	Similarity measurement on logarithmic spectrum	27 people each 10 signs, 560 genuine and 650 forged for testing	Features based on coefficients of the logarithmic spectrum	FRR=1.4 % and FAR=2.8 %
Zhang, Pratikakis, Cornelis and Nyssen (2000)	Corner point matching algorithm and Point to point matching algorithm	188 signatures, from 19 people	corner points extracted based on velocity information	0.1 % mismatch in segments in case of corner point algorithm and 0.4 % mismatch in case of point to point matching algorithm
Jain, Griess and Connell (2002)	String matching and common threshold	1232 signatures of 102 individual	Number of strokes, co-ordinate distance between two points, angle with respect to x and y axis, curvature, distance from centre of gravity, grey value in 9X9 neighborhood and velocity features	Type I: 2.8% Type II: 1.6%
Feng and Wah (2003)	Extreme Points Warping (both Euclidean distance and Correlation Coefficients used)	25 users contributed 30 genuine signatures and 10 forged signatures	x and y trajectories used, apart from torque and center of mass.	EER (Euclidean) = 25.4 % EER (correlation) = 27.7 %

so that the input signature can be classified as genuine or forgery. In addition, it must also have a low intra personal variability so that an authentic signature is accepted. Therefore, one has to be extremely cautious, while choosing the feature set, as increase in dimensionality does not necessarily mean an increase in efficiency of a system.

FUTURE TRENDS

Biometrics is gradually replacing the conventional password and ID based devices, since it is both convenient and safer than the earlier methods. Today, it is not difficult at all to come across a fingerprint scanner or an online signature pad. Nevertheless, it still requires a lot of research to be done to make the system infallible, because even an accuracy rate of 99% can cause failure of the system when scaled to the size of a million.

So, it will not be strange if we have ATMs in near future granting access only after face recognition, fingerprint scan and verification of signature via embedded devices, since a multimodal system will have a lesser chance of failure than a system using a single biometric or a password/ID based device. Currently online and off-line signature verification systems are two disjoint approaches. Efforts must be also made to integrate the two approaches enabling us to exploit the higher accuracy of online verification method and greater applicability of off-line method.

CONCLUSION

Most of the online methods claim near about 99% accuracy for signature verification. These systems are gaining popularity day by day and a number of products are currently available in the market. However, online verification is facing stiff competition from fingerprint verification system which is both more portable and has higher accuracy. In addition, the problem of maintaining a balance between FAR and FRR has to be maintained. Theoretically, both FAR and FRR are inversely related to each other. That is, if we keep tighter thresholds to decrease FAR, inevitably we increase the FRR by rejecting some genuine signatures. Further research is thus still required to overcome this barrier.

KEY TERMS

Equal Error Rate: The error rate when the proportions of FAR and FRR are equal. The accuracy of the biometric system is inversely proportional to the value of EER.

False Acceptance Rate: Rate of acceptance of a forged signature as a genuine signature by a handwritten signature verification system.

False Rejection Rate: Rate of rejection of a genuine signature as a forged signature by a handwritten signature verification system.

Global Features: The features are extracted using the complete signature image or signal as a single entity.

Local Features: The geometric information of the signature is extracted in terms of features after dividing the signature image or signal into grids and sections.

Online Signature Recognition: The signature is captured through a digitizer or an instrumented pen and both geometric and temporal information are recorded and later used in the recognition process.

Random Forgery: Random forgery is one in which the forged signature has a totally different semantic meaning and overall shape in comparison to the genuine signature.

Simple Forgery: Simple forgery is one in which the semantics of the signature are the same as that of the genuine signature, but the overall shape differs to a great extent, since the forger has no idea about how the signature is done.

Skilled Forgery: In skilled forgery, the forger has a prior knowledge about how the signature is written and practices it well, before the final attempt of duplicating it.

Traced Forgery: For traced forgery, a signature instance or its photocopy is used as a reference and tried to be forged.

Ontologies and Medical Terminologies

James Geller
New Jersey Institute of Technology, USA

INTRODUCTION

Ontologies

The term "Ontology" was popularized in Computer Science by Thomas Gruber at the Stanford Knowledge Systems Lab (KSL). Gruber's highly influential papers defined an ontology as "an explicit specification of a conceptualization." (Gruber, 1992; Gruber 1993). Gruber cited a conceptualization as being "the objects and concepts, and other entities that are assumed to exist in some area of interest and the relationships that hold among them." (Genesereth & Nilsson, 1987). The term "Ontology" has been used in computer science at least since (Neches, 1991), but is derived from philosophy where it defines a "systematic account of existence," usually contrasted with "Epistemology."

Gruber's work is firmly grounded in Knowledge Representation and Artificial Intelligence research going back to McCarthy and Hayes classical paper (McCarthy & Hayes, 1969). Gruber's work also builds on frame systems (Minsky, 1975; Fikes and Kehler, 1985) which have their roots in Semantic Networks, pioneered by (Quillian, 1968) and popularized through the successful and widespread KL-ONE family (Brachman & Schmolze, 1985). One can argue that Gruber's ontologies are structurally very close to previous work in frame-based knowledge representation systems. However, Gruber focused on the notion of knowledge sharing which was a popular topic at KSL around the same time, especially in the form of the Knowledge Interchange Format (KIF) (Genesereth, 1991).

Ontologies have recently moved center stage in Computer Science as they are a major ingredient of the Semantic Web (Berners-Lee et al., 2001), the next generation of the World-Wide Web. Ontologies have also been used in Data Mining (see below) and in (database) schema integration.

Medical Terminologies

In the field of Medical Informatics a rich set of Medical Terminologies has been developed over the past twenty years. Many of these terminologies have as their backbone a taxonomy of concepts and IS-A (subclass) relationships. This IS-A hierarchy was pioneered in the semantic networks and frame systems mentioned above. With this structural commonality of ontologies and Medical Terminologies in mind, we will treat both kinds of knowledge representation systems together. Some of the largest existing ontologies have been developed in Medical Informatics, which makes this field especially interesting. For example, the Unified Medical Language System (UMLS; Humphreys et al., 1998) Metathesaurus contains information about over 1.5 million biomedical concepts and 7.2 million concept names.[1]

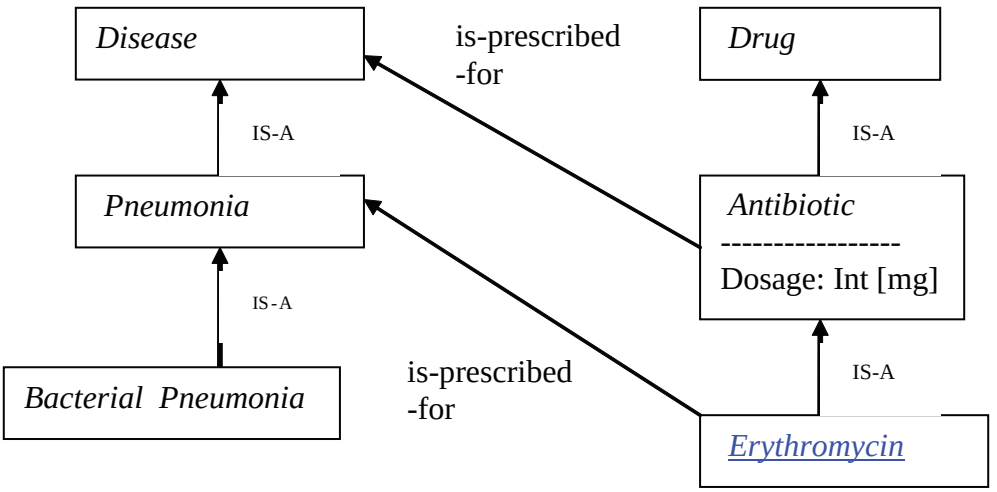
BACKGROUND

The easiest way to understand ontologies is to look at them from a structural perspective. Quillian's original semantic network was a computer data structure that mimicked a dictionary. In the KL-ONE implementation of a semantic network, the IS-A relationship took center stage. Thus, an ontology is (visually) a network of nodes (boxes) and links (arrows) connecting the nodes. Figure 1 shows a tiny excerpt of an ontology.[2]

The basic unit of knowledge in a terminology is a concept. *Drug, Pneumonia, Antibiotic* and *Erythromycin* are concepts. For each concept various kinds of attributes may be specified, e.g., name, ID number, synonyms and other alphanumeric attributes. These attributes provide additional information about the given concepts. In Figure 1, Dosage is an attribute.

Concepts may also refer to other concepts by relationships. In Figure 1, relationships are shown as thin arrows. Relationships have labels attached, such as "is-prescribed-for" and are called "semantic relationships." Semantic Relationships are distinct from the

Figure 1. Example of Medical Terminology applied to the treatment of bacterial pneumonia



special purpose IS-A relationships (bold arrows), which form a specialization/generalization hierarchy. Thus, *Erythromycin* IS-A *Antibiotic* says that *Antibiotic* is more general than *Erythromycin*. In other words, all real-world instances of *Erythromycin* form a subset of all real-world instances of *Antibiotics*. Similarly, *Pneumonia* IS-A *Disease*. The IS-A relationship allows simple forms of reasoning with the concepts of the terminology. The most popular form of reasoning is inheritance. Thus, *Erythromycin* has the attribute Dosage, even though it is not shown in the figure. Dosage is inherited (automatically) along the IS-A link (against the direction of the arrow) from the parent concept *Antibiotic*.

Many ontologies also include *individuals* and/or support different forms of logic-based reasoning. Axioms may be attached to concepts in the taxonomy. The most popular logic formalism is called First Order Predicate Logic (FOPL). Unfortunately, FOPL is neither decidable nor tractable, which means that finding true results may be impossible or may take exponential amounts of time (e.g., millions of years). Thus, weaker logical formalisms have been invented. Indeed, many older and all modern members of the KL-ONE family itself were reconceived as "Description Logics" (Baader et al., 2003).

Description Logics maintain the basic KL-ONE structure and aim for well-defined tradeoffs between computability and expressiveness (Brachman & Levesque, 1984). Meanwhile improved First Order Logic (FOL) provers have also been developed. Tsarkov and Horrocks (2003) presented a comparison between DL and FOL systems. Given the long history of *building* ontologies it is somewhat surprising that *using* ontologies is still not a straightforward process, a phenomenon referred to as *knowledge use paradox* in (Geller et al., 2004).

MAIN FOCUS

Ontologies come in many different shapes and forms. An early categorization of ontologies can be found in (Noy & Friedman, 1997). They distinguished between ontologies based on generality, domain, size, formalism used, etc. John Bateman's comprehensive ontology portal[3] lists ontologies in linguistics, medicine, geography, translation, information reuse, business, general knowledge, engineering, software, etc. Ontologies may also be categorized into terminological versus axiomatized ontologies. Fensel (2004) provides a good, compact review of ontologies and how they will be useful in Electronic Commerce. An easy introduction to ontologies in Bioinformatics is (Baclawski & Niu, 2006). A comprehensive account of many aspects of ontologies is (Gomez-Perez et al., 2004).

One of the most widely used and successful lexical ontologies is WordNet (Fellbaum, 1998). It has inspired similar projects in other languages, such as GermaNet (Hamp and Feldweg, 1997). The CYC project also

deserves special mention (Lenat, 1995). Envisioned by Doug Lenat and Ed Feigenbaum at Stanford, CYC (from enCYClopedia) was a ten-year project (1984-1994) intended to codify once and for all human common sense knowledge into a large set of concepts and axioms. CYC had what no other AI project had had before it, namely a multi-million-dollar budget and a dedicated development staff. Nevertheless, CYC was not finished by the planned end of the project and is still being actively developed by CYCORP, Lenat's company.[4]

We will focus on three areas of special interest: Ontologies for the Semantic Web, Ontologies in Database Integration and Ontologies in Data Mining.

Ontologies and the Semantic Web

Tim Berners-Lee, the inventor of the World-Wide Web and the co-inventor of the Semantic Web (Berners-Lee et al., 2001) describes "the third basic component of the Semantic Web, collections of information called ontologies." Furthermore, Ontologies "can be used … to improve the accuracy of Web searches … More advanced applications will use ontologies to relate the information on a page to … inference rules." While historically ontologies had been represented in formats based on the LISP programming language, ontologies on the Web are written as RDF triples[5] which are themselves implemented in an XML-based formalism. OWL is currently a popular language for implementing Web Ontologies.[6] Editing of OWL is possible with the widely used Protégé tool.[7] Logic-based reasoners have been developed for OWL, such as RACER[8] and Pellet.[9] The implementation language of choice is typically Java. It should be noted that even a successful Semantic Web would (most likely) not be equivalent to a truly intelligent system.

Ontologies and Schema Integration

Ontologies have become popular in the field of databases to overcome difficulties in areas such as schema integration. When databases have to be merged, large database schemata need to be integrated, which is a difficult task. Much research has gone into automating schema matching (Rahm and Bernstein, 2001), but it is still an unresolved problem. Ontologies have been recognized as a tool for this purpose (Hakimpour & Geppert, 2001). For example, recognizing that two column names of two tables refer to the same real world property requires the kind of human knowledge that is often represented in synonym lists of ontologies.

Ontologies and Data Mining

A number of natural connections between ontologies and (data) mining have been explored. As the building of ontologies by hand is a difficult and error prone process, attempts have been made to automate the building of ontologies. Some of those attempts have been based on Web mining and/or text mining, e.g., Missikoff et al. (2003). At the opposite end of the spectrum are approaches that use ontologies to improve data or Web mining, e.g., Bernstein et al. (2005). A third connection between ontologies and data mining has been explored by Geller et al. (2005). In this approach, called *Raising*, raw transaction data is preprocessed using an ontology before the actual data mining step. As a result, rules with better support and more generality can be derived.

Medical Terminologies

One may argue that the most comprehensive ontologies (or ontology-like terminologies) today exist in the field of Medical Informatics. Research in Artificial Intelligence had concentrated on the properties of representation systems and reasoning systems, with building of actual (large) ontologies as a later goal, not realized until the start of the CYC project in 1984. Medical Informatics, in contrast, started as an attempt to organize the enormous amounts of existing medical terms, which go far beyond the mental capacity of any medical practitioner or even researcher, for practical purposes such as literature search.

The 1940 *Quarterly Cumulative Index Medicus* Subject Headings may be considered as the "grandfather" of modern medical terminologies.[10] This index was developed by the National Library of Medicine into the Medical Subject Headings (MeSH, 1963), which have been greatly extended and are still in use today. Today, the UMLS (Unified Medical Language System) is considered the most comprehensive and probably most important medical terminology. Under development since 1986 at the National Library of Medicine, the UMLS consists of over 100 other terminologies and its main part is therefore considered to be a Metathesaurus. The UMLS Semantic Network is

used as an upper layer for organizing the information in the Metathesaurus. Recently there has been great interest in the application of structural computer science techniques to the UMLS (Perl & Geller, 2003).

Another major medical terminology is SNOMED-CT (Systematized Nomenclature of Medicine - Clinical Terms). Contrary to the UMLS, which was the result of multiple integration processes, the SNOMED has been developed as a fairly homogeneous terminology by the College of American Pathologists (CAP). (The SNOMED CT is the result of the integration of the United Kingdom's National Health Service (NHS) Read codes with the prior SNOMED RT.).[11] The SNOMED CT contains over 311,000 concepts and more than 800,000 descriptions.[12] Since 2004, the SNOMED CT has been integrated into the UMLS.

Other important medical terminologies are ICD9-CM, HL7, and LOINC. In Europe, the GALEN project (Rogers et al., 2001), implemented in the GRAIL language, was developed for storing detailed clinical information about patients in a format useable by both medical doctors and computers. Due to the explosive growth of the field of genomics, the Gene Ontology (GO)[13] is also considered of increasing importance. Modern terminologies are expected to conform to Cimino's desiderata (Cimino et al., 1989), which include, e.g., Concept Orientation (non-redundant, non-ambiguous, permanent), multiple inheritance (called polyhierarchy by Cimino), and the use of Semantic Relationships.

FUTURE TRENDS

Semantic Web

The Semantic Web has made the first exciting steps out of the lab and into the commercial environment.[14] The Semantic Web provides a genuinely new mechanism of sharing islands of terminologies between different Web pages by referring to their URIs. Researchers involved in ontologies for the Semantic Web need to be careful to avoid some of the mistakes of their parent discipline Knowledge Representation, such as primacy of formal properties. A rapid expansion and wide scale sharing of RDF-encoded ontologies needs to be achieved. Writing of Semantic Web pages needs to become as easy as creating personal home pages, which is still a difficult goal. Comparing the speed of development of the World-Wide Web with the Semantic Web, we find that the WWW has both grown and gained acceptance much faster without any prior expectations.

Medical Terminologies

Medical Terminologies are increasingly included in production-quality systems ranging from hospitals to insurance companies. Because of that, dangers could arise for patient populations, unless great care is taken to ensure the correctness of all terms. This author believes that in the future *auditing of medical terminologies* will take center-stage. Some methods of auditing can be found in (Geller et al., 2003).

CONCLUSION

Ontologies and Medical Terminologies are major mechanisms for including human-like knowledge in software systems. As there is pressure on software developers to create more intelligent programs, the importance of ontologies and Medical Terminologies will only increase. However, in order to achieve widespread acceptance, great care has to be taken to make them both user-friendly and correct.

KEY TERMS

Description Logics: A description logic is an inheritance network, structurally similar to a semantic network or frame system. It differs from the above in that the meaning of each network structure can always be expressed by a translation into predicate logic. Description logics do not allow full logical reasoning but implement inheritance and classification reasoning (where to place a concept in a given inheritance network). The purpose of this limitation is to make reasoning tractable (computable in polynomial time).

Directed Acyclic Graph (DAG): The IS-A hierarchy of an ontology is either a tree structure or a Directed Acyclic Graph. In a tree every concept has exactly one parent (more general) concept that it is connected to. (The only exception is the root, which has no parent). In a DAG, a node might have several parents. However, when traversing the DAG from a node following the IS-A links in the direction of the given arrow heads, it is impossible to ever return to the start node. This implements the intuition that a concept cannot be more general and more specific than itself.

IS-A Hierarchy (Subclass Hierarchy, Concept Taxonomy): An IS-A hierarchy consists of concept nodes connected by IS-A links, forming a graph structure. IS-A links express generalization and are used for inheriting information downwards. Thus, a link from a concept LIVER to a concept ORGAN would express that ORGAN is a more general concept. At the same time, all information about the concept ORGAN would also apply to LIVER and is therefore said to be "inherited" by LIVER.

Medical Terminology: Most medical terminologies are collections of medical terms, which are structurally similar or sometimes even identical to ontologies. Historically, some medical terminologies existed in paper form before adequate computational resources became available.

Ontology: A representation of human-like knowledge in a computer-implemented graph structure. The major components of most ontologies are concepts, local information attached to concepts (attributes), IS-A

relationships and semantic relationships between pairs of concepts. Many ontologies also contain attached axioms for logical reasoning.

Semantic Relationship (Role): A semantic relationship expresses a real-world connection between two concepts, such as PERSON is-owner-of CAR, with is-owner-of being the relationship. The semantic relationships of an ontology together with the concepts form a graph in which cycles are not just allowed but the norm. In some systems semantic relationships appear in pairs, e.g., is-owner-of and is-owned-by, pointing into opposite directions.

Semantic Web: The Semantic Web is a new generation of the World-Wide Web (WWW), co-invented by Tim Berners-Lee, the inventor of the WWW. Its primary goal is to make the WWW machine-processable. A key ingredient of the Semantic Web is the use of ontologies, represented in a special format called RDF (Resource Description Framework).

UMLS: The UMLS (Unified Medical Language System) of the NLM (National Library of Medicine) is the largest existing medical terminology. It consists of the very large Metathesaurus, the Semantic Network, and the Specialist Lexicon. The Metathesaurus consists of over 100 medical terminologies. The Semantic Network consists of few (135) very general "semantic types" connected by 54 relationships. Every concept in the Metathesaurus has its meaning constrained by assigning it at least one, but often several, Semantic Types.

Order Preserving Data Mining

INTRODUCTION

Data mining has emerged over the last decade as probably the most important application in databases. To reproduce one of the most popular but accurate definitions for data mining; "it is the process of nontrivial extraction of implicit, previously unknown and potentially useful information (such as rules, constraints and regularities) from massive databases" (Piatetsky-Shapiro & Frawley 1991). In practice data mining can be thought of as the "crystal ball" of businessmen, scientists, politicians and generally all kinds of people and professions wishing to get more insight on their field of interest and their data. Of course this "crystal ball" is based on a sound and broad scientific basis, using techniques borrowed from fields such as statistics, artificial intelligence, machine learning, mathematics and database research in general among others. Applications of data mining range from analyzing simple point of sales transactions and text documents to astronomical data and homeland security (*Data Mining and Homeland Security: An Overview*). Usually different applications may require different data mining techniques. The main kinds of techniques that are used in order to discover knowledge from a database are categorized into association rules mining, classification and clustering, with association rules being the most extensively and actively studied area. The problem of finding association rules can be formulated as follows: Given a large data base of item transactions, find all frequent itemsets, where a frequent itemset is one that occurs in at least a user-specified percentage of the data base. In other words find rules of the form X→Y, where X and Y are sets of items. A rule expresses the possibility that whenever we find a transaction that contains all items in X, then this transaction is likely to also contain all items in Y. Consequently X is called the body of the rule and Y the head. The validity and reliability of association rules is expressed usually by means of support and confidence. An example of such a rule is {smoking, no_workout→heart_disease (sup=50%, conf=90%)}, which means that 90% of the people that smoke and do not work out present heart problems, whereas 50% of all our people present all these together.

Nevertheless the prominent model for contemplating data in almost all circumstances has been a rather simplistic and crude one, making several concessions. More specifically objects inside the data, like for example items within transactions, have been attributed a Boolean hypostasis (i.e. they appear or not) with their ordering being considered of no interest because they are considered altogether as sets. Of course similar concessions are made in many other fields in order to come to a feasible solution (e.g. in mining data streams). Certainly there is a trade off between the actual depth and precision of knowledge that we wish to uncover from a database and the amount and complexity of data that we are capable of processing to reach that target.

In this work we concentrate on the possibility of taking into consideration and utilizing in some way the order of items within data. There are many areas in real world applications and systems that require data with temporal, spatial, spatiotemporal or ordered properties in general where their inherent sequential nature imposes the need for proper storage and processing. Such data include those collected from telecommunication systems, computer networks, wireless sensor networks, retail and logistics. There is a variety of interpretations that can be used to preserve data ordering in a sufficient way according to the intended system functionality.

BACKGROUND

Taking into consideration and using the order of items within transactions has been considered in another form and for an alternate goal; that is with the task of sequential pattern mining. Essentially in association rule mining we try to find frequent items that appear together in the same transactions. In sequential pattern mining we are interested in sets of items that appear frequently in different transactions. Thus association rules mining can be thought as an intra-transactional search process whereas sequential pattern mining as an inter-transactional.

A formulation of the task of sequential pattern mining is as follows (Dunham, 2003; Tan, Steinbach & Kumar, 2006): Let D be a database of customer transactions, and $I=\{i_1, i_2, \ldots, i_m\}$ be a set of distinct attributes called items. A transaction or else called an event is a non-empty collection of items (in most cases ordered), denoted as $(i_1, i_2, \ldots, i_k)$. A sequence α on the other hand is a collection of events such that $(\alpha_1 \rightarrow \alpha_2 \rightarrow \ldots \rightarrow \alpha_t)$, where α_i is an event. The support or frequency of a sequence, denoted as $\sigma(\alpha, D)$, is the total number of sequences in the database D that contain α. Consequently the process of sequential pattern mining concerns with extracting those sequential patterns whose support exceed a user predefined minimum support value; though the items within every transaction were reordered, thus destroying the initial purchase order.

Sequential pattern mining can be used in a wide range of areas from biology and medicine, to business processes and web sessions. The problem of mining sequential patterns was first introduced in (Agrawal and Srikant, 1995), where three algorithms were presented with algorithm AprioriAll having the best performance. An enhanced algorithm by the name GSP was proposed in (Srikant & Agrawal, 1996) that outperformed AprioriAll by up to 20 times. In the same period Mannila, Toivonen and Verkamo (1997) proposed a work for mining frequent episodes, which was further extended in (Mannila & Toivonen, 1996) in order to discover generalized episodes. Algorithms MEDD (Multi-Event Dependency Detection) and MSDD (Multi-Stream Dependency Detection) in (Oates, Schmill, Jensen, & Cohen, 1997) discover patterns in multiple event sequences, by exploring instead of the sequence space directly the rule space.

Other works include Zaki's SPADE (Zaki, 2001), a method that employs lattice based search techniques and simple joins in order to decompose the search space into sub-lattices small enough to be processed in main memory, thus reducing the number of database scans. PrefixSpan (Pei et al., 2001) employs an internal representation of the data made of database projections over sequence prefixes. Finally a family of works where time plays the dominant role are (Vautier, Cordier, & Quiniou, 2005) and the most recent work in (Giannotti, Nanni & Pedreschi, 2006). Interested reader can refer to (Zhao & Bhowmick, 2003) for a broader and more detailed view of the specific area.

ORDERED DATA: A NEW PERSPECTIVE

Traditional algorithms and approaches for association rules mining work on the rather naive assumption that every item inside a transaction has an influence on all the rest items inside the same transaction. Nevertheless items may appear together in several transactions but this does not necessarily mean they all influence one another. For example suppose we have a transaction that contains the following items in the exact order as they were purchased:

[V, G, A, S, C]

Then according to current approaches item V is considered to have influenced the purchase of all other items (i.e. items G, A, S and C). Items G, A, S, C are also considered to have influenced the purchase of all other items inside the transaction. However the reasonable question that arises from this assumption is how an event that occurred in the future could have influenced an event in the past. More specifically how can we claim for example that the choice of item A was influenced by the purchase of item S or C since when A was purchased items S and C were not even in the basket. It is fairly logical to presume that there exists the possibility that an item purchased might have an influence on the decision to purchase or not an item afterwards, but how can we claim the opposite? This scenario is especially evident in on-line stores where the purchases are made in a chain-like fashion (i.e. one item at a time and usually without following some predefined shopping list), resembling a lot the web browsing behaviour of the world wide web users. Hence in our opinion every item inside a transaction influences only the subsequent items inside the same transaction. This leads us to the following observation: the choice

of any item inside a transaction can be considered to be independent from the choice of all subsequent items inside the same transaction and is only influenced by preceding items.

Taking the order of items into consideration is not as trivial as it seems, and many questions and ambiguities would have to be solved. Bellow we mention some of the most important ones.

Order Recording

In order for the above observation to be in effect and to be able to be utilized, the initial purchase order will have to be preserved. As noted before though, traditional algorithms for association rules mining up to now do not preserve the order by which the items inside a transaction were purchased, but rather order them in various ways mainly so that they can facilitate more efficient counting (e.g. according to Agrawal and Srikant (1994) as well as in almost all works thereafter it is assumed that items in each itemset as well as in every transaction are lexically ordered so that the formation of the set of candidate itemsets and their counting can be done more effectively). Even with sequential pattern mining there exists also a reordering phase that destroys the initial purchase order.

Nevertheless current systems and databases could record the order of items with little modifications, requiring practically little effort and costs. Depending on the precision and the accuracy of rules we want to discover we could record only the order, the date or even the exact time that an item was chosen. Consequently we could propose the obvious rules such as people that buy some items with a specific order also buy some other, or people that buy these items then they should be proposed also some others after a specific time period. Again we must note that in comparison to sequential pattern mining, we discover ordered pairs in every transaction and not between transactions, and also we keep the initial ordering within every transaction.

Order Quantification

The first question that arises is how we are going to quantify the order of items within every transaction. Let's take for example the transaction discussed above (i.e. transaction [V, G, A, S, C]), assuming again that the initial order of appearance of every item has been preserved. As noted previously we assume that items influence only the choice of items that come after them (e.g. item A influences the choices of items S and C). So one obvious way to model this suggestion would be to suppose that every item has the same degree of influence on all the following items. An alternative suggestion though would be to take into consideration also the actual distance between any two items. For example item G has the biggest degree of influence on the item just after it (i.e. item A) and this influence diminishes as we move away from it. The degree of influence of every item could be coupled with the time factor associated with every purchase. For example if we chose item G and in the same transaction but after 30 whole minutes we chose item A, then the two purchases could be considered independent (of course this depends on the nature of items sold and the application). This adds some to the complexity of the problem but leads us to far more accurate suggestions. Also one might consider the case where in long transactions the influence of an item actually disappears after a certain number of items.

Assigning Importance to Every Item

All items are not equally important. If we take for example the case of a retail store, an expensive item or more accurately an item with large profit margins is probably more important than another one with fewer profit margins even if it does not appear that often. A classical example is the case of chewing gums and caviar, where despite the fact that chewing gums appear in almost all transactions if we wish to be accurate they cannot be considered more important than caviar. Also inherent differences in the natures of items or in their purchasing patterns suggest also different approaches for handling them, in terms of their importance. Another example would be that with items that are rare but on the other hand appear always together. For example people that work as lifeguards present an extremely high percentage of skin cancer, despite the fact that both these events when viewed separately are very rare. Consequently the importance of an item, regardless of how it would be measured, should be coupled efficiently with the quantification of items within transactions in order to assign the correct degree of influence to every item.

Cooping with Increased Complexity

Probably the most serious problem that would have to be surmounted regards the increased complexity that the above observations imply. As noted previously the more accurate rules we wish to produce and the more information we use, the more complex and sluggish a specific system becomes. So we have to either disregard some information or to find ways to reduce system complexity.

The Matrix Based Itemset Recommendation

In this section we briefly present a simple but straightforward solution for taking into consideration the order of items within transactions. Let I be the set of items. Let D be the set of transactions, where each transaction T is a set of items such that $T=\{i_1, i_2, i_3,\ldots, i_k\}$, where $i_i \in I$. The specific transaction is shown here as an ordered list of items since in our case items in a transaction are stored in the exact order as they first appear.

What we propose is a system that tries to mimic the function of an on-line collaborative filtering system that manages though also to take into consideration the exact order of the items in the transactions, as well as their special importance. Every item in our database is represented in a two dimensional table, called adjacency matrix like the one shown in Figure 1. Using every transaction we assign weights between all items using a scheme like the one proposed above (see section **Order Quantification**). For example suppose we have transaction [A, N, C, I, J, M]. Assigning a weight of 1 to every item preceding another one results in the adjacency matrix shown bellow. This process is repeated for every transaction, summing up the corresponding weights at every step.

Proposal Phase

After having constructed the adjacency matrix using every available transaction, our system is ready to make itemsets proposals to its users, using a very simple procedure. Suppose a customer puts an item in his basket. Then the system reads the entries for the specific item, sorts the values of all items present in descending order and proposes the most significant ones to the users. When two or more items are chosen then we read their lists, combine the value for every entry, sort them in descending order and again propose the most significant ones to the users.

FUTURE TRENDS

In the context of this work there exist two intriguing and important possible future directions. Using a time stamp for ordering items within transactions is an important attribute of each dataset since it can give us more accurate and useful information in the process of data mining. It would be very interesting though if we could couple the time attribute with a space attribute. In other words what would happen if we stored also the locations or the distances where some purchases were

Figure 1. An adjacency matrix

	A	C	F	I	J	M	N
A	0	1	0	1	1	1	1
C	0	0	0	1	1	1	0
F	0	0	0	0	0	0	0
I	0	0	0	0	1	1	0
J	0	0	0	0	0	1	0
M	0	0	0	0	0	0	0
N	0	1	0	1	1	1	0

made and process the whole database as a spatiotemporal dataset. Equally interesting would be the recording and utilization of items removal from transactions or data in general. Objects are not only inserted in a database but also removed. For example in a transaction some items are chosen and later removed. So it would be very interesting to examine how we could incorporate this information also.

CONCLUSION

In this work we tried to bring out and examine a parameter in data mining research that was left aside, namely the order of items within every transaction. Consequently we pinpointed other techniques that might have even vaguely or in some small extent engaged with a similar notion. We gave some possible problems that one might face trying to utilize items ordering and we concluded with the proposal of a possible solution to the specific problem. Although it may seem too simple, it has the advantage of being very straightforward and thus easy to grasp and implement.

Among other applications our proposed approach is especially suitable in the area of Web Mining, where the discovered rules could be used to extract frequent patterns based on the initial preserved order of the data in log files. For example for building a link predictor; i.e. a system-aided Web navigation application that processes and analyzes the click-stream-paths from many different users of a site over time and generates rules, which can be used to predict future navigational behavior of other users under a personalized framework. Also these rules could also be applied to enhance server performance through HTTP request prediction.

Researchers and techniques have to move away from the rather static way data were mostly treated until now especially regarding association rules, and assume a more dynamic view. Even in the most static database every day new data is inserted, old data is deleted while some existing is updated.

KEY TERMS

Association Rules: An implication of the form $X \rightarrow Y$ where X and Y are itemsets. An association rule expresses the possibility that whenever we find a transaction that contains all items in *X*, then this transaction is likely to also contain all items in *Y*.

Data Mining: The nontrivial extraction of implicit, previously unknown, and potentially useful information from data.

Itemset: A set of database items/entities occurring together.

Item Reordering: The preprocessing phase, where items are reordered in order to facilitate more efficient counting.

Ordered Data: Data (itemsets) where their original order of appearance is preserved.

Order Preserving Data Mining: The task concerned with finding association rules among ordered data.

Sequential Pattern Mining: The task concerned with finding sets of items that appear frequently in different transactions.

Outlier Detection

Sharanjit Kaur
University of Delhi, India

INTRODUCTION

Knowledge discovery in databases (KDD) is a non-trivial process of detecting valid, novel, potentially useful and ultimately understandable patterns in data (Fayyad, Piatetsky-Shapiro, Smyth & Uthurusamy, 1996). In general KDD tasks can be classified into four categories i) Dependency detection, ii) Class identification, iii) Class description and iv) Outlier detection. The first three categories of tasks correspond to patterns that apply to many objects while the task (iv) focuses on a small fraction of data objects often called outliers (Han & Kamber, 2006). Typically, outliers are data points which deviate more than user expectation from the majority of points in a dataset.

There are two types of outliers: i) data points/objects with abnormally large errors and ii) data points/objects with normal errors but at far distance from its neighboring points (Maimon & Rokach, 2005). The former type may be the outcome of malfunctioning of data generator or due to errors while recording data, whereas latter is due to genuine data variation reflecting an unexpected trend in data. Outliers may be present in real life datasets because of several reasons including errors in capturing, storage and communication of data. Since outliers often interfere and obstruct the data mining process, they are considered to be nuisance.

In several commercial and scientific applications, a small set of objects representing some rare or unexpected events is often more interesting than the larger ones. Example applications in commercial domain include credit-card fraud detection, criminal activities in e-commerce, pharmaceutical research etc.. In scientific domain, unknown astronomical objects, unexpected values of vital parameters in patient analysis etc. manifest as exceptions in observed data. Outliers are required to be reported immediately to take appropriate action in applications like network intrusion, weather prediction etc., whereas in other applications like astronomy, further investigation of outliers may lead to discovery of new celestial objects. Thus exception/outlier handling is an important task in KDD and often leads to a more meaningful discovery (Breunig, Kriegel, Raymond & Sander, 2000).

In this article different approaches for outlier detection in static datasets are presented.

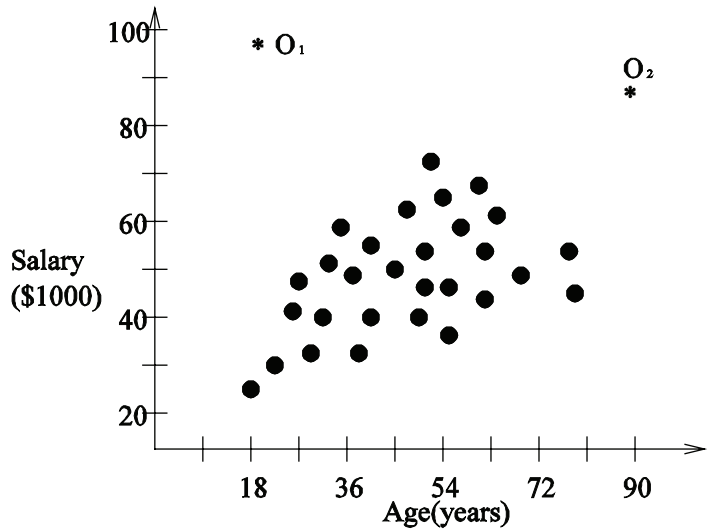
BACKGROUND

Outliers are data points which deviate *much* from the majority of points in a dataset. Figure 1 shows two outliers (O_1 and O_2) in Employee dataset with two attributes age and salary. Points O_1 and O_2 represent employees drawing high salary with age 18 and 90 respectively. These points are considered outliers because i) there is no other point in their neighborhood and ii) they are substantially different from the rest of points. Further exploration of such points may reveal some interesting facts.

Although exact definition of an outlier is application and context dependent, two commonly used general definitions for outliers are as follows. The classical definition is given by Hawkins (Hawkins, 1980) according to which, an outlier is an observation that deviates so much from other observations so as to arouse suspicion that it was generated by a different mechanism. A more recent definition, given by Johnson (Johnson, 1992), defines outlier as an observation which appears to be inconsistent with the remainder of the dataset.

Outlier detection in statistics has been studied extensively both for univariate and multivariate data, where a point not falling inside the distribution model is treated as outlier. Most of the approaches used in statistics are either suitable for univariate data or data with known distribution model e.g. Normal, Poisson etc. (Maimon & Rokach, 2005). In univariate approaches, only one feature is used, whereas in multivariate approaches multiple features are used to distinguish outliers from the normal objects. Multivariate approaches, which

Figure 1. Distinction between normal data and outliers



are computationally more expensive than univariate approaches, yield efficient results for low dimensional numeric dataset with known distribution model. However, for real life multidimensional datasets with unknown distribution, expensive tests for model fitting need to be performed. Data mining approaches do not assume any distribution model and overcome some of these limitations.

DATA MINING APPROACHES FOR OUTLIER DETECTION

Outlier detection is an important area in data mining to reveal interesting, unusual patterns in both static and dynamic datasets. In this article, we focus on non-parametric approaches for outlier detection in static datasets. These approaches detect outliers without any prior knowledge about underlying dataset and view dataset *S* as consisting of two components.

$$S = P + O \quad (1)$$

Here *P* represents normal data points and *O* represents exceptions or outliers. These approaches are categorized as: i) Clustering-based approach, ii) Distance-based approach and iii) Density-based approach, on the basis of their most distinct feature (Breunig, Kriegel, Raymond & Sander, 2000; Papadimitriou, Kitawaga, Gibbons & Faloutsos, 2003) .

Clustering-Based Approach

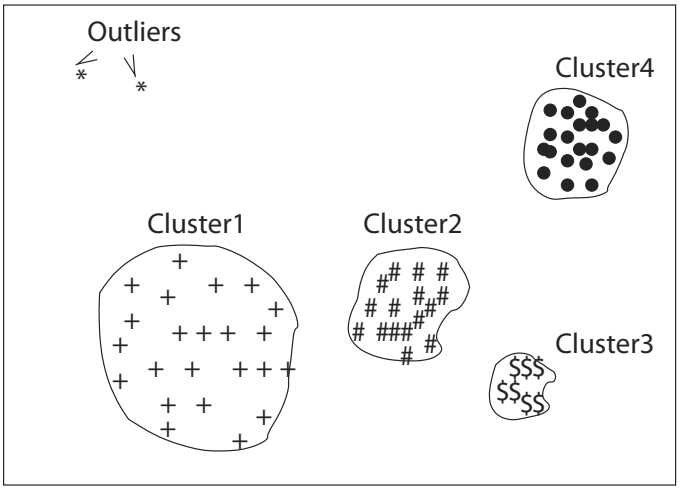
Clustering is a database segmentation technique which partitions a dataset into unknown groups as per prevalent data characteristics (Han & Kamber, 2006). Grouping is done such that data points in one group are more similar to each other than those belonging to different groups. These groups are called clusters. The data points which are not member of any cluster (Figure 2) are reported as outliers (Maimon & Rokach, 2005).

Clustering algorithms for large datasets like Balanced Iterative Reducing and Clustering using Hierarchy (BIRCH), Density Based Spatial Clustering of Applications with Noise (DBSCAN) and Clustering Using Representatives (CURE) report outliers as a by-product of the clustering process (Dunham, 2004). The objective of these algorithms, however, is to optimize clustering and not outlier detection.

BIRCH maintains compressed information required for clustering in *Cluster Feature Tree* (CF-Tree), which is a balanced tree. Each leaf in CF-Tree represents a set of points with a specified diameter and is treated as a pseudo point during clustering. The algorithm removes a leaf if the number of points is less than a user-defined threshold (λ) and reports all points as outliers.

DBSCAN uses a formal notion of density reachability to discover arbitrary shaped clusters with user defined minimum neighborhood δ and density *m*. *Density* of a point *p* is defined as a minimum number of points within a certain distance from *p*. A point is

Figure 2. Outliers detection using clustering approach



declared an outlier if there are less than *m* points in δ-neighborhood.

CURE uses both hierarchical and partitioning approaches for clustering. Initial clustering is performed on a sample drawn from the dataset. The sample is divided into equal sized partitions. Each partition is clustered using hierarchical approach. Clusters with points less than user specified threshold, are removed and points are reported as outliers.

Major disadvantage of clustering-based approach for outlier detection is that there is no standard measure to quantify *degree of outlyingness*. Outliers discovered are highly dependent on clustering scheme used and their detection criteria can not be inferred from the clustering method (Papadimitriou, Kitawaga, Gibbons & Faloutsos, 2003).

It is worth mentioning here that classical *k-Means* clustering algorithm does not differentiate between normal data and outliers. It reports clustering considering all data points including outliers, thereby deteriorating the quality of clustering scheme. Some refinements of *k-Means* have been suggested using rough set theory to improve its performance in the presence of outliers (Peters, 2005).

Distance-Based Approach

Distance-based approach for outlier detection computes neighbors of each point in the dataset using some distance metric like Euclidean distance or Mahalanobis distance. Although both metrics give comparable result but high computational complexity of Mahalanobis distance due to covariance matrix, makes it less popular as compared to Euclidean distance.

Knorr & Ng (1998) has proposed a distance-based method which overcomes limitations of clustering approach. The authors proposed the notion of distance-based outliers where *outlyingness* of a point w.r.t. another point is measured by Euclidean distance metric. For any two *d*-dimensional points *p* and *q*, *dist*(*p*,*q*) is given as follows:

$$dist(p,q) = \sqrt{\sum_{i=1}^{d} (p_i - q_i)^2} \quad (2)$$

In a dataset *S* of size *N*, an object *o* is defined as *DB*(*f*,*D*)-outlier if at least fraction *f* of objects in *S* lies at distance greater than *D* from *o*. For each object, neighborhood objects within distance *D* are counted and if the count is less than $N(1-f)$, the object is reported as an outlier. A major limitation of this approach is the setting of two crucial parameters *f* and *D*. A new user may find it difficult to set appropriately these parameters for successful outlier detection. Further, this approach does not rank outliers i.e. an outlier with very few neighbors and an outlier with more neighbors within distance *D* are not differentiated (Ramaswamy, Rastogi & Shim, 2000).

A variation of this approach is proposed by Ramaswamy et. al. (Ramaswamy, Rastogi & Shim, 2000), where the distance of k^{th} nearest neighbor of point *p* denoted as $D^k(p)$ is used to declare *p* as an

outlier. Given the number of nearest neighbors (k) to be checked and number of outliers to be reported (n), a point p is reported as outlier if no more than $n - 1$ points in the dataset have a higher value for $D^k(p)$. This approach reports n points with maximum $D^k(p)$ as *top-n* outliers. Although this approach ranks outliers without user specified distance D, it still requires two input parameters k and n and does not work efficiently for high dimensional datasets.

In order to overcome the computational expense of distance-based approach, Knorr & Ng propose following three strategies.

a. **Use of Index structure:** Various standard multidimensional indexing structures like k-d tree, R-tree etc. are used to execute a range search within distance D for each object o, to find its $N(1-f)$ neighbors. The worst case complexity is $O(dN^2)$ for d dimensions. Further additional cost of building index structure makes this strategy uncompetitive (Knorr & Ng, 1998). Maintaining minimum bounding rectangle (MBR) for each node optimizes the usage of index structure to reduce search time (Ramaswamy, Rastogi & Shim, 2000). While searching neighbors, if minimum distance between p and MBR of a node exceeds $D^k(p)$, then subtree of the node is not traversed.

b. **Use of Nested Loop:** It is a brute force approach for outlier detection where distance of each point is computed w.r.t rest of points in dataset. It is a computationally expensive approach with worst case complexity $O(N^2)$, but avoids the cost of building an index structure. To further optimize, Knorr & Ng (Knorr & Ng, 1998) proposed a variation by dividing dataset in blocks of fixed size. It reads two blocks at a time in the memory, referred as *first* and *second array*. For every point in *first array*, a count of neighboring points within distance D is maintained. As soon as count exceeds $N(1-f)$, it is marked as *non-outlier* and the process continues with the next point. Subsequently, the neighbors of unmarked points are searched in *second array* and count is updated. If points still remain unmarked, then *second array* is swapped by another unprocessed block and steps are repeated. Once all blocks are processed, each unmarked point in *first array* is reported as outlier. The process is repeated for the rest of data blocks which have not served as *first array* any time. Nested Loop is the most effective technique for detecting outliers from large datasets but is computationally more expensive.

c. **Use of Partition-based strategy:** This strategy partitions the data space such that points that are close together are assigned to the same partition. If a partition does not have any outlier then its points are not used in detecting outliers from rest of partitions. Knorr & Ng (1998) partition the dataset using cell-based approach which scales linearly with N, but is exponential w.r.t. d. Ramaswamy, Rastogi & Shim (2000) partition the dataset using some clustering method where each cluster represents a partition (p). It computes lower and upper bounds ($p.lower$, $p.upper$) for each partition p s.t. $p.lower \leq D^k(p) \leq p.upper$. A partition with $p.upper \leq mindist$ (minimum distance threshold) is pruned because it cannot contain outliers. Although this method works better than cell-based approach, it does not scale well for high dimensional dataset (Bay & Schwabacher, 2003).

Distance-Based Approach for High Dimensional Datasets

Major drawback of distance-based algorithms, explained so far, is their non-scalability with high-dimensional, large datasets. Orca and RBRP (Recursive Binning and Re-Projection) are the two recently proposed distance-based algorithms to detect *top-n* outliers from high-dimensional, large datasets.

ORCA (Bay & Schwabacher, 2003) optimizes nested loop strategy using randomization and pruning to reduce its worst case complexity from quadratic to linear in time. A set of points referred as *examples* is selected randomly from the dataset. An *outlier score* for each *example* is maintained on the basis of its distance from closest neighbor. The algorithm uses Euclidean distance for continuous features and Hamming distance for discrete features. An *example* is removed/pruned as soon as its outlier score becomes less than a cut-off threshold (χ). ORCA shows near linear scaling behavior only when the example set has a large number of outlying points and updates χ on the basis of outliers detected so far. Its complexity is near quadratic when *examples* are from mixed data distribution with lesser number of outlying points.

RBRP (Ghoting, Parthasarthy & Otey, 2006) uses two phase approach to reduce worst case complexity

of ORCA. In the first phase, dataset is recursively partitioned into equisized groups (bins). In the second phase extension of nested loop technique is used to find outliers. RBRP outperforms ORCA in scalability because of its pre-processing step for faster determination of approximate nearest neighbors.

Intuitively, distance-based approach works best for outliers possessing low neighborhood densities. As outlier is defined on the basis of some global parameters like *D* or *k*, distance-based approach does not give good result for the dataset with both sparse and dense regions (Tang, Chen, Fu & Cheung, 2006).

Density-Based Approach

Outlier detection algorithms using density-based approach compute outlying factor of each data point on the basis of number of points in the neighborhood (density). The main objective is to find how dense is the neighborhood of the point or how much it is alienated from others. LOF (Local Outlying Factor) and LOCI (Local Correlation Integral), two recent density-based algorithms are described below.

LOF (Breunig, Kriegel, Raymond & Sander, 2000) computes a *local outlier factor* (*lof*) for each point, indicating its *degree of outlyingnes*s. This *outlier factor* is computed using local density of the point and that of its neighbors. Neighborhood of a point is determined by the area covering a user specified minimum number of points (*k*). For a point *p*, the algorithm first computes *k*-nearest neighbor i.e. $D^k(p)$. Subsequently, for given *k*, it computes *reachability distance* for each point *p* w.r.t. another point *o* ($reach\text{-}dist_k(p)$) as the maximum of $dist(p,o)$ and $D^k(p)$. Figure 3 explains the concept for $k = 5$. $reach\text{-}dist_k(s)$ is simply a distance between points *s* and *r* as they are very far from each other. But points *q* and *r* are closer, hence $reach\text{-}dist_k(q)$ is equal to $D^k(r)$. For each *p*, *lof* is computed using $reach\text{-}dist_k(p)$ and those of *p*'s *k*-nearest neighbors. Points with high *lof* are reported as outliers. Although LOF works effectively for high-dimensional datasets, but selection of *k* is non-trivial.

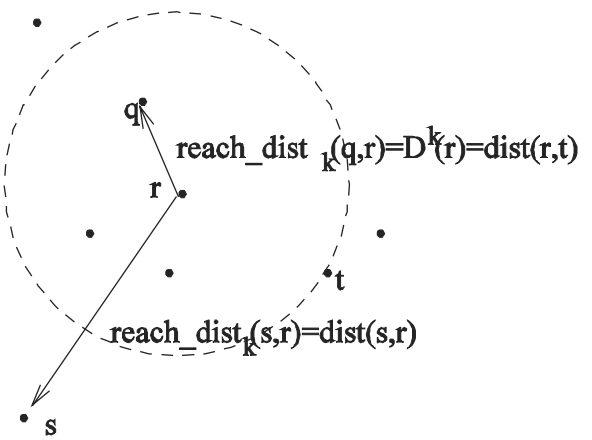
A similar technique LOCI (Papadimitriou, Kitawaga, Gibbons & Faloutsos, 2003), handles the difficulty of selecting values for *k* in LOF using *local correlation integral*. Instead of just computing *outlier score* for each point, it provides detailed information like the data in the vicinity of the point, diameter of neighboring area and inter-region distance etc.. It detects both isolated outliers as well as outlying clusters.

Density-based approach for outlier detection is more powerful than the distance-based approach when a dataset contains patterns with diverse characteristics like density, compactness etc. (Tang, Chen, Fu & Cheung, 2006). It does not suffer from the local density problem because only restricted neighbors of each data point are taken into account while computing *degree of outlyingness*. It also does not scale well for high-dimensional datasets because of index structure used for neighbor search.

OUTLIER DETECTION IN MIXED DATASET

Real life applications require both continuous as well categorical attributes, and detection of outliers from mixed data is still a challenging task. Ghoting, Otey & Parthasarathy (2004) propose LOADED (Link-based Outlier and Anomaly Detection in Evolving Datasets) which is probably the first algorithm to detect outliers from high-dimensional, evolving data with mixed attributes. The algorithm uses a link-based metric that allows outlier detection using efficient determination of dependencies between categorical and continuous attributes. Although it can be tuned to application needs (computation cost vs. accuracy), its performance degrades with increase in the number of categorical attributes.

Figure 3. Computation of $reach\_dist_k$ of points q and s w.r.t. point r for k=5 (Adapted from Breunig, Kreigel, Raymond, & Sander 2000)



FUTURE TRENDS

Outlier detection has been extensively researched for high-dimensional, large static datasets. With rapid change in data capturing technologies, it has become essential for many applications like network monitoring, video capturing, medical condition monitoring etc. to detect outliers on-line. Detection of such outliers is an upcoming and challenging area. Rough-set theory, Neural Network, Density estimation etc. are some upcoming techniques for on-line outlier detection. Different streaming window models like sliding window model, damped window model can be used for this purpose. Bhatnagar & Kaur (2007) detect outliers on the fly using grid-based clustering algorithm in stream.

CONCLUSION

The article introduces the problem of outlier detection and presents three data mining approaches for outlier detection in massive static datasets viz. clustering, distance and density computation. The basic concepts underlying each approach are discussed. Clustering-based approach reports outliers as a by product of clustering and do not rank outliers on the basis of their *outlyingness*. Density-based approaches perform better than distance-based approach for datasets with dense and sparse regions. Outlier detection in stream is an upcoming and challenging task.

KEY TERMS

Clustering: The process of partitioning dataset S into clusters $C_1,\ldots..,C_k$ by finding similarities between data as per characteristics found.

$$S=\bigcup_{i=1}^{k}C_i \quad and \quad C_i \cap C_j = \varphi \quad for \quad i \neq j$$

Data Mining: Extraction of interesting, non-trivial, implicit, previously unknown and potentially useful patterns from large dataset.

Density: It is the number of points in the ε-neighborhood of a point where ε is user input.

Outlier: A point which is substantially different from rest of the points either on single attribute or has an unusual combination of values for more than one attributes.

Local Outlier Factor (*lof*): It represents *outlyingness* of a point *p* w.r.t to its *k* neighbors and is computed as the average of ratio of the local reachability density of *p* and those of *p*'s *k*-nearest neighbors.

$$lof_k(p)=\frac{\sum_{o\in N_k(p)}\frac{lrd_k(o)}{lrd_k(p)}}{|N_k(p)|}$$

Local Reachability Density: It is used to measure compactness of a point *p* w.r.t to its *k* neighbors where highly compact indicates more reachable. It is computed as the inverse of the average reachability distance based on the *k*-nearest neighbors of point *p* .

$$lrd_k(p)=1/\left(\frac{\sum_{o\in N_k(p)} reach-dist_k(p,o)}{|N_k(p)|}\right)$$

where *lrd* stands for local reachability densityand $N_k(p)$ is number of points within $D^k(p)$

Reachability Distance: The *reachabilty distance* of point *p* w.r.t point *o* is defined as

$reach\text{-}dist_k(p,o) = \max\{D^k(o), dist(p,o)\}$

where $D^k(o)$ is the distance of nearest k^{th} neighbor from *o* and *dist*(*p*,*o*) is the distance between points *p* and *o*.

Outlier Detection Techniques for Data Mining

Fabrizio Angiulli
University of Calabria, Italy

INTRODUCTION

Data mining techniques can be grouped in four main categories: clustering, classification, dependency detection, and outlier detection. Clustering is the process of partitioning a set of objects into homogeneous groups, or clusters. Classification is the task of assigning objects to one of several predefined categories. Dependency detection searches for pairs of attribute sets which exhibit some degree of correlation in the data set at hand.

The outlier detection task can be defined as follows: "Given a set of data points or objects, find the objects that are considerably dissimilar, exceptional or inconsistent with respect to the remaining data". These exceptional objects as also referred to as outliers.

Most of the early methods for outlier identification have been developed in the field of statistics (Hawkins, 1980; Barnett & Lewis, 1994). Hawkins' definition of outlier clarifies the approach: "An outlier is an observation that deviates so much from other observations as to arouse suspicions that it was generated by a different mechanism". Indeed, statistical techniques assume that the given data set has a distribution model. Outliers are those points that satisfy a discordancy test, that is, that are significantly far from what would be their expected position given the hypothesized distribution.

Many clustering, classification and dependency detection methods produce outliers as a by-product of their main task. For example, in classification, mislabeled objects are considered outliers and thus they are removed from the training set to improve the accuracy of the resulting classifier, while in clustering, objects that do not strongly belong to any cluster are considered outliers. Nevertheless, it must be said that searching for outliers through techniques specifically designed for tasks different from outlier detection could not be advantageous. As an example, clusters can be distorted by outliers and, thus, the quality of the outliers returned is affected by their presence. Moreover, other than returning a solution of higher quality, outlier detection algorithms can be vastly more efficient than non ad-hoc algorithms.

While in many contexts outliers are considered as noise that must be eliminated, as pointed out elsewhere, "one person's noise could be another person's signal", and thus outliers themselves can be of great interest. Outlier mining is used in telecom or credit card frauds to detect the atypical usage of telecom services or credit cards, in intrusion detection for detecting unauthorized accesses, in medical analysis to test abnormal reactions to new medical therapies, in marketing and customer segmentations to identify customers spending much more or much less than average customer, in surveillance systems, in data cleaning, and in many other fields.

BACKGROUND

Approaches to outlier detection can be classified in supervised, semi-supervised, and unsupervised.

Supervised methods exploit the availability of a labeled data set, containing observations already labeled as normal and abnormal, in order to build a model of the normal class. Since usually normal observations are the great majority, these data sets are unbalanced and specific classification techniques must be designed to deal with the presence of rare classes (Chawla et al., 2004).

Semi-supervised methods assume that only normal examples are given. The goal is to find a description of the data, that is a rule partitioning the object space into an accepting region, containing the normal objects, and a rejecting region, containing all the other objects. These methods are also called one-class classifiers or domain description techniques, and they are related to novelty detection since the domain description is used to identify objects significantly deviating form the training examples.

Unsupervised methods search for outliers in an unlabelled data set by assigning to each object a score which reflects its degree of abnormality. Scores are usually computed by comparing each object with objects belonging to its neighborhood.

Data mining researchers have largely focused on unsupervised approaches. Most of the unsupervised approaches proposed in the data mining literature can be classified as deviation-based (Arning et al., 1996), distance-based (Knorr & Ng, 1998), density-based (Breunig et al., 2000), and MDEF-based (Papadimitriou et al., 2003).

Deviation-based techniques (Arning et al., 1996) identify as exceptional the subset I_x of the overall data set I whose removal maximizes the similarity among the objects in $I–I_x$.

Distance-based outlier detection has been introduced by (Knorr & Ng, 1998) to overcome the limitations of statistical methods: an object O is an outlier in a data set with respect to parameters k and R if at least k objects in the data set lie within distance R from O. This definition generalizes the definition of outlier in statistics. Moreover, it is suitable in situations when the data set does not fit any standard distribution.

(Ramaswamy et al., 2000), in order to provide a ranking of the outliers, modified the previous definition as follows: given two integers k and n, an object O is said to be the n-th top outlier if exactly $n–1$ objects have higher value for D^k than O, where D^k denotes the distance of the k-th nearest neighbor of the object.

Subsequently, (Angiulli & Pizzuti, 2002) with the aim of taking into account the whole neighborhood of the objects, proposed to rank them on the basis of the average distance from their k nearest neighbors, also called weight.

Density-based methods, introduced in (Breunig et al., 2000), are based on the notion of local outlier. Informally, the Local Outlier Factor (LOF) measures the degree of an object to be an outlier by comparing the density in its neighborhood with the average density in the neighborhood of its neighbors. The density of an object is related to the distance to its k-th nearest neighbor. Density-based methods are useful when the data set is composed of subpopulations with markedly different characteristics.

The multi-granularity deviation factor (MDEF), introduced in (Papadimitriou et al., 2003), is in principle similar to the LOF score, but the neighborhood of an object consists of the objects within an user-provided radius and the density of an object is defined on the basis of the number of objects lying in its neighborhood.

In order to discover outliers in spatial data sets, specific definitions are needed: spatial outliers (Shekhar et al., 2003) are spatially referenced object whose non-spatial attribute values are significantly different from the values of their spatial neighborhood, e.g. a new house in an old neighbourhood.

MAIN FOCUS

We overview several recent data mining techniques for outlier detection. We will focus on distance and density-based methods for large data sets, on subspace outlier mining approaches, and on algorithms for data streams.

Algorithms for Distance- and Density-Based Outliers

Distance-based outlier scores are monotonic non-increasing with respect to the portion of the data set already explored. This property allows to design effective pruning rules and very efficient algorithms.

The first two algorithms for mining distance-based outliers in large data sets were presented in (Knorr et al., 2000). The first one is a block nested loop that runs in time quadratic in the size of the data set. The second one is a cell-based algorithm whose temporal cost is exponential in the dimensionality of the data. These methods do not scale well for both large and high-dimensional data. Thus, efforts for developing scalable algorithms have been subsequently made. (Ramaswamy et al., 2000) present two algorithms to detect the top outliers. The first assumes that the dataset is stored in a spatial index. Since the first method is computationally expensive, they also introduce a clustering-based based algorithm, which has been tested up to ten dimensions.

The distance-based outlier detection algorithm ORCA (Bay & Schwabacher, 2003) enhances the naïve block nested loop algorithm with a simple pruning rule and randomization and exhibits good scaling behavior on large and high dimensional data. ORCA manages disk resident data sets and employs a memory buffer of fixed size. Its I/O cost, that is the total number of disk blocks accesses, my become quadratic due to the nested loop strategy. (Ghoting et al., 2006) use a divisive hierarchical clustering algorithm to partition data in a suitable data structure and then employ the strategy of ORCA on this structure, obtaining improved performances. Differently than ORCA, the whole data set must be accommodated in a main memory resident

ad-hoc data structure, hence it is not profitable if the data set does not fit in main memory. (Tao et al., 2006) point out that ORCA may present quadratic I/O cost in terms of pages read from disk. Then, they introduce an algorithm, named SNIF, whose goal is to reduce I/O cost. The algorithm loads in main memory a randomly selected subset of the data set, in order to prune inliers, and then scans three times the data set file. It can be used only with data belonging to a metric space. The DOLPHIN algorithm (Angiulli & Fassetti, 2007a) detects distance-based outliers in disk resident data sets with two scans. It maintains in main memory a provable small fraction of the data set and integrates pruning rules and database indexing technologies. This method is very fast and able to manage large collections of data. It is profitable for metric data, but can be used with any type of data for which a distance function is defined.

The HilOut algorithm (Angiulli & Pizzuti, 2005) detects the top distance-based outliers, according to the weight score, in a numerical data sets. It makes use of the Hilbert space-filling curve and consists of two phases: the first phase guarantees an approximate solution with temporal cost linear in the data set size, but, depending on the characteristics of the data set, may return also the exact solution; the second phase provides the exact solution. HilOut has been experimented with data up to 128 dimensions. It is the only distance-based outlier algorithm guaranteeing an approximate solution within a deterministic factor in time linear with respect to the data set size.

In domains where distance computations are very expensive, e.g. the edit distance between subsequences or the quadratic distance between image color histograms, determining the exact solution may become prohibitive. (Wu & Germaine, 2006) consider this scenario and describe a sampling algorithm for detecting distance-based outliers with probabilistic accuracy guarantees.

There are less proposals of scalable algorithms for the density-based definition than for the distance-based one. Among the algorithms for density-based outliers there are aLOCI (Papadimitriou et al., 2003), which detects MDEF-based outliers, and the micro-cluster-based algorithm of (Jin et al., 2001) for mining the top local outliers according to the LOF definition. The last method compresses the data set into hyper-spherical micro-clusters, and then computes upper and lower bounds for the LOF of objects in each micro-cluster and exploits them to prune inliers.

Distance and density based definitions are mainly considered in the context of unsupervised outlier detection, but can also be used as semi-supervised methods (Lazarevic et al., 2003). (Angiulli et al., 2006) introduce the concept of outlier detection solving set for the definition provided in (Angiulli & Pizzuti, 2005), which is a compressed representation for outlier prediction. (Angiulli, 2007) generalizes the aforementioned approach in order to encompass the definition provided in (Knorr & Ng, 1998) and compares it with well-established one-class classification methods.

(Xiong et al., 2006), besides presenting a novel method called HCleaner, experiment distance- and density-based outlier detection definitions as noise removal techniques, concluding that outlier detection can enhance quality of data analysis.

Subspace Outlier Mining

Aforementioned methods considered search for objects which can be regarded as anomalous by looking at the full dimensional space. In many real situations an object exhibits exceptional characteristics only when the attention is restricted to a subset of the features, also said subspace. Thus, some recent approaches to outlier detection deal with the enormous search space composed by all the subsets of the overall set of attributes.

(Knorr & Ng, 1999) focus on the identification of the intensional knowledge associated with distance-based outliers. First, they detect the outliers in the full attribute space and then, for each outlier O, they search for the subspace that better explains why it is exceptional, that is the minimal subspace in which O is still an outlier.

In many situations it is of interest to single out the properties that mostly deviate a single individual, which is not necessarily an outlier in the full dimensional space, from the whole population. The algorithm HighDOD (Zhang & Wang, 2006) searches for the subspaces in which an input point is an outlier according to definition provided in (Angiulli & Pizzuti, 2002). The algorithm is a dynamic subspace search method that utilizes a sampling-based learning process to identify promising subspaces. (Zhang et al., 2006) present a variant of the previously described task based on the definition provided in (Ramaswamy et al., 2000).

(Aggarwal & Yu, 2001) detect anomalies in a d-dimensional data set by identifying abnormal lower

dimensional projections. Each attribute is divided into equi-depth ranges, and then k-dimensional hyper-cubes ($k<d$) in which the density is significantly lower than expected are searched for. The technique is based on evolutionary algorithms. Also (Wei et al., 2003) exploit subspaces in order to detect outliers in categorical data sets. They search for sets of attributes being able to single out a portion of the data set in which the value assumed by some objects on a single additional attribute becomes infrequent with respect to the mean frequency of the values in the domain of that attribute.

Subspaces can be useful to perform example-based outlier detection: a set of example outliers is given as input and the goal is to detect the data set objects which exhibit the same exceptional characteristics as the example outliers. (Zhu et al., 2005) accomplish this task by means of a genetic algorithm searching for the subspace minimizing the density associated with hyper-cubes containing user examples.

Another interesting direction is exploiting subspaces to improve accuracy. In this context (Lazarevic & Kumar, 2005) experiment feature bagging: the same outlier detection algorithm is executed multiple times, each time considering a randomly selected set of features from the original feature set, and finally outlier scores are combined in order to find outliers of better quality.

Online and Data Streams Algorithms

Methods previously discussed are designed to work in the batch framework, that is under the assumption that the whole data set is stored in either secondary or main memory, and that multiple passes over the data can be accomplished. Hence these methods are not specific for the online paradigm or for processing data streams.

The SmartSifter system (Yamanishi, 2000) is an example of online algorithm. It employs an online discounting learning algorithm to learn a probabilistic model representing the data source. Every time a datum is input, SmartSifter evaluates how large the datum is deviated relative to a normal pattern.

In the data stream scenario, (Aggarwal, 2005) focuses on detecting rare events. Rare events are defined on the basis of their deviation from expected values computed on historical trends. (Subramaniam et al., 2006) present a distributed framework to approximate data distributions coming from a sensor network. Kernel estimators are exploited to approximate data distributions in order to report distance-based or MDEF-based outlying values in the union of the readings coming from multiple sensors. The STORM algorithm (Angiulli & Fassetti, 2007b) mines exact or approximate distance-based outliers under the sliding window model, where outlier queries are performed in order to detect anomalies in the current window.

FUTURE TRENDS

Searching for outliers in subspaces, or exploiting subspaces to improve accuracy or to explain outlierness is a relatively novel research topic, which has not been sufficiently explored. Also fast approximate unsupervised methods and condensed representations for the semi-supervised setting deserve further investigation. Currently there is great interest in novel definitions and methods specifically designed for rich data types, such has various forms of sequences and graphs, and for specific environments, such as grids and sensor networks. For instance, (Sun et al., 2006) present an approach to mine for sequential outliers using Probabilistic Suffix Trees, while (Palatin et al., 2006) consider a grid monitoring system which automatically detects oddly behaving machines by means of a distributed version of the HilOut algorithm. A very interesting direction concerns also the capability of exploiting domain knowledge in order to guide search for anomalous observations, as, for example, accounted for in (Angiulli et al., 2008).

CONCLUSION

We introduced the outlier detection task from a data mining perspective. We provided an up-to-date view on distance- and density-based methods for large data sets, on subspace outlier mining approaches, and considered also some algorithms for processing data streams. Throughout the work we presented different outlier mining tasks, pointed out peculiarities of the various methods, and addressed relationships among them. There is an intense activity in this field, which is even expected to increase due to the broad applicability of outlier detection techniques, and to challenging future directions.

KEY TERMS

Distance-Based Outlier: An observation lying in a scarcely populated region of the feature space. Formally, an object such that at lest a fraction p of the objects lies greater than distance R from it, where p and R are user-provided parameters. This definition generalizes some statistical definitions for outliers.

Example-Based Outlier: An object whose exceptional characteristics are similar to those of a set of user-provided examples.

Local Outlier: An object whose density significantly deviates from the average density of its nearest neighbors. The density of an object can be defined in several ways; e.g., the reciprocal of the average distance to its nearest neighbors. A local outlier is also called a density-based outlier.

Noise: An object whose presence may degrade the quality of the output of a data analysis technique, as for example the predictive accuracy of a classification method.

Outlier: An observation which appears to be inconsistent with the remainder of the set of data.

Spatial Outlier: A spatially referenced object (e.g., houses, roads, traffic sensors, etc) whose non-spatial attribute values (e.g., age, owner, manufacturer, measurement readings, etc) are significantly different from the values of its spatial neighborhood.

Subspace Outlier: An object which becomes an outlier only when a specific subset of the overall set of attributes is considered.

Path Mining and Process Mining for Workflow Management Systems

Jorge Cardoso
SAP AG, Germany

W.M.P. van der Aalst
Eindhoven University of Technology, The Netherlands

INTRODUCTION

Business process management systems (Smith and Fingar 2003) provide a fundamental infrastructure to define and manage business processes and workflows. These systems are often called process aware information systems (Dumas, Aalst et al. 2005) since they coordinate the automation of interconnected tasks. Well-known systems include Tibco, WebSphere MQ Workflow, FileNet, COSA, etc. Other types of systems, such as ERP, CRM, SCM, and B2B, are also driven by explicit process models and are configured on the basis of a workflow model specifying the order in which tasks need to be executed.

When process models or workflows are executed, the underlying management system generates data describing the activities being carried out which is stored in a log file. This log of data can be used to discover and extract knowledge about the execution and structure of processes. The goal of process mining is to extract information about processes from logs.

When observing recent developments with respect to *process aware information systems* (Dumas, Aalst et al. 2005) three trends can be identified. First of all, workflow technology is being embedded in service oriented architectures. Second, there is a trend towards providing more flexibility. It is obvious that in the end business processes interface with people. Traditional workflow solutions expect the people to adapt to the system. However, it is clear that in many situations this is not acceptable. Therefore, systems are becoming more flexible and adaptable. The third trend is the omnipresence of event logs in today's systems. Current systems ranging from cross-organizational systems to embedded systems provide detailed event logs. In a service oriented architecture events can be monitored in various ways. Moreover, physical devices start to record events. Already today many professional systems (X-ray machines, wafer stepper, high-end copiers, etc.) are connected to the internet. For example, Philips Medical Systems is able to monitor all events taking place in their X-ray machines.

The three trends mentioned above are important enablers for path mining and process mining. The abundance of recorded events in structured format is an important enabler for the analysis of run-time behavior. Moreover, the desire to be flexible and adaptable also triggers the need for monitoring. If processes are not enforced by some system, it is relevant to find out what is actually happening, e.g., how frequently do people deviate from the default procedure.

BACKGROUND

Path mining can be seen as a tool in the context of Business Process Intelligence (BPI). This approach to path mining uses generic mining tools to extract implicit rules that govern the path of tasks followed during the execution of a process. Generally, the realization of a process can be carried out by executing a subset of tasks. Path mining is fundamentally about identifying the subset of tasks that will be potentially be triggered during the realization of a process. Path mining is important to process Quality of Service (QoS) prediction algorithms (Cardoso, Miller et al. 2004). In processes for e-commerce, suppliers and customers define a contract between the two parties, specifying QoS items such as products or services to be delivered, deadlines, quality of products, and cost of services. A process, which typically has a graph-like representation, includes a number of linearly independent control paths (i.e. paths that are

executed in parallel). Depending on the path followed during the execution of a process, the QoS may substantially be different. If we can predict with a certain degree of confidence the path that will be followed at runtime, we can significantly increase the precision of QoS estimation algorithms for processes.

Process mining has emerged as a way to analyze systems and their actual use based on the event logs they produce (Aalst, Dongen, et al. 2003; Aalst, Weijters, Maruster, 2004; Aalst, Reijers, et al. 2007). Note that, unlike classical data mining, the focus of process mining is on concurrent processes and not on static or mainly sequential structures. Process mining techniques attempt to extract non-trivial and useful information from event logs. One element of process mining is control-flow discovery, i.e., automatically constructing a process model (e.g., a Petri net) describing the causal dependencies between activities. In many domains, processes are evolving and people, typically, have an oversimplified and incorrect view on the actual business processes. Therefore, it is interesting to compare reality (as recorded in the log) with models. Since process mining is so important for organizations, there was the need to develop a system which implements the most significant algorithms developed up to date. Therefore, the ProM framework has been developed as a completely plug-able environment. Different research groups spread out over the world have contributed to ProM. Currently there are more than 150 plug-ins available, thus supporting all aspects of process mining (Aalst, Reijers, et al. 2007).

SETTINGS

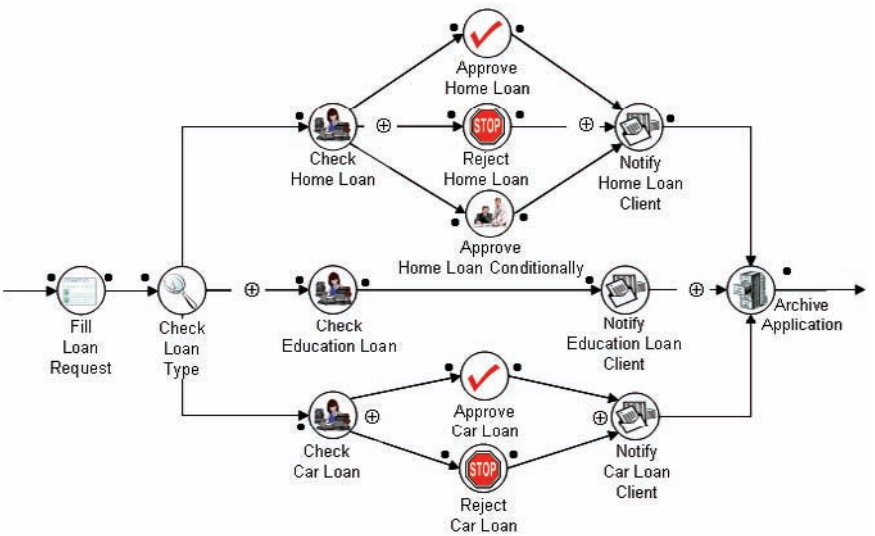
This section presents a typical business process model and illustrates also a typical process log. These two elements will be use to explain the concepts of path mining and process mining in the next section.

Business Process Scenario

A major bank has realized that to be competitive and efficient it must adopt a new and modern information system infrastructure. Therefore, a first step was taken in that direction with the adoption of a workflow management system to support its business processes. All the services available to customers are stored and executed under the supervision of the workflow system. One of the services supplied by the bank is the loan process depicted in Figure 1.

The process of the scenario is composed of fourteen tasks. For example, The Fill Loan Request task allows clients to request a loan from the bank. In this step, the client is asked to fill in an electronic form with personal information and data describing the condition of the loan being requested. The second task, Check Loan Type, determines the type of loan a client has requested

Figure 1. The loan process



and, based on the type, forwards the request to one of three tasks: Check Home Loan, Check Educational Loan, or Check Car Loan.

Process Log

Many systems have some kind of event log often referred to as "history", "audit trail", "transaction log", etc. (Agrawal, Gunopulos et al. 1998; Grigori, Casati et al. 2001; Sayal, Casati et al. 2002; Aalst, Dongen et al. 2003). The event log typically contains information about events referring to a task and a case. The case (also named process instance) is the "thing" which is being handled, e.g., a customer order, a job application, an insurance claim, or a building permit. Table 1 illustrates an example of a process log.

PATH MINING

To perform path mining, current process logs need to be extended to store information indicating the values and the type of the input parameters passed to tasks and the output parameters received from tasks. Table 2 shows an extended process log which accommodates input/output values of tasks parameters that have been generated at runtime. Each 'Parameter/Value' entry has a type, a parameter name, and a value (for example, string loan-type="car-loan").

Additionally, the process log needs to include path information, a path describing the tasks that have been executed during the enactment of a process. For example, in the process log illustrated in Table 2, the service NotifyUser is the last service of a process. The log has been extended in such a way that the NotifyUser record contains information about the path that has been followed during the process execution.

Process Profile

When beginning work on path mining, it is necessary to elaborate a profile for each process. A profile provides the input to machine learning and it is characterized by its values on a fixed, predefined set of attributes. The attributes correspond to the task input/output parameters that have been stored previously in the process log. Path mining will be performed on these attributes.

Profile Classification

The attributes present in a profile trigger the execution of a specific set of tasks. Therefore, for each profile previously constructed, we associate an additional attribute, the path attribute, indicating the path followed

Table 1. Process log

Date	Process	Case	Task	Task instance	Cost	Dur.	…
6:45 03-03-04	LoanApplication	LA04	RejectCarLoan	RCL03	$1.2	13 min	…
6:51 03-03-04	TravelRequest	TR08	FillRequestTravel	FRT03	$1.1	14 min	…
6:59 03-03-04	TravelRequest	TR09	NotifyUser	NU07	$1.4	24 hrs	…
7:01 03-03-04	InsuranceClaim	IC02	SubmitClaim	SC06	$1.2	05 min	…
…	…	…	…	…	…	…	…

Table 2. Extended process log

…	Case	Task	Task instance	Parameter/Value	Path	…
…	LA04	NotifyCLoanClient	NLC07	string e-mail="jf@uma.pt"	…	…
…	LA05	CheckLoanRequest	CLR05	double income=12000; string Name="Eibe Frank";	…	…
…	TR09	NotifyUser	NU07	String e-mail=jf@uma.pt; String telef="35129170023"	FillForm->CheckForm->Approve->Sign->Report	…
…	…	…	…		…	…

when the attributes of the profile have been assigned to specific values. The path attribute is a target class. Classification algorithms classify samples or instances into target classes. Once the profiles and a path attribute value for each profile have been determined, we can use data mining methods to establish a relationship between the profiles and the paths followed at runtime.

Experiments

In this section, we present the results of applying an algorithm to a synthetic loan dataset. To generate a synthetic dataset, we start with the process presented in the introductory scenario, and using this as a process model graph, log a set of process instance executions.

The data are lists of event records stored in a process log consisting of process names, instance identification, task names, variable names, etc.Table 3 shows the additional data that have been stored in the process log. The information includes the task variable values that are logged by the system and the path that has been followed during the execution of instances. Each entry corresponds to an instance execution.

Process profiles are characterized by a set of six attributes: income, loan_type, loan_amount, loan_years, name and SSN. These attributes correspond to the task input/output parameters that have been stored previously in the process log presented inTable 3. Each profile is associated with a class indicating the path that has been followed during the execution of a process when the attributes of the profile have been assigned specific values. The last column ofTable 3 shows the class named path.

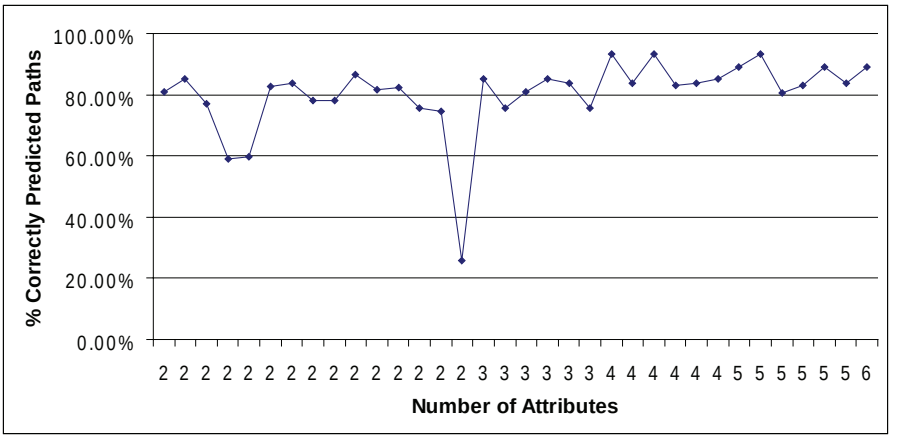
Once profiles are constructed and associated with paths, this data is combined and formatted to be analyzed using Weka (Weka 2004). We have used the J.48 algorithm, which is Weka's implementation of the C4.5 (Hand, Mannila et al. 2001; Weka 2004) decision tree learner to classify profiles.

Each experiment has involved data from 1000 process executions and a variable number of attributes (ranging from 2 attributes to 6 attributes). We have conducted 34 experiments, analyzing a total of 34000 records containing data from process instance executions. Figure 2 shows the results that we have obtained.

Table 3. Additional data stored in the process log

income	loan_type	Loan_ amount	loan_ years	name	SSN	Path
1361.0	Home-Loan	129982.0	33	Bernard-Boar	10015415	FR>CLT>CHL>AHL>NHC>CA
Unknown	Education-Loan	Unknown	Unknown	John-Miller	15572979	FR>CLT>CEL>CA
1475.0	Car-Loan	15002.0	9	Eibe-Frank	10169316	FR>CLT>CCL>ACL>NCC>CA
…	…	…	…	…	…	…

Figure 2. Experimental results



The path mining technique developed has achieved encouraging results. When three or more attributes are involved in the prediction, the system is able to predict correctly the path followed for more than 75% of the process instances. This accuracy improves when four attributes are involved in the prediction, in this case more than 82% of the paths are correctly predicted. When five attributes are involved, we obtain a level of prediction that reaches a high of 93.4%. Involving all the six attributes in the prediction gives excellent results: 88.9% of the paths are correctly predicted. When a small number of attributes are involved in the prediction, the results are not as good. For example, when only two attributes are selected, we obtain predictions that range from 25.9% to 86.7%.

PROCESS MINING

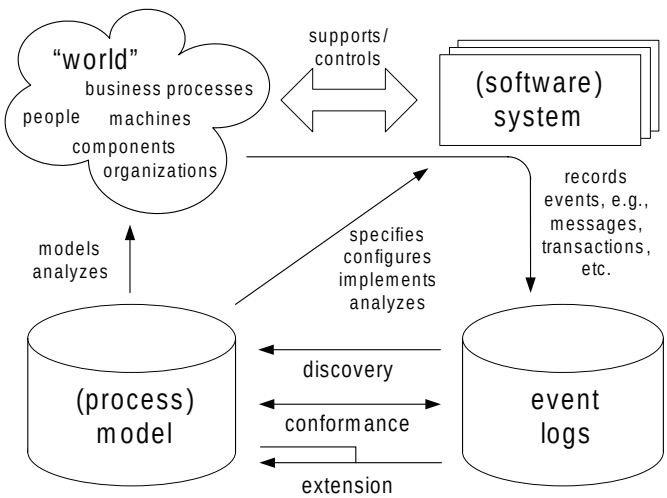
Assuming that we are able to log events, a wide range of process mining techniques comes into reach (Aalst, Dongen, et al. 2003; Aalst, Weijters, Maruster, 2004; Aalst, Reijers, et al. 2007). The basic idea of process mining is to learn from observed executions of a process and (1) to discover new models (e.g., constructing a Petri net that is able to reproduce the observed behavior), (2) to check the conformance of a model by checking whether the modeled behavior matches the observed behavior, and (3) to extend an existing model by projecting information extracted from the logs onto some initial model (e.g., show bottlenecks in a process model by analyzing the event log).

Process discovery: Traditionally, process mining has been focusing on discovery, i.e., deriving information about the original process model, the organizational context, and execution properties from enactment logs. An example of a technique addressing the control flow perspective is the alpha algorithm, which constructs a Petri net model (Aalst, Weijters, Maruster, 2004) describing the behavior observed in the event log. For example, based on a log like the one depicted in Table 1 it is possible to discover the process model shown in Figure 1. In fact to discover this process model, only the columns “Case” and “Task” are needed.

Conformance checking: Conformance checking compares an a-priori model with the observed behavior as recorded in the log. In (Rozinat, Aalst, 2005) it is shown how a process model (e.g., a Petri net) can be evaluated in the context of a log using metrics such as “fitness” (is the observed behavior possible according to the model?) and “appropriateness” (Is the model “typical” for the observed behavior?). In the example, we could compare the observed behavior in Table 1 with the modeled behavior in Figure 1.

Process extension: There are different ways to extend a given process model with additional perspectives

Figure 3. The three types of process mining (discovery, conformance, and extension) and their relations with models and event logs



based on event logs, e.g., decision mining (Rozinat, Aalst, 2006). Starting from a process model, one can analyze how data attributes influence the choices made in the process based on past process executions. A process model can be extended with timing information (e.g., bottleneck analysis). Clearly, decision mining is closely related to path mining. For example, it is possible to highlight bottlenecks in a discovered process model using the timestamps typically present in a log.

Figure 3 shows the three types of process mining introduced above (discovery, conformance, and extension). Each of the techniques involves a model and an event log. In case of discovery the process model is discovered on the basis of the data present in the log. In case of conformance and extension there is already some initial model.

ProM

In recent years ProM (www.processmining.org) has emerged as a broad and powerful process analysis tool, supporting all kinds of analysis related to business processes (such as verification and error checking). In contrast to many other analysis tools the starting point was the analysis of real processes rather than modeled processes, i.e., using *process mining* techniques ProM attempts to extract non-trivial and useful information from so-called "event logs".

Traditionally, most analysis tools focusing on processes are restricted to *model-based analysis*, i.e., a model is used as the starting point of analysis. For example, a purchasing process can be modeled using EPCs (Event-Driven Process Chains) and verification techniques can then be used to check the correctness of the protocol while simulation can be used to estimate performance aspects. Such analysis is *only useful if the model reflects reality*. Therefore, ProM can be used to both analyze models and logs. Basically, ProM supports all types of analysis mentioned before and the goal is to support the entire spectrum shown in Figure 3. It provides a plug-able environment for process mining offering a wide variety of plug-ins for process discovery, conformance checking, model extension, model transformation, etc. ProM is open source and can be downloaded from www.processmining.org. Many of its plug-ins work on Petri nets, e.g., there are several plug-ins to discover Petri nets using techniques ranging from genetic algorithms and heuristics to regions and partial orders. Moreover, Petri nets can be analyzed in various ways using the various analysis plug-ins. However, ProM allows for a wide variety of model types, conversions, and import and export facilities. For example, it is possible to convert Petri nets into BPEL, EPCs and YAWL models and vice versa.

FUTURE TRENDS

In the future, it is expected to see a wider spectrum of applications managing processes in organizations. According to the Aberdeen Group's estimates, spending in the Business Process Management software sector (which includes workflow systems) reached $2.26 billion in 2001 (Cowley 2002).

We are currently extending and improving mining techniques and continue to do so given the many challenges and open problems. For example, we are developing genetic algorithms to improve the mining of noisy logs. Recently, we added a lot of new functionality to the ProM framework. ProM is already able to mine from FLOWer logs and we applied this in a Dutch social security agency. Moreover, we have used ProM to analyze the processes of different hospitals, municipalities, governmental agencies, and banks. We use process mining to analyze the actual use of copiers, medical equipment, and wafer steppers. Furthermore, we are extending ProM with quality metrics to analyze business processes (Vanderfeesten, Cardoso et al. 2007; Mendling, Reijers et al. 2007).

CONCLUSION

Business Process Management Systems, processes, workflows, and workflow systems represent fundamental technological infrastructures that efficiently define, manage, and support business processes. The data generated from the execution and management of processes can be used to discover and extract knowledge about the process executions and structure.

We have shown that one important area of processes to analyze is path mining, i.e. the prediction of the path that will be followed during the execution of a process. From the experiments, we can conclude that classification methods are a good solution to perform path mining on administrative and production processes. We have also shown that business process mining aims at the extraction of knowledge from the behavior observed

in the event log. This type of mining can be used to, for example, construct a model based on an event log or to check if reality conforms to the model. Several process mining techniques have been implemented and are made available through the ProM framework.

KEY TERMS

Business Process: A set of one or more linked activities which collectively realize a business objective or goal, normally within the context of an organizational structure.

Business Process Management System: A Business Process Management System (BPMS) provides an organization with the ability to collectively define and model their business processes, deploy these processes as applications that are integrated with their existing software systems, and then provide managers with the visibility to monitor, analyze, control and improve the execution of those processes.

Process Definition: The representation of a business process in a form which supports automated manipulation or enactment by a workflow management system.

Process Log: During the execution of processes, events and messages generated by the enactment sys-

tem are recorded and stored in a process log. It is an electronic archive in which the history of instances is recorded. It contains various details about each instance, such as starting time, tasks performed and resources allocated.

Task: A task is an "atomic" process: one which is not further subdivided into component processes. It is thus a logical unit of work; in other words a task is either carried out in full or not at all.

Workflow: The automation of a business process, in whole or part, during which documents, information or tasks are passed from one participant to another for action, according to a set of procedural rules.

Workflow Engine: A workflow engine provides the actual management of workflows. Amongst other things, it is concerned with task-assignment generation, resource allocation, activity performance, the launching of applications and the recording of logistical information.

Workflow Management System: A system that defines, creates and manages the execution of workflows through the use of software which is able to interpret the process definition, interact with participants and, where required, invoke the use of tools and applications.

Pattern Discovery as Event Association

INTRODUCTION

A basic task of machine learning and data mining is to automatically uncover **patterns** that reflect regularities in a data set. When dealing with a large database, especially when domain knowledge is not available or very weak, this can be a challenging task. The purpose of **pattern discovery** is to find non-random relations among events from data sets. For example, the "exclusive OR" (XOR) problem concerns 3 binary variables, A, B and C=A⊗B, i.e. C is true when either A or B, but not both, is true. Suppose not knowing that it is the XOR problem, we would like to check whether or not the occurrence of the compound event [A=T, B=T, C=F] is just a random happening. If we could estimate its frequency of occurrences under the random assumption, then we know that it is not random if the observed frequency deviates significantly from that assumption. We refer to such a compound event as an event association pattern, or simply a **pattern**, if its frequency of occurrences significantly deviates from the default random assumption in the statistical sense. For instance, suppose that an XOR database contains 1000 samples and each primary event (e.g. [A=T]) occurs 500 times. The expected frequency of occurrences of the compound event [A=T, B=T, C=F] under the independence assumption is $0.5\times0.5\times0.5\times1000 = 125$. Suppose that its observed frequency is 250, we would like to see whether or not the difference between the observed and expected frequencies (i.e. 250 – 125) is significant enough to indicate that the compound event is not a random happening.

In statistics, to test the correlation between random variables, **contingency table** with chi-squared statistic (Mills, 1955) is widely used. Instead of investigating variable correlations, pattern discovery shifts the traditional correlation analysis in statistics at the variable level to association analysis at the event level, offering an effective method to detect statistical association among events.

In the early 90's, this approach was established for second order event associations (Chan & Wong, 1990). A higher order **pattern discovery** algorithm was devised in the mid 90's for discrete-valued data sets (Wong & Yang, 1997). In our methods, patterns inherent in data are defined as statistically significant associations of two or more primary events of different attributes if they pass a statistical test for deviation significance based on **residual analysis**. The discovered high order patterns can then be used for classification (Wang & Wong, 2003). With continuous data, events are defined as Borel sets and the pattern discovery process is formulated as an optimization problem which recursively partitions the sample space for the best set of significant events (patterns) in the form of high dimension intervals from which probability density can be estimated by Gaussian kernel fit (Chau & Wong, 1999). Classification can then be achieved using Bayesian classifiers. For data with a mixture of discrete and continuous data (Wong & Yang, 2003), the latter is categorized based on a global optimization discretization algorithm (Liu, Wong & Yang, 2004). As demonstrated in numerous real-world and commercial applications (Yang, 2002), pattern discovery is an ideal tool to uncover subtle and useful patterns in a database.

In pattern discovery, three open problems are addressed. The first concerns learning where noise and uncertainty are present. In our method, noise is taken as inconsistent samples against statistically significant patterns. Missing attribute values are also considered as noise. Using a standard statistical **hypothesis testing** to confirm statistical patterns from the candidates, this method is a less ad hoc approach to discover patterns than most of its contemporaries. The second problem

concerns the detection of polythetic patterns without relying on exhaustive search. Efficient systems for detecting monothetic patterns between two attributes exist (e.g. Chan & Wong, 1990). However, for detecting polythetic patterns, an exhaustive search is required (Han, 2001). In many problem domains, polythetic assessments of feature combinations (or higher order relationship detection) are imperative for robust learning. Our method resolves this problem by directly constructing polythetic concepts while screening out non-informative pattern candidates, using statistics-based heuristics in the discovery process. The third problem concerns the representation of the detected patterns. Traditionally, if-then rules and graphs, including networks and trees, are the most popular ones. However, they have shortcomings when dealing with multilevel and multiple order patterns due to the non-exhaustive and unpredictable hierarchical nature of the inherent patterns. We adopt **attributed hypergraph** (AHG) (Wang & Wong, 1996) as the representation of the detected patterns. It is a data structure general enough to encode information at many levels of abstraction, yet simple enough to quantify the information content of its organized structure. It is able to encode both the qualitative and the quantitative characteristics and relations inherent in the data set.

BACKGROUND

In the ordinary sense, "discovering regularities" from a system or a data set implies partitioning the observed instances into classes based on similarity. Michalski and Stepp (1983) pointed out that the traditional distance-based statistical clustering techniques make no distinction among relevant, less relevant and irrelevant attributes nor do they render conceptual description of the clusters with human input. They proposed CLUSTER/2 as a conceptual clustering algorithm in a noise-free environment. It is effective for small data sets containing no noise yet computationally expensive for a large data set even with its Hierarchy-building Module. To deal with noise, COBWEB was introduced by Fisher (1987). However, the concept tree generated by COBWEB might be very large. For deterministic pattern discovery problems such as the MONK, COBWEB does not work well when compared with other AI and connectionist approaches (Han, 2001).

The Bayesian methods provide a framework for reasoning with partial beliefs under uncertainty. To perform inferences, they need to estimate large matrices of probabilities for the network during training (Pearl, 1988). When going to high-order cases, the contingency table introduces a heavy computation load.

Agrawal and Srikant (1994) proposed association rule mining to detect relationship among items in transactional database. It is well-suited to applications such as market basket analysis but not applicable in some other applications such as capturing correlations between items where association rules may be misleading (Han, 2001). Hence, Brin, Motwani and Silverstein (1997) proposed to detect correlation rules from the contingency table. However, correlation rule mining is not accurate when the contingency table is sparse or larger than 2×2 (Han, 2001) since it is designed for testing the correlation of two random variables.

Pattern discovery shifts the statistical test from the entire **contingency table** to the individual cells in the table. A **hypothesis test** at each individual cell is formalized by **residual analysis**. Therefore, it handles sparse and high dimensional contingency table much more effectively.

Recent development in pattern discovery methodologies includes building classifiers based on the discovered patterns. A typical example is Liu, Hsu and Ma 's CBA (1998) that uses association rules to classify data. More recent works include HWPR (Wang & Wong, 2003) and DeEPs (Li et. al., 2004). HWPR employs event associations as classification rules whereas DeEPs uses emerging patterns, a variation of association rules, to classify data. A detailed evaluation and comparison of these methods can be found in (Sun et. al., 2006).

MAIN FOCUS

Event Associations

Consider a data set D containing M data samples. Every sample is described by N attributes, each of which can assume values from its own finite discrete alphabet. Let $\mathbf{X} = \{ X_1, \ldots, X_N \}$ represent this attribute set. Then, each attribute, X_i, $1 \leq i \leq N$, can be seen as a random variable taking on values from its alphabet $\alpha_i = \{\alpha_i^1, ..., \alpha_i^{m_i}\}$, where m_i is the cardinality of the alphabet of the ith attribute. Thus, a realization of $\mathbf{X}$ can be denoted by $\mathbf{x} = \{ x_1, \ldots, x_N \}$, where x_i can assume

any value in α_i. In this manner, each data sample **x** is a realization of **X**.

Definition 1: *A primary event of a random variable X_i ($1 \le i \le N$) is a realization of X_i taking on a value from α_i.*

The pth ($1 \le p \le m_i$) primary event of X_i can be denoted as

$$[X_i = \alpha_i^p]$$

or simply x_{ip}. We use x_i to denote the realization of X_i.

Let **s** be a subset of integers $\{1, \ldots, N\}$ containing k elements ($k \le N$) and $\mathbf{X}^s$ be a subset of **X** such that

$$\mathbf{X}^s = \{X_i \mid i \in \mathbf{s}\}$$

Then $\mathbf{x}^s_p$ represents the pth realization of $\mathbf{X}^s$. We use $\mathbf{x}^s$ to denote a realization of $\mathbf{X}^s$.

Definition 2: *A compound event associated with the variable subset $\mathbf{X}^s$ is a set of primary events instantiated by a realization $\mathbf{x}^s$ with order $|\mathbf{s}|$.*

A 1-compound event is a primary event. A k-compound event is made up of k primary events of k variables. Every sample is an N-compound event. For example, in the XOR problem, [A=T] is a primary event, [A=F, C=T] is a two-compound event, and, [A=T, B=F, C=T] is a three-compound event.

Definition 3: *Let T be a statistical significance test. If the frequency of occurrences of a compound event $\mathbf{x}^s$ is significantly deviated from its expectation based on a default probabilistic model, we say that $\mathbf{x}^s$ is a significant association pattern, or a pattern of order $|\mathbf{s}|$.*

The default model in definition 3 is the hypothesis that the variables in $\mathbf{X}^s$ are mutually independent. We then use the *standardized residual* (Haberman, 1974) to test the significance of its occurrence against the independence assumption. In the XOR example in the introduction section, the standardized residual of the compound event [A=T, B=T, C=F] is 11.18, larger than 1.96 which is the value at the 95% significant level. Thus, we conclude that the compound event *significantly deviates* from its independence expectation. Therefore, this compound event is a third-order pattern.

Let us denote the observed occurrences of compound event $\mathbf{x}^s$ as $o_{\mathbf{x}^s}$ and its expected occurrences as $e_{\mathbf{x}^s}$. Then,

$$e_{\mathbf{x}^s} = M \prod_{i \in \mathbf{s}, x_i \in \mathbf{x}^s} P(x_i) \qquad (1)$$

where $P(x_i)$ is estimated by the proportion of the occurrence of x_i to the sample size M.

To test whether or not $\mathbf{x}^s$ is a significant association pattern, *standardized residual* defined in (Haberman, 1974) is used to measure the deviation between $o_{\mathbf{x}^s}$ and $e_{\mathbf{x}^s}$:

$$z_{\mathbf{x}^s} = \frac{o_{\mathbf{x}^s} - e_{\mathbf{x}^s}}{\sqrt{e_{\mathbf{x}^s}}} \qquad (2)$$

Standardized residual $z_{\mathbf{x}^s}$ is the square root of χ^2. It has an asymptotic normal distribution with a mean of approximately zero and a variance of approximately one. Hence, if the value of $z_{\mathbf{x}^s}$ exceeds 1.96, by conventional criteria, we conclude that the primary events of $\mathbf{x}^s$ are "associated" and likely to occur together, with a confidence level of 95 percent. In this case, $\mathbf{x}^s$ is referred to as a positive pattern. If $z_{\mathbf{x}^s}$ is less than -1.96, we conclude that the primary events are unlikely to co-occur. It is referred to as a negative pattern.

Standardized residual is considered to be of normal distribution only when the asymptotic variance of $z_{\mathbf{x}^s}$ is close to one, otherwise, it has to be adjusted by its variance for a more precise analysis. The adjusted residual is expressed as:

$$d_{\mathbf{x}^s} = \frac{z_{\mathbf{x}^s}}{\sqrt{v_{\mathbf{x}^s}}} \qquad (3)$$

where $v_{\mathbf{x}^s}$ is the maximum likelihood estimate of the variance of $z_{\mathbf{x}^s}$ (Wong & Wang, 1997). To avoid exhaustive search, two criteria for eliminating impossible pattern candidates are used. One is the validation of a significance test and the other is testing of higher order negative patterns. An efficient "test-and-discard" search algorithm was developed to prune the searching space (see Wong and Wang (1997) for its complexity analysis).

As an illustration, we apply **pattern discovery** to an XOR data set containing 102 samples with 15% noise randomly added. Figure 1 shows all the patterns detected. Here, the four compound events are found to be

Figure 1. Patterns discovered from the XOR data set with noises

Index	Residual	Probability	Order	A	B	C	
0	3.973630	0.23	3	F	F	F	
1	3.279978	0.19	3	T	F	T	
2	2.784015	0.2	3	F	T	T	+ve
3	1.990939	0.18	3	T	T	F	
4	-2.014950	0.07	3	T	T	T	
5	-2.746582	0.07	3	F	T	F	
6	-3.228580	0.04	3	T	F	F	-ve
7	-4.037667	0.02	3	F	F	T	

statistically significant from their expectations positively, and four others negatively. The output reflects exactly the XOR relationship, e.g. the positive pattern [A=F, B=F, C=F] (the first pattern) states that C=A⊗B=F if A=F and B=F. Furthermore, the negative pattern [A=T, B=T, C=T] (the fifth pattern) states that three events will not occur at the same time. More details about the XOR experiments and others by pattern discovery can be found in Wong and Wang (1997).

Classification based on Event Associations

A well-developed **classification** method is built using the discovered patterns (Wang & Wong, 2003). It generates classification rules by using *weight of evidence* to quantify the evidence of significant association patterns in support of, or against a certain class membership.

In information theory, the difference in the gain of information when predicting attribute Y taking on the value y_i against taking on other values, given $\mathbf{x}$, is a measure of evidence provided by $\mathbf{x}$ in favor of y_i being a plausible value of Y as opposed to Y taking other values. This difference, denoted by $W(Y = y_i / Y \neq y_i \mid \mathbf{x})$, is defined as the weight of evidence:

$$W(Y = y_i / Y \neq y_i \mid \mathbf{x}) = I(Y = y_i : \mathbf{x}) - I(Y \neq y_i : \mathbf{x})$$

$$= \log \frac{P(Y = y_i \mid \underline{\mathbf{x}})}{P(Y = y_i)} - \log \frac{P(Y \neq y_i \mid \underline{\mathbf{x}})}{P(Y \neq y_i)}$$

$$= \log \frac{P(\underline{\mathbf{x}} \mid Y = y_i)}{P(\underline{\mathbf{x}} \mid Y \neq y_i)} \qquad (4)$$

where $I(\cdot)$ is the mutual information. It is positive if $\mathbf{x}$ provides positive evidence supporting Y taking on y_i, otherwise, it is negative, or zero.

Suppose that n sub-compound events $\mathbf{x}_1,\ldots,\mathbf{x}_n$ are detected, where $(\mathbf{x}_k, Y = y_i)$ is a significant event association and

$$\bigcup_{k=1}^{n} \underline{\mathbf{x}}_k = \underline{\mathbf{x}};$$

$$\underline{\mathbf{x}}_p \bigcap \underline{\mathbf{x}}_q = \varphi$$

when $p \neq q$, $1 \leq k, p, q \leq n$. According to Wang and Wong (2003), $W(Y = y_i / Y \neq y_i \mid \mathbf{x})$ can be obtained from the sum of the weights of evidence for all event associations in $\mathbf{x}$ supporting $Y = y_i$. That is

$$W(Y = y_i / Y \neq y_i \mid \mathbf{x}) =$$

$$\log \frac{P(\underline{\mathbf{x}}_1 \mid Y = y_i)}{P(\underline{\mathbf{x}}_1 \mid Y \neq y_i)} + \ldots + \log \frac{P(\underline{\mathbf{x}}_n \mid Y = y_i)}{P(\underline{\mathbf{x}}_n \mid Y \neq y_i)}$$

$$= W(Y = y_i / Y \neq y_i \mid \mathbf{x}_1) + \ldots + W(Y = y_i / Y \neq y_i \mid \mathbf{x}_n)$$

$$= \sum_{k=1}^{n} W(Y = y_i \ / \ Y \neq y_i \mid \underline{\mathbf{x}}_k) \qquad (5)$$

Thus, the calculation of weight of evidence is to find a proper set of disjoint significant event associations from $\mathbf{x}$ and to sum individual weights of evidence provided by each of them. The task of **classification** is to maximize the term in Equation (5) so as to find the most plausible value y_i of Y with the highest weight.

As an illustration and a comparison with other methods, we apply our classification method to the mushroom database from UCI (Murph & Aha, 1987) with 8,124 samples characterized by 23 attributes, including the class label (edible, poisonous). We conducted the experiment in two ways. First, a subset of 500 instances was randomly sampled from the original 8,124 instances. Of the 500, 400 (80%) are used in the discovery phase while the remaining 100 (20%) are used for testing. This process is repeated for 10 times to obtain an average performance. In the 10 trials, the lowest classification accuracy we obtain is 97% and the highest is 100%. The average accuracy is 98.9%. In the second setting, the original 8,124 instances are divided into a subset of 5,416 (66.7%) for pattern discovery and a subset of 2,708 (33.3 %) for classification testing. The accuracy for this one-trial classification is 99.1%. These performances are consistent with others using the same data set. Table 1 is a comparison with the others' results available with the data set in UCI repository. We also ran two common associative classifiers CBA (Liu, Hsu and Ma, 1998) and DeEPs (Li et. al., 2004) and a conventional decision tree C4.5 classifier on the mushroom data. More detailed comparisons can be found in (Sun et. al., 2006).

A specific characteristic of our method is that the rules used for classification can be made explicit for interpretation and further analysis. On the one hand, if we select a particular rule, its detailed usage for classification can be displayed. For example, figure 2 shows that rule 25032 correctly classifies samples 263, 264, etc; and incorrectly classifies samples 300, 326, etc. On the other hand, if we select a particular sample, its detailed classification information can be shown. Figure 3 shows that sample 8 is supported by 8 rules (rules 1108, 25032, etc) as belonging to class edible with infinity weight of evidence.

FUTURE TRENDS

The ultimate goal of automatic knowledge acquisition is to discover useful knowledge inherent in data sets automatically. Once patterns of different orders are discovered, to extract knowledge from patterns, they should be organized and represented in a form appropriate for further analysis and interpretation. Ongoing research in pattern discovery focuses on methods for effective organization and representation of discovered patterns, especially in situations when the number of discovered patterns is enormous. A method known as **pattern clustering** is developed which simultaneously clusters high order patterns and their associated data (Wong & Li, in preparation). It uses an information theoretic measure to reflect the change of uncertainty before and after merging two pattern-associated data sets. At the end of the process, patterns are grouped together into pattern clusters; and their associated data are grouped according to the patterns. The relations among data clusters formed via pattern clustering are then represented in an **attributed hypergraph** which is lucid for pattern interpretation and analysis (Wang & Wong 1996). From the organized relations among data clusters, flexible visualization techniques are under development to enable users to

Table 1. Classification results for mushroom data

Classifier	Training Sample#	Classification Accuracy	Note
STAGGER	1000	95%	asymptoted
HILLARY	1000	95%	ten-trial average
CBA	5416	97.8%	one-trial
DeEPs	5416	99.0%	one-trial
C4.5	5416	99.3%	one-trial
Our method	500	98.9%	ten-trial average
Our method	5416	99.1%	one-trial

Figure 2. The detailed classification usage of rule 235

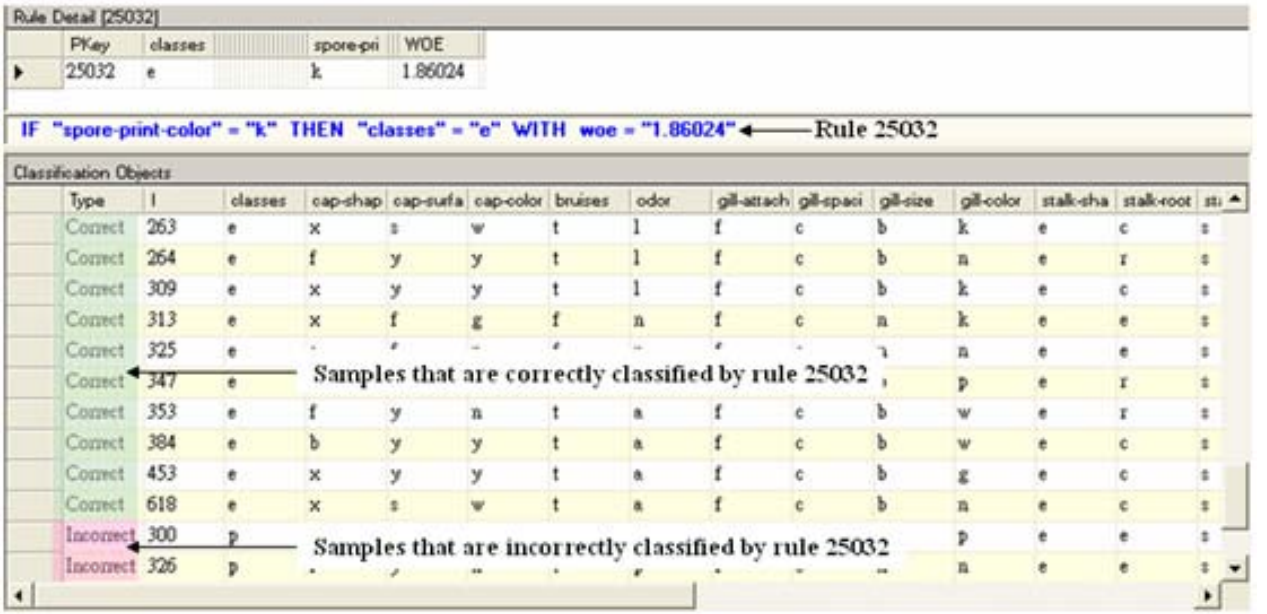

Figure 3. The detailed classification information of sample 8

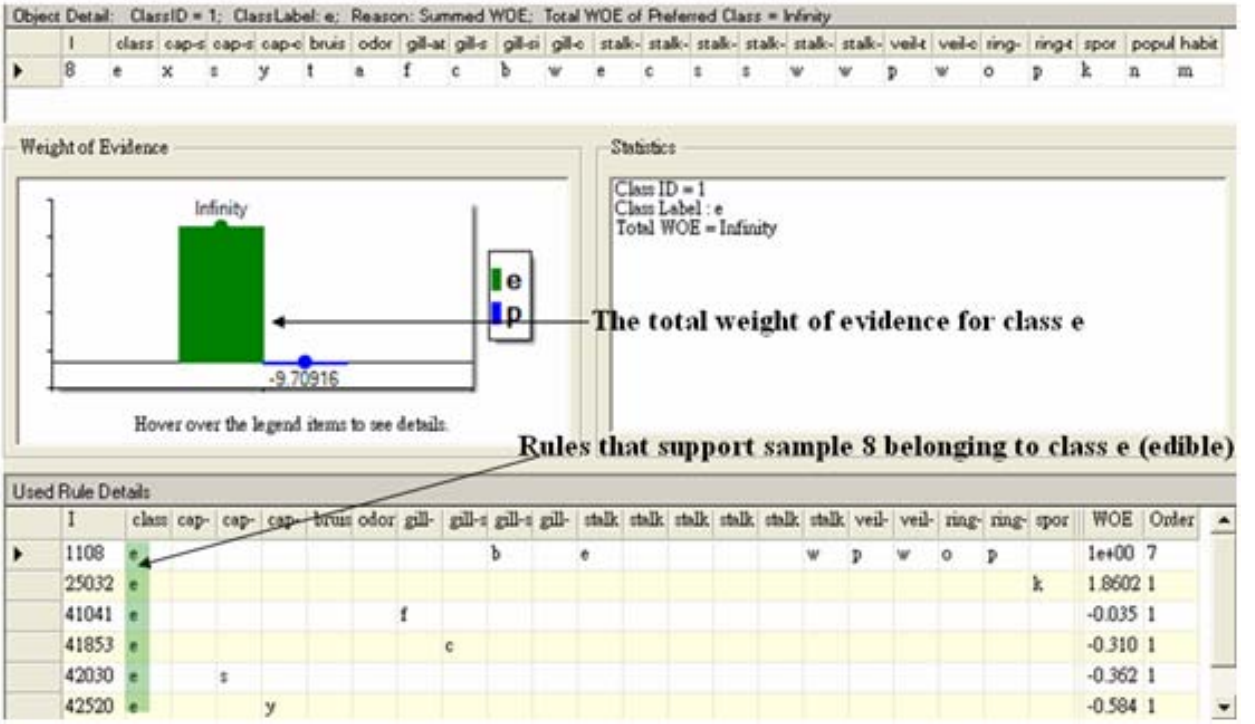

acquire and display the discovered patterns in an effective ways.

In the applications aspect, with its ability to handle mixed mode data, it is generic to handle a great variety of problems. Because it can automatically discover association patterns of residues, genes and gene expression levels, it will be an ideal tool to uncover probabilistic patterns inherent in genomic and microarray data. It is able to relate data groups with similar associated patterns

to drug discovery as well as diagnostic, therapeutic and prognostic supports in healthcare.

CONCLUSION

The fundamental questions pattern discovery methodologies addresses are "what is a pattern?" and "where are the patterns?" By defining patterns as statistical significant event associations, pattern discovery renders an effective and efficient method to automatically discover patterns wherever they are in a data set. The discovered patterns can be used in decision support such as classification, clustering and density estimation. When the discovered patterns and their relations are made explicit, users would have a better understanding of how events are associated and related. Thus pattern discovery provides a means to its users for in-depth understanding, comprehensive interpretation and automatic yet systematic organization of statistically significant associated events with empirical supports that help the growth and reliable use of knowledge.

KEY TERMS

Associative Classification: A classification method based on association patterns/rules.

Attributed Hypergraph: A hypergraph whose vertices and hyperedges have attributes.

Event Association Pattern: A compound event whose occurrence significantly deviates from the random model.

Negative Pattern: An event association pattern with negative residual.

Pattern Clustering: An automatic dual process that simultaneously clusters event association patterns and their associated data.

Pattern Discovery: An methodology for automatically discovering non-random relations inherent among events from data sets.

Positive Pattern: An event association pattern with positive residual.

Pattern Preserving Clustering

INTRODUCTION

Clustering and association analysis are important techniques for analyzing data. Cluster analysis (Jain & Dubes, 1988) provides insight into the data by dividing objects into groups (clusters), such that objects in a cluster are more similar to each other than to objects in other clusters. Association analysis (Agrawal, Imielinski & Swami, 1993), on the other hand, provides insight into the data by finding a large number of strong patterns -- frequent itemsets and other patterns derived from them -- in the data set. Indeed, both clustering and association analysis are concerned with finding groups of *strongly related* objects, although at different levels. Association analysis finds strongly related objects on a local level, i.e., with respect to a subset of attributes, while cluster analysis finds strongly related objects on a global level, i.e., by using all of the attributes to compute similarity values.

Recently, Xiong, Tan & Kumar (2003) have defined a new pattern for association analysis -- the hyperclique pattern -- which demonstrates a particularly strong connection between the overall similarity of all objects and the itemsets (local pattern) in which they are involved. The hyperclique pattern possesses a *high affinity property*: the objects in a hyperclique pattern have a guaranteed level of global pairwise similarity to one another as measured by the cosine similarity (uncentered Pearson correlation coefficient). Since clustering depends on similarity, it seems reasonable that the hyperclique pattern should have some connection to clustering.

Ironically, we found that hyperclique patterns are mostly destroyed by standard clustering techniques, i.e., standard clustering schemes do not preserve the hyperclique patterns, but rather, the objects comprising them are typically split among different clusters. To understand why this is not desirable, consider a set of hyperclique patterns for documents. The high affinity property of hyperclique patterns requires that these documents must be similar to one another; the stronger the hyperclique, the more similar the documents. Thus, for strong patterns, it would seem desirable (from a clustering viewpoint) that documents in the same pattern end up in the same cluster in many or most cases. As mentioned, however, this is not what happens for traditional clustering algorithms. This is not surprising since traditional clustering algorithms have no built in knowledge of these patterns and may often have goals that are in conflict with preserving patterns, e.g., minimize the distances of points from their closest cluster centroids.

More generally, the breaking of these patterns is also undesirable from an application point of view. Specifically, in many application domains, there are fundamental patterns that dominate the description and analysis of data within that area, e.g., in text mining, collections of words that form a topic, and in biological sciences, a set of proteins that form a functional module (Xiong et al. 2005). If these patterns are not

respected, then the value of a data analysis is greatly diminished for end users. If our interest is in patterns, such as hyperclique patterns, then we need a clustering approach that preserves these patterns, i.e., puts the objects of these patterns in the same cluster. Otherwise, the resulting clusters will be harder to understand since they must be interpreted solely in terms of objects instead of well-understood patterns.

There are two important considerations for developing a pattern persevering clustering approach. First, in any clustering scheme, we must take as our starting point the sets of objects that comprise the patterns of interest. If the objects of a pattern of interest are not together when we start the clustering process, they will often not be put together during clustering, since this is not the goal of the clustering algorithm. Second, if we start with the sets of objects that comprise the patterns of interest, we must not do anything in the clustering process to breakup these sets. Therefore, for pattern preserving clustering, the pattern must become the basic *object* of the clustering process. In theory, we could then use any clustering technique, although modifications would be needed to use sets of objects instead of objects as the basic starting point. Here, we use hyperclique patterns as our patterns of interest, since they have some advantages with respect to frequent itemsets for use in pattern preserving clustering: hypercliques have the high affinity property, which guarantees that keeping objects together makes sense, and finding hypercliques is computationally much easier than finding frequent itemsets. Finally, hyperclique patterns, if preserved, can help cluster interpretation.

BACKGROUND

Cluster analysis has been the focus of considerable work, both within data mining and in other fields such as statistics, psychology, and pattern recognition. Several recent surveys may be found in Berkhin (2002), Han, Kamber & Tung (2001), and Jain, Murty & Flynn (1999), while more extensive discussions of clustering are provided by the following books (Anderberg, 1973; Jain & Dubes, 1988; Kaufman & Rousseeuw, 1990).

While there are innumerable clustering algorithms, almost all of them can be classified as being either *partitional*, i.e., producing an un-nested set of clusters that partitions the objects in a data set into disjoint groups, or *hierarchical*, i.e., producing a nested sequence of partitions, with a single, all-inclusive cluster at the top and singleton clusters of individual points at the bottom. While this standard description of hierarchical versus partitional clustering assumes that each object belongs to a single cluster (a single cluster within one level, for hierarchical clustering), this requirement can be relaxed to allow clusters to overlap.

Perhaps the best known and widely used partitional clustering technique is K-means (MacQueen, 1999), which aims to cluster a dataset into K clusters---K specified by the user---so as to minimize the sum of the squared distances of points from their closest cluster centroid. (A cluster centroid is the mean of the points in the cluster.) K-means is simple and computationally efficient, and a modification of it, bisecting K-means (Steinbach, Karypis & Kumar, 2000), can also be used for hierarchical clustering.

Traditional hierarchical clustering approaches (Jain & Dubes, 1988) build a hierarchical clustering in an *agglomerative* manner by starting with individual points or objects as clusters, and then successively combining the two most similar clusters, where the similarity of two clusters can be defined in different ways and is what distinguishes one agglomerative hierarchical technique from another. These techniques have been used with good success for clustering documents and other types of data. In particular, the agglomerative clustering technique known as Group Average or UPGMA, which defines cluster similarity in terms of the average pairwise similarity between the objects in the two clusters, is widely used because it is more robust than many other agglomerative clustering approaches.

As far as we know, there are no other clustering methods based on the idea of preserving patterns. However, we mention two other types of clustering approaches that share some similarity with what we are doing here: constrained clustering and frequent item set based clustering. Constrained clustering (Wagstaff and Cardie, 2000, Tung, Ng, Lakshmanan & Han, 2001, Davidson and Ravi, 2005) is based on the idea of using standard clustering approaches, but restricting the clustering process. Our approach can be viewed as constraining certain objects to stay together during the clustering process. However, our constraints are automatically enforced by putting objects in hypercliques together, before the clustering process begins, and thus, the general framework for constrained clustering is not necessary for pattern preserving clustering.

Pattern preserving clustering techniques are based on an association pattern, the hyperclique pattern, but there have been other clustering approaches that have used frequent itemsets or other patterns derived from them. One of these approaches is Frequent Itemset-based Hierarchical Clustering (FIHC) (Benjamin, Fung & Wang 2003), which starts with clusters built around frequent itemsets. However, while our approach to clustering objects finds hypercliques of objects, and then uses them as initial clusters, FIHC uses selected itemsets -- sets of binary attributes -- to group objects (transactions), i.e., any object that supports an itemset goes into the same cluster. Thus, the approach of FIHC is quite different from pattern preserving clustering techniques, as is the approach of other clustering algorithms that are also based on frequent itemsets, e.g., Beil, Ester & Xu, 2002; Wang, Xu & Liu, 1999.

MAIN FOCUS

As the inspiration for pattern preserving clustering, the hyperclique pattern has been used to explore pattern preserving clustering. The concept of hyperclique patterns (Xiong, Tan & Kumar, 2003, Xiong, Tan & Kumar 2006) is based on the concepts of the frequent itemset and association rule (Agrawal, Imielinski & Swami, 1993).

Hyperclique Patterns

Let $I = \{i_1, i_2, ..., i_m\}$ be a set of distinct items. Each transaction T in database D is a subset of I. We call $X \subseteq I$ an itemset. The support of X, denoted by $supp(X)$, is the fraction of transactions containing X. If $supp(X)$ is no less than a user-specified minimum support, X is called a frequent itemset. The confidence of the association rule $X_1 \rightarrow X_2$ is defined as $conf(X_1 \rightarrow X_2) = supp(X_1 \cup X_2)/supp(X_1)$. It is the fraction of the transactions containing the items in X_1 that also contain the items in X_2, and is an estimate of the conditional probability of X_2 given X_1.

A hyperclique pattern (Xiong, Tan & Kumar, 2003) is a new type of association pattern that contains items that are *highly affiliated* with each other. By high affiliation, we mean that the presence of an item in a transaction strongly implies the presence of every other item that belongs to the same hyperclique pattern. The h-confidence measure (Xiong, Tan & Kumar, 2003) is specifically designed to capture the strength of this association. Formally, the h-confidence of an itemset $P = \{i_1, i_2, ..., i_m\}$ is defined as $hconf(P) = min_{1 \leq k \leq m}\{conf(i_k \rightarrow P - i_k)\}$. Given a set of items I and a minimum h-confidence threshold h_c, an itemset $P \subseteq I$ is a hyperclique pattern if and only if $hconf(P) \geq h_c$. For a hyperclique pattern P, the presence of any item $i \in P$ in a transaction implies the presence of all other items $P - \{i\}$ in the same transaction with probability at least h_c. This suggests that h-confidence is useful for capturing patterns containing items which are strongly related to each other. A hyperclique pattern is a maximal hyperclique pattern if no superset of this pattern is a hyperclique pattern.

Table 1 shows some hyperclique patterns identified from words of the LA1 dataset, which is part of the TREC-5 collection (http://trec.nist.gov) and includes articles from various news categories such as 'financial,' 'foreign,' 'metro,' 'sports,' and 'entertainment.' One hyperclique pattern listed in the table is {*mikhail*, *gorbachev*}, who is the former president of the Soviet

Table 1. Examples of hyperclique patterns from words of the LA1 data set

Hyperclique patterns	Support	H-confidence
{gorbachev, mikhail}	1.4%	93.6%
{photo, graphic, writer}	14.5%	42.1%
{sentence, convict, prison}	1.4%	32.4%
{rebound, score, basketball}	3.8%	40.2%
{season, team, game, play}	7.1%	31.4%

Union. Certainly, the presence of *mikhail* in one document strongly implies the presence of *gorbachev* in the same document and vice-versa.

HICAP: Hierarchical Clustering with Pattern Preservation

HICAP (Xiong et al., 2004) is based on the Group Average agglomerative hierarchical clustering technique, which is also known as UPGMA (Jain & Dubes, 1988). However, unlike the traditional version of UPGMA, which starts from clusters consisting of individual objects or attributes, HICAP uses hyperclique patterns to define the initial clusters, i.e., the objects of each hyperclique pattern become an initial cluster.

This algorithm consists of two phases. In phase I, HICAP finds maximal hyperclique patterns, which are the patterns we want to preserve in the HICAP algorithm. We use only maximal hyperclique patterns since any non-maximal hyperclique will, during the clustering process, tend to be absorbed by its corresponding maximal hyperclique pattern and will, therefore, not affect the clustering process significantly. Thus, the use of non-maximal hypercliques would add complexity without providing any compensating benefits.

In phase II, HICAP conducts hierarchical clustering and outputs the clustering results. We highlight several important points. First, since hyperclique patterns can be overlapping, some of the resulting clusters will be overlapping. Second, identified maximal hyperclique patterns typically cover only *10%* to *20%* of all objects, and thus, HICAP also includes each uncovered object as a separate initial cluster, i.e., the hierarchical clustering starts with maximal hyperclique patterns and uncovered objects. Finally, the similarity between clusters is calculated using the average of the pairwise similarities between objects, where the similarity between objects is computed using the cosine measure.

Hyperclique Patterns vs. Frequent Itemsets

As mentioned, there has been some prior work that uses frequent itemsets as the basis for clustering algorithms (Beil, Ester & Xu, 2002; Benjamin, Fung & Wang 2003; Wang, Xu & Liu, 1999). While the goals and methods of that work are different from our own, we could have used frequent itemsets instead of hypercliques in HICAP. We chose hypercliques because we feel that they have several advantages for pattern preserving clustering. First, since hyperclique patterns have the high affinity property; that is, they include objects that are strongly similar to each other with respect to cosine similarity and that should, therefore, naturally be within the same cluster. In contrast, many pairs of objects from a frequent itemset may have very poor similarity with respect to the cosine measure. Second, the hyperclique pattern mining algorithm has much better performance at low levels of support than frequent itemset mining algorithms. Thus, capturing patterns occurring at low levels of support is much easier for hyperclique patterns than frequent itemsets. Finally, the size of maximal hyperclique patterns is significantly smaller than the size of maximal frequent itemsets. In summary, a version of HICAP that uses hypercliques is far more computationally efficient that a version of HICAP that uses frequent patterns, and is more likely to produce meaningful clusters.

FUTURE TRENDS

While this chapter showed the potential usefulness of pattern preserving clustering based on a hierarchical clustering approach, more work is necessary to show the broad applicability and usefulness of a pattern preserving approach to clustering. We also hope to investigate how pattern preserving clustering might be incorporated into non-hierarchical clustering schemes.

Hierarchical Clustering with Pattern Preservation can be made more general by focusing on patterns other than hyperclique patterns. We need to investigate what conditions these patterns must meet for this to be meaningful. In particular, do patterns need to possess the high affinity property? More generally, we hope to understand what must be done to modify clustering techniques to be compatible with the goal of preserving patterns.

CONCLUSIONS

In this chapter, we have introduced a new goal for clustering algorithms, namely, the preservation of patterns, such as the hyperclique pattern, that capture strong connections between objects. Without such an explicit goal, clustering algorithms tend to find clusters that split the objects in these patterns into different

clusters. However, keeping these patterns together aids cluster interpretation.

KEY TERMS

Clustering Analysis: The process of dividing objects into groups (clusters) in a way such that objects in a cluster are more similar to each other than to objects in other clusters.

Confidence: The confidence of an association rule $X_1 \rightarrow X_2$ is defined as $conf(X_1 \rightarrow X_2) = supp(X_1 \cup X_2)/supp(X_1)$. It is the fraction of the transactions containing the items in X_1 that also contain the items

in X_2, and is an estimate of the conditional probability of X_2 given X_1.

H-Confidence: The h-confidence of an itemset $P = \{i_1, i_2, ..., i_m\}$ is defined as $hconf(P) = min_{1 \le k \le m}\{conf(i_k \rightarrow P - i_k)\}$.

Hierarchical Clustering: It is a clustering approach which produces a nested series of partitions of the data.

Hyperclique Pattern: Given a set of items I and a minimum h-confidence threshold h_c, an itemset $P \subseteq I$ is a hyperclique pattern if and only if $hconf(P) \ge h_c$.

Itemset: Let $I = \{i_1, i_2, ..., i_m\}$ be a set of distinct items. Each transaction T in database D is a subset of I. We call $X \subseteq I$ an itemset.

Maximal Hyperclique Pattern: A hyperclique pattern is a maximal hyperclique pattern if no superset of this pattern is a hyperclique pattern.

Pattern Preserving Clustering: It is a clustering approach which preserves meaningful and interpretable patterns during the clustering process. The patterns preserved in clusters can help interpret the clustering results.

Support: The support of an itemset X, denoted by $supp(X)$, is the fraction of transactions containing the itemset X.

Pattern Synthesis for Nonparametric Pattern Recognition

P. Viswanath
Indian Institute of Technology-Guwahati, India

M. Narasimha Murty
Indian Institute of Science, India

Shalabh Bhatnagar
Indian Institute of Science, India

INTRODUCTION

Parametric methods first choose the form of the model or hypotheses and estimates the necessary parameters from the given dataset. The form, which is chosen, based on experience or domain knowledge, often, need not be the same thing as that which actually exists (Duda, Hart & Stork, 2000). Further, apart from being highly error-prone, this type of methods shows very poor adaptability for dynamically changing datasets. On the other hand, non-parametric pattern recognition methods are attractive because they do not derive any model, but works with the given dataset directly. These methods are highly adaptive for dynamically changing datasets. Two widely used non-parametric pattern recognition methods are (a) the nearest neighbor based classification and (b) the Parzen-Window based density estimation (Duda, Hart & Stork, 2000). Two major problems in applying the non-parametric methods, especially, with large and high dimensional datasets are (a) the high computational requirements and (b) the curse of dimensionality (Duda, Hart & Stork, 2000). Algorithmic improvements, approximate methods can solve the first problem whereas feature selection (Isabelle Guyon & André Elisseeff, 2003), feature extraction (Terabe, Washio, Motoda, Katai & Sawaragi, 2002) and bootstrapping techniques (Efron, 1979; Hamamoto, Uchimura & Tomita, 1997) can tackle the second problem. We propose a novel and unified solution for these problems by deriving a *compact and generalized abstraction* of the data. By this term, we mean a compact representation of the given patterns from which one can retrieve not only the original patterns but also some artificial patterns. The compactness of the abstraction reduces the computational requirements, and its generalization reduces the curse of dimensionality effect. Pattern synthesis techniques accompanied with compact representations attempt to derive compact and generalized abstractions of the data. These techniques are applied with (a) the nearest neighbor classifier (NNC) which is a popular non-parametric classifier used in many fields including data mining since its conception in the early fifties (Dasarathy, 2002) and (b) the Parzen-Window based density estimation which is a well known non-parametric density estimation method (Duda, Hart & Stork, 2000).

BACKGROUND

Pattern synthesis techniques, compact representations and its application with NNC and Parzen-Window based density estimation are based on more established fields:

- **Pattern recognition:** Statistical techniques, parametric and non-parametric methods, classifier design, nearest neighbor classification, probability density estimation, curse of dimensionality, similarity measures, feature selection, feature extraction, prototype selection, and clustering techniques.
- **Data structures and algorithms:** Computational requirements, compact storage structures, efficient nearest neighbor search techniques, approximate search methods, algorithmic paradigms, and divide-and-conquer approaches.
- **Database management:** Relational operators, projection, cartesian product, data structures, data management, queries, and indexing techniques.

MAIN FOCUS

Pattern synthesis, compact representations followed by its application with NNC and Parzen-Window density estimation are described below.

Pattern Synthesis

Generation of artificial new patterns using the given set of patterns is called pattern synthesis. Instance based pattern synthesis uses the given training patterns and some of the properties of the data. It can generate a finite number of new patterns. Computationally this can be less expensive than deriving a model from which the new patterns can be extracted. This is especially useful for non-parametric methods like NNC and Parzen-Window based density estimation (Duda, Hart and Stork, 2000) which directly use the training instances. It is argued that using a larger synthetic set can reduce the bias of the density estimation or classification (Viswanath, Murty & Bhatnagar, 2006). Further, the usage of the respective compact representations can result in reduction of the computational requirements.

This chapter presents two instance based pattern synthesis techniques called *overlap based pattern synthesis* and *partition based pattern synthesis* and their corresponding compact representations.

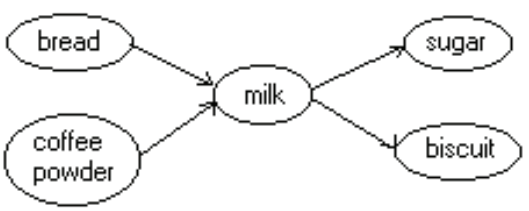
Overlap Based Pattern Synthesis

Let F be the set of features (or attributes). There may exist a three-block partition of F, say, $\{A, B, C\}$ with the following properties. For a given class, there is a dependency (probabilistic) among features in A U B. Similarly, features in B U C have a dependency. However, features in A (or C) can affect those in C (or A) only through features in B. That is, to state more formally, A and C are statistically independent given B. Suppose that this is the case and we are given two patterns $X = (a_1, b, c_1)$ and Y = (a_2, b, c_2) such that a_1 is a feature-vector that can be assigned to the features in A, b to the features in B and c_1 to the features in C, respectively. Similarly, a_2, b and c_2 are feature-vectors that can be assigned to features in A, B, and C, respectively. Then, our argument is that the two patterns (a_1, b, c_2) and (a_2, b, c_1) are also valid patterns in the same class or category as X and Y. If these two new patterns are not already in the class of patterns then it is only because of the finite nature of the set. We call this type of generation of additional patterns as *overlap based pattern synthesis*, because this kind of synthesis is possible only if the two given patterns have the same feature-values for features in B. In the given example, feature-vector b is common between X and Y and therefore is called the *overlap*. This method is suitable only with discrete valued features (can be of symbolic or categorical types also). If more than one such partition exists then the synthesis technique is applied sequentially with respect to the partitions in some order.

One simple example to illustrate this concept is as follows. Consider a supermarket sales database where two records, *(bread, milk, sugar)* and *(coffee, milk, biscuits)* are given. Let us assume, it is known that there is a dependency between (i) *bread* and *milk*, (ii) *milk* and *sugar*, (iii) *coffee* and *milk*, and (iv) *milk* and *biscuits*. Then the two new records that can be synthesized are *(bread, milk, biscuits)* and *(coffee, milk, sugar)*. Here *milk* is the overlap. A compact representation in this case is shown in Figure 1 where a path from left to right ends denotes a data item or pattern. So we get four patterns in total from the graph shown in Figure 1 (two original and two synthetic patterns). Association rules derived from association rule mining (Han & Kamber, 2001) can be used to find these kinds of dependencies. Generalization of this concept and its compact representation for large datasets are described below.

If the set of features, F can be arranged in an order such that $F = \{f_1, f_2, ..., f_d\}$ is an ordered set with f_k being the k^{th} feature and all possible three-block partitions can be represented as $P_i = \{A_i, B_i, C_i\}$ such that $A_i = (f_1, ..., f_a)$, $B_i = (f_{a+1}, ..., f_b)$ and $C_i = (f_{b+1}, ..., f_d)$ then the compact representation called *overlap pattern graph* is described with the help of an example.

Figure 1.

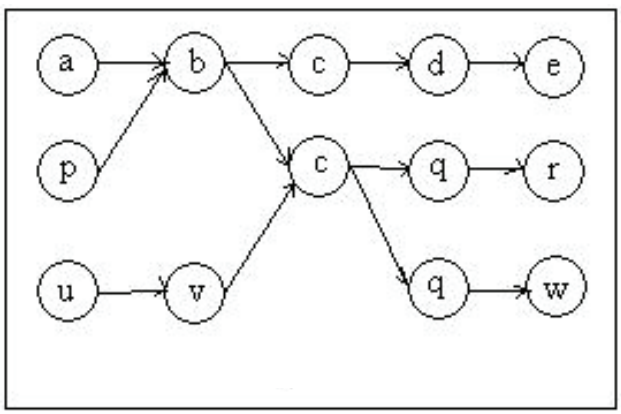


Overlap Pattern Graph (OLP-graph)

Let $F = (f_1, f_2, f_3, f_4, f_5)$. Let two partitions satisfying the conditional independence requirement be $P_1 = \{ \{f_1\}, \{f_2, f_3\}, \{f_4, f_5\}\}$ and $P_2 = \{ \{f_1, f_2\}, \{f_3, f_4\}, \{f_5\}\}$. Let three given patterns be *(a,b,c,d,e), (p,b,c,q,r)* and *(u,v,c,q,w)*, respectively. Since *(b,c)* is common between the1st and 2nd patterns, two synthetic patterns that can be generated are *(a,b,c,q,r)* and *(p,b,c,d,e)*. Likewise three other synthetic patterns that can be generated are *(p,b,c,d,e), (p,b,c,q,w)* and *(a,b,c,q,w)* (note that, the last synthetic pattern is derived from two earlier synthetic patterns). A compact representation called *overlap pattern graph (OLP-graph)* for the entire set (including both given and synthetic patterns) is shown in Figure 2 where a path from left end to right end represents a pattern. The graph is constructed by inserting the given patterns, whereas the patterns that can be extracted out of the graph form the entire synthetic set consisting of both original and synthetic patterns. Thus from the graph given in Figure 2, a total of eight patterns can be extracted, out of which five are new synthetic patterns.

OLP-graph can be constructed by scanning the given dataset only once and is independent of the order in which the given patterns are considered. An approximate method for finding partitions, a method for construction of OLP-graph and its application to NNC are described in (Viswanath, Murty & Bhatnagar, 2005). For large datasets, this representation reduces the space requirement drastically.

Figure 2.



Partition Based Pattern Synthesis

Let $P = \{A1, A2,...,Ak\}$ be a k block partition of F such that $A1, A2,...,Ak$ are statistically independent subsets. Let $\mathbf{Y}$ be the given dataset and $Proj_{A1}(\mathbf{Y})$ be the projection of $\mathbf{Y}$ onto features in the subset $A1$. Then the cartesian product:

$$Proj_{A1}(\mathbf{Y}) \times Proj_{A2}(\mathbf{Y}) \times \ldots \times Proj_{Ak}(\mathbf{Y})$$

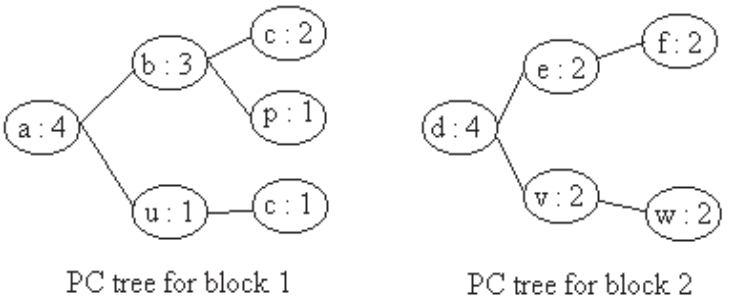
is the synthetic set generated using this method.

The partition P satisfying the above requirement can be obtained from domain knowledge or from association rule mining. Approximate partitioning methods using mutual information or pair-wise correlation between the features can also be used to get suitable partitions and are experimentally demonstrated to work well with NNC in (Viswanath, Murty & Bhatnagar, 2004).

Partitioned Pattern Count Tree (PPC-Tree)

This compact representation, suitable for storing the partition based synthetic patterns, is based on Pattern Count Tree (PC-tree) (Ananthanarayana, Murty & Subramanian, 2001) which is a prefix tree like structure. PPC-tree is a generalization of PC-tree such that a PC-tree is built for each of the projected patterns i.e., $Proj_{Ai}(\mathbf{Y})$ for I = 1 to k. PPC-tree is a more compact structure than PC-tree which can be built by scanning the dataset only once and is independent of the order in which the given patterns are considered. The construction method and properties of PPC-tree can be found in (Viswanath, Murty & Bhatnagar, 2004). As an example, consider four given patterns *viz., (a,b,c,d,e,f), (a,u,c,d,v,w), (a,b,p,d,e,f), (a,b,c,d,v,w)* and a two block partition where the first block consists of first three features and the second block consists of remaining three features. The corresponding PPC-tree is shown in Figure 3 where each node contains a *feature-value* and an integer called *count* which gives the number of patterns sharing that node. There are two PC-trees, one corresponding to each block. A path in the PC-tree for block 1 (from root to leaf) concatenated with a path in the PC-tree for block 2 gives a pattern that can be extracted. So, in total six patterns can be extracted from the structure shown in Figure 3.

Figure 3.



An Application of Synthetic Patterns with Nearest Neighbor Classifier and Parzen-Window Based Density Estimation

Classification and prediction methods are among various elements of data mining and knowledge discovery such as association rule mining, clustering, link analysis, rule induction, etc (Wang, 2003). The nearest neighbor classifier (NNC) is a very popular non-parametric classifier (Dasarathy, 2002). It is widely used in various fields because of its simplicity and good performance. Theoretically, with infinite number of samples its error rate is upper-bounded by twice the error of Bayes classifier (Duda, Hart, & Stork, 2000). NNC is a lazy classifier in the sense that no general model (like a decision tree) is built until a new sample needs to be classified. So, NNC can easily adapt to situations where the dataset changes frequently. But, computational requirements and curse of dimensionality are the two major issues that need to be addressed in order to make the classifier suitable for data mining applications (Dasarathy, 2002). Prototype selection (Susheela Devi & Murty, 2002), feature selection (Isabelle Guyon & Andre Elisseeff, 2003), feature extraction (Terabe, Washio, Motoda, Katai & Sawaragi, 2002), compact representations of the datasets (Maleq Khan, Qin Ding & William Perrizo, 2002) and bootstrapping (Efron, 1979 and Hamamoto, Uchimura & Tomita, 1997) are some of the remedies to tackle these problems. But all these techniques need to be followed one after the other, *i.e.*, they cannot be combined together. Pattern synthesis techniques and compact representations described in this chapter provide a unified solution. Similar to NNC, the Parzen-Window based density estimation is a popular non-parametric density estimation method (Viswanath, Murty, & Kambala, 2005).

Efficient implementations of NNC which can directly work with OLP-graph are given in (Viswanath, Murty & Bhatnagar, 2005). These use dynamic programming techniques to reuse the partial distance computations and thus reduce the classification time requirement. Partition based pattern synthesis is presented in along with efficient NNC methods (Viswanath, Murty, & Bhatnagar, 2006). An *efficient NNC implementation with constant classification time* is presented in (Viswanath, Murty, & Bhatnagar, 2004). Pattern synthesis and compact representation schemes can reduce the bias of the density estimation and are shown to perform well in a density based intrusion detection system (Viswanath, Murty, & Kambala, 2005). These methods are, in general, based on the divide-and-conquer approach and are efficient to work directly with the compact representation. Thus, the computational requirements are reduced. Since the total number of patterns (i.e., the size of the synthetic set) considered is much larger than those in the given training set, the effect of curse of dimensionality is reduced.

FUTURE TRENDS

Integration of various data mining tasks like association rule mining, feature selection, feature extraction, classification, etc., using compact and generalized abstractions is a very promising direction. Apart from NNC and Parzen-Window based density estimation methods, other applications using synthetic patterns and corresponding compact representations like decision tree induction, rule deduction, clustering, etc., are also interesting areas which can give valuable results.

CONCLUSION

Pattern synthesis is a novel technique which can enhance the generalization ability of lazy learning methods like NNC and Parzen-Window based density estimation by reducing the curse of dimensionality effect and also the corresponding compact representations can reduce the computational requirements. In essence, it derives a compact and generalized abstraction of the given dataset. Overlap based pattern synthesis and partition based pattern synthesis are two instance based pattern synthesis methods where OLP-graph, PPC-tree are respective compact storage structures.

KEY TERMS

Bootstrapping: Generating artificial patterns from the given original patterns. (This does not mean that the artificial set is larger in size than the original set, also artificial patterns need not be necessarily distinct from the original patterns.)

Curse of Dimensionality Effect: The number of samples needed to estimate a function (or model) grows exponentially with the dimensionality of the data.

Compact and Generalized Abstraction of the Training Set: A compact representation built by using the training set from which not only the original patterns but some of new synthetic patterns can also be derived.

Prototype Selection: The process of selecting a few representative samples from the given training set suitable for the given task.

Training Set: The set of patterns whose class labels are known and which are used by the classifier in classifying a given pattern.

Pattern Synthesis in SVM Based Classifier

INTRODUCTION

An important problem in pattern recognition is that of pattern classification. The objective of classification is to determine a discriminant function which is consistent with the given training examples and performs reasonably well on an unlabeled test set of examples. The degree of performance of the classifier on the test examples, known as its generalization performance, is an important issue in the design of the classifier. It has been established that a good generalization performance can be achieved by providing the learner with a sufficiently large number of discriminative training examples. However, in many domains, it is infeasible or expensive to obtain a sufficiently large training set. Various mechanisms have been proposed in literature to combat this problem. Active Learning techniques (Angluin, 1998; Seung, Opper, & Sompolinsky, 1992) reduce the number of training examples required by carefully choosing discriminative training examples. Bootstrapping (Efron, 1979; Hamamoto, Uchimura & Tomita, 1997) and other pattern synthesis techniques generate a synthetic training set from the given training set. We present some of these techniques and propose some general mechanisms for pattern synthesis.

BACKGROUND

Generalization performance is generally quantified using the technique of structural risk minimization (Vapnik, 1998). The risk of misclassification is dependent on the training error, the V-C dimension of the classifier and the number of training examples available to the classifier. A good classifier is one which has a low training error and low V-C dimension. The generalization performance of the classifier can also be improved by providing a large number of training examples.

The number of training examples required for efficient learning depends on the number of features in each training example. Larger the number of features, larger is the number of training examples required. This is known as the curse of dimensionality. It is generally accepted that at least ten times as many training examples per class as the number of features are required (Jain & Chandrasekharan, 1982).

However, in most applications, it is not possible to obtain such a large set of training examples. Examples of such domains are:

1. **Automated Medical diagnosis:** This involves designing a classifier which examines medical reports and determines the presence or absence of a particular disorder. For efficient classification, the classifier must be trained with a large number of positive and negative medical reports. However, an adequate number of medical reports may not be available for training because of the possible high cost of performing the medical tests.
2. **Spam Filtering:** A good mail system aims at identifying and filtering out spam mails with minimum help from the user. The user labels mails as spam as and when she encounters them. These labeled mails are used to train a classifier which can further be used to identify spam mails. For the mail system to be useful, the user should be presented with the least possible number of spam mails, which calls for an efficient classifier. However, sufficient training examples are not available to the learner to perform efficient classification.
3. **Web page recommendations:** The user is provided recommendations based on her browsing history. If good recommendations are to be provided early, then the recommendation system will have to manage with a relatively low number of

examples representing web pages of interest to the user.

There are two major techniques that can be employed to combat the lack of a sufficiently large training set: Active Learning and Pattern Synthesis.

ACTIVE LEARNING

Active Learning is a technique in which the learner exercises some control over the training set. In pool-based active learning, a learner is provided with a small set of labeled training examples and a large set of unlabeled examples. The learner iteratively chooses a few examples from the unlabeled examples for labeling; the user provides the labels for these examples and the learner adds these newly labeled examples to its training set.

In the "membership query" paradigm of active learning, the learner queries the user for the label of a point in the input region (Angluin, 1998).

Active Learning aims at finding a good discriminant function with minimum number of labeled training examples. The version space for a given set of training examples is defined as the set of all discriminant functions that consistently classify the training examples. Version space is the region of uncertainty, the region which contains those examples whose labels the learner is uncertain about. Active Learning methods choose from this region, those unlabeled examples for labeling, which reduce the version space as fast as possible, ideally by half in each iteration.

Various algorithms for active learning have been proposed in literature. Some of them are "Query by Committee" (Seung, Opper, & Sompolinsky, 1992), "Committee Based Sampling" (Dagan, & Engelson, 1995), etc. These techniques train a committee of classifiers and after each iteration of training, the labels of the unlabeled examples are determined individually by each member of the committee. That unlabeled example for which there is maximum disagreement among the committee members is chosen for labeling. Active Learning has been incorporated along with the Expectation – Maximization algorithm to improve efficiency (Nigam, McCallum, Thrun, & Mitchell, 2000). This technique has also been employed in SVM training (Tong & Koller, 2001; Tong & Chang, 2001).

PATTERN SYNTHESIS

In some domains it may not be possible to obtain even unlabeled examples. In some others, the user may not be available or may not be in a position to provide the labels for the unlabeled examples. In especially such circumstances, it is useful to generate artificial training patterns from the given training set. This process is known as pattern synthesis.

Various techniques have been devised in literature to obtain an artificial training set. Some of the techniques are described below in brief:

1. **Bootstrapping:** This technique involves approximating the sample probability distribution from the given examples and drawing random samples from this distribution. This sample is called the bootstrap sample and the distribution is called the bootstrap distribution. The bootstrap distribution can be estimated through various means, including direct calculation, Monte Carlo estimation and Taylor's series expansion (Efron, 1979). This technique has been successfully applied in Nearest Neighbor Classifier design (Hamamoto, Uchimura & Tomita, 1997).
2. **Using Domain-related information:** These techniques involve exploiting domain knowledge such as radial symmetry (Girosi & Chan, 1995) and transformation invariance (Niyogi, Girosi & Poggio, 1998). Such invariances have been applied to the support vectors obtained from a Support Vector Machine (Scholkopf, Burges & Vapnik, 1996). In this technique, an initial model is learnt to determine the support vectors in the training set. The transformations are then applied to these support vectors to obtain synthetic patterns.

MAIN FOCUS

General Pattern Synthesis Techniques

These techniques involve applying a transformation to the given training examples to obtain new training

examples. The transformation applied should ensure that the generated examples lie in the same class region as their corresponding parent examples. Finding such a transformation would be simple if the actual class distributions were known apriori. However, this information is not available in practical classification problems. If this information was available, it could be used to learn the discriminant directly instead of generating training examples. Thus obtaining such a transformation is in itself an important problem.

The determination of the transformation can be formulated as the following optimization problem: Let $X = \{x_k, y_k\}_{k=1}^{N}$ be the available training set where x_k are vectors in $\Re^n$ and $y_k \in \{-1,1\}$ are the corresponding class labels. We synthesize a set of patterns X' using X by applying a transformation T to it. Let J be the optimizing criterion for the classifier, $f(x)$ be the discriminant function learnt when only X is provided as the training set to the learner and $g(x)$ be the discriminant function learnt when $X \cup X'$ is provided for training.

$$\begin{aligned} &min \quad J \\ subject\ to \quad &f(x_k)g(T(x_k)) \geq 0 \\ &y_k g(T(x_k)) \geq 0 \\ &y_k g(x_k) \geq 0 \quad k = 1,2,...,N \end{aligned}$$

The first constraint ensures that the parent pattern from X and the corresponding synthesized pattern in X' are given the same label by the classifier. The second and third constraints ensure that $g(x)$ consistently classifies patterns belonging to both X and X'.

We examine two different types of transformations that can be applied to the training set to obtain the artificial training set:

- Scaling which uses the transformation $T(x) = \gamma x$.
- Perturbation which uses the transformation $T(x) = x + \gamma$.

In both these methods the value of γ should be chosen such that all the constraints in the above optimization problem are satisfied.

Pattern Synthesis in Support Vector Machines

Support Vector Machines (SVM) (Burges, 1998; Sastry, 2003) find a hyperplane which separates the training examples with the largest possible margin. If the training examples are not linearly separable, the training examples are projected into a higher dimensional space where they are more likely to be linearly separable. The separating hyperplane in this higher dimension translates to a non-linear discriminant in the original input space. SVMs achieve a good generalization performance by minimizing both the training error and the V-C dimension.

A Δ margin separating hyperplane is one which classifies a test example x using the following decision rule:

if $w^T x + b > \Delta$ class $y = +1$
if $w^T x + b \leq \Delta$ class $y = -1$

The V-C dimension (Vapnik, 1998) of such a Δ margin separating hyperplane classifier in $\Re^n$ is bounded above as follows:

$$h \leq \min\left(\left[\frac{\rho^2}{\Delta^2}\right], n\right) + 1$$

where ρ is the radius of the sphere which encloses all the training examples. SVMs find the classifier that maximizes the margin Δ and hence has a low V-C dimension.

However, the SVM classifier may perform badly when the right training examples are not available. Consider the situation shown in Figure 1.

In order to classify the noisy examples correctly, the input examples may be projected to a higher dimensional space and the SVM may find a non-linear discriminant as shown in Figure 2.

This non-linear classifier is more complex than a simple hyperplane which ignores the noisy examples (Figure 3). This results in the deterioration of the performance of the classifier. Through pattern synthesis it is possible to obtain sufficient number of training examples which truly represent the class distributions, hence reducing the effect of such noisy patterns and improving the generalization performance of the classifier.

Figure 1.

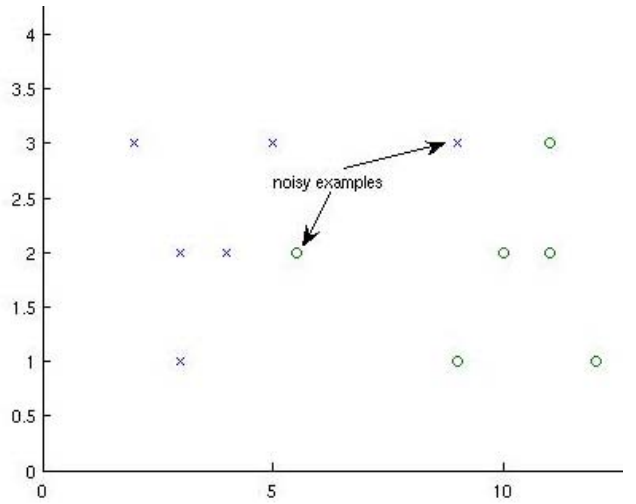

Figure 2.

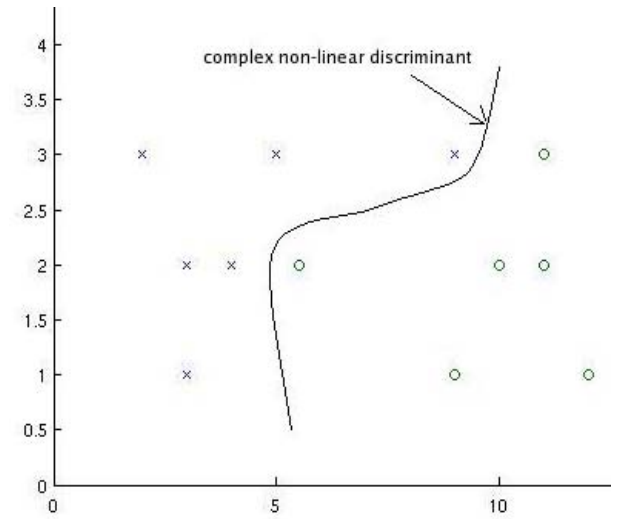

Figure 3.

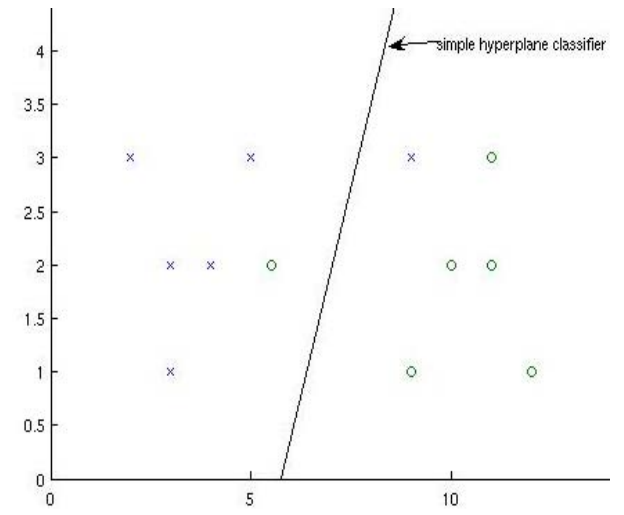

In an SVM, the most important patterns are the Support Vectors, the patterns closest to the separating hyperplane. Hence, it is more meaningful to use these Support Vectors for pattern synthesis. We describe two algorithms based on the scaling and perturbation techniques discussed above, in the context of SVMs.

PATTERN SYNTHESIS THROUGH SCALING

Pattern Synthesis is performed as per the following algorithm: Using the given set of training patterns train an SVM and determine its support vectors. Scale each support vector pattern x_i by a factor γ_i chosen uniformly at random from the range $[0,\gamma]$ where γ is a user-defined parameter. Add the scaled patterns to the training set and repeat the training and synthesis process for a fixed number of iterations.

For example, again consider the situation in Figure 1. During the first training phase, the two noisy examples become support vectors. The feature vectors of these two examples are X_1 = (5.5, 2) and X_2 = (9, 3). By scaling X_1 by a factor of 2, we obtain X'_1 = (11, 4) which falls well into the region of the positive examples (marked as circles). Similarly, by scaling X_2 by a factor of 0.5, we obtain X'_2 = (4.5, 1.5) which falls well into the region of the negative examples (marked as crosses). Figure 4 illustrates the effect of such scaling.

Since the scaling factor for each example is different, each pattern shifts by a small amount producing an overall shift in the separating hyperplane. As the process of shifting is repeated a large number of times with random scaling factors, there is a high probability that the final separating hyperplane obtained truly separates the class regions.

Pattern Synthesis through Perturbation

Perturbation is used for pattern synthesis as follows: Determine the support vectors of the SVM trained using the given training patterns. For each of these support vector patterns, choose $m = n * p$ features to perturb. Here p is the perturbation probability, a user input and n is the dimension of the training patterns. Perturb each selected feature f_j by δ_j chosen uniformly at random in the range $[0, \Delta]$ where Δ is the maximum allowed perturbation, again provided by the user. Add the perturbed pattern to the training set. Repeat the

Figure 4.

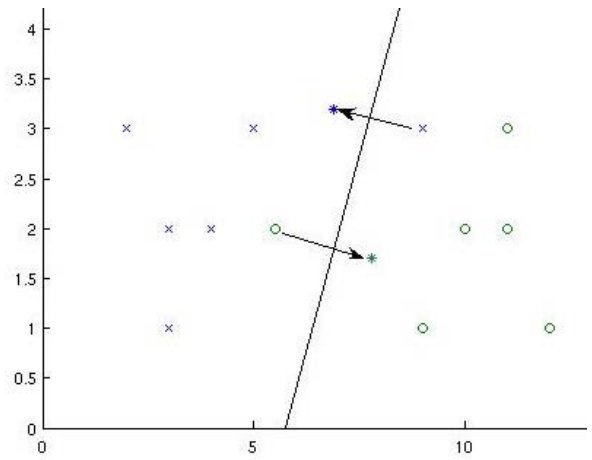

Figure 5.

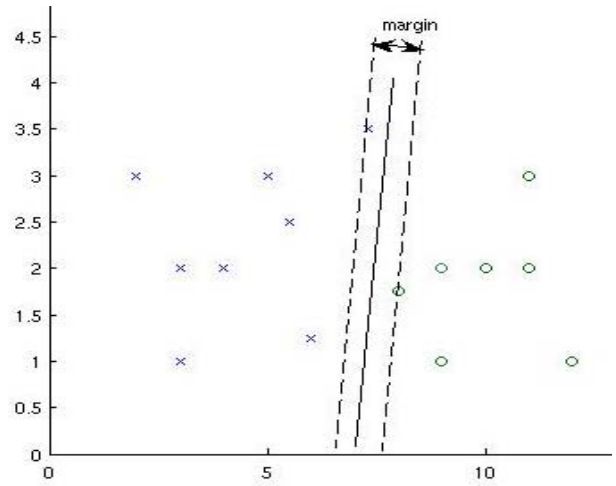

Figure 6.

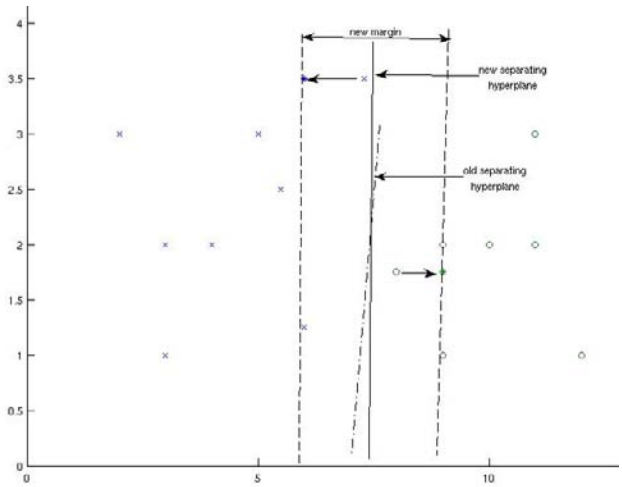

training and synthesis processes for a fixed number of iterations. The value of Δ can be decided either using domain knowledge or based on the training patterns.

The generated pattern lies in the vicinity of the parent pattern and hence we may be assured that the synthetic pattern and its corresponding parent pattern have the same class label.

The perturbation method is particularly useful when small shifts are sufficient to arrive at the true separating hyperplane. Consider the situation in Figure 5.

SVM finds a separating hyperplane of a very small margin due to the possibly noisy patterns lying on the supporting hyperplanes. If these patterns were shifted slightly, a hyperplane with a larger margin can be found as shown in Figure 6. Larger margin implies lower V-C dimension which in turn implies better generalization performance.

FUTURE TRENDS

The pattern synthesis techniques proposed could be applied in other learning problems such as regression, clustering and association rule mining where a large and discriminative training set is useful. In the context of classification, the performance of these techniques with other classification algorithms such as Nearest Neighbor, Decision trees, etc. is to be verified.

CONCLUSION

This chapter presents some general techniques to synthesize an artificial training set which can be employed in addition to the original training set for training the classifier. The synthetic training set contributes significantly to the improvement in the generalization performance of the classifier.

In the context of pattern synthesis in SVMs, it can also be seen that the pattern synthesis technique induces an iterative nature into the training process. In each iteration, the training algorithm deals with a small subset of the entire training set, consisting only of the support vectors from the previous iteration. Therefore these techniques also contribute to reducing the time and space complexity of the training algorithm.

KEY TERMS

Active Learning: A technique in which the learner carefully chooses the training examples with the objective of minimizing the number of training examples required for effective learning.

Bootstrapping: A technique for synthetic pattern generation which involves approximating the sample probability distribution from the given training examples and drawing random samples from this distribution.

Curse of Dimensionality: The number of training examples required to determine an accurate discriminant function grows exponentially with the dimensionality of the training data. This phenomenon is known as the curse of dimensionality.

Linear separability: A set of examples $\{x_k, y_k\}$ $k = 1, 2, ..., N$ where x_k are vectors in $\Re^n$ and $y_k \in \{-1,+1\}$ are said to be linearly separable if there exist $w \in \Re^n$ and $b \in \Re$ such that

$$w^T x_k + b > 0 \text{ if } y_k = +1 \qquad \text{and}$$
$$w^T x_k + b \leq 0 \text{ if } y_k = -1 \qquad \forall k = 1 \text{ to } N$$

Pattern Synthesis: Pattern synthesis may be defined as the generation of artificial patterns from a given set of patterns.

Risk of Misclassification: This is the loss incurred when a set of test examples are misclassified.

Support Vector Machine: Support vector machines are linear classifiers which map input vectors to a higher dimensional space where the training examples

become linearly separable and find a maximal separating hyperplane in this space.

Vapnik-Chervonenkis (V-C) dimension: This is a measure of the capacity of a class of classifiers. Let $F = \{f(x,a), a \in \Lambda\}$ be a set of discriminant functions which take values +1 or -1 and let X be a training set. A finite set $B = \{x_1, x_2, ..., x_m\} \subset X$ is said to be shattered by F if for any $C \subset B$, we can find a $\alpha \in \Lambda$ such that $f(x,a) = +1$ if $x \in C$ and $f(x,a) = +1$ if $x \in B - C$. The V-C dimension of F is defined to be the cardinality of the largest shattered subset of X.

The Personal Name Problem and a Data Mining Solution

Clifton Phua
Monash University, Australia

Vincent Lee
Monash University, Australia

Kate Smith-Miles
Deakin University, Australia

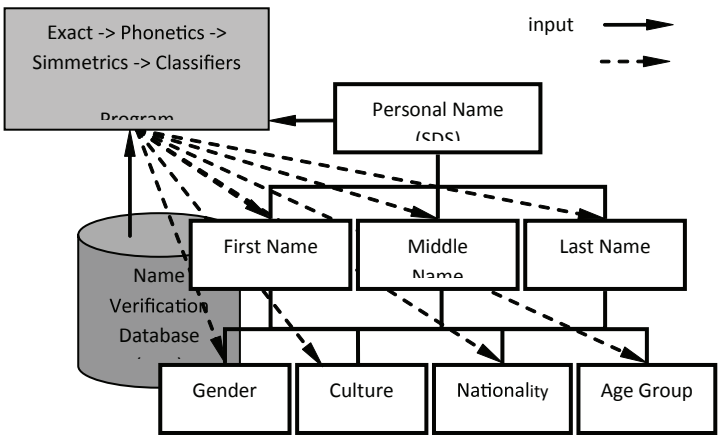
INTRODUCTION

Almost every person has a life-long personal name which is officially recognised and has only one correct version in their language. Each personal name typically has two components/parts: a first name (also known as given, fore, or Christian name) and a last name (also known as family name or surname). Both these name components are strongly influenced by cultural, economic, historical, political, and social backgrounds. In most cases, each of these two components can have more than a single word and the first name is usually gender-specific. (see Figure 1).

There are three important practical considerations for personal name analysis:

- Balance between manual checking and analytical computing. Intuitively, a small proportion of names should be manually reviewed, the result has to be reasonably accurate, and each personal name should not take too long to be processed.
- Reliability of the verification data has to be examined. By keeping the name verification database's updating process separate from incoming names, it can prevent possible data manipulation/corruption over time. However, the incompatibility of names in databases can also be caused by genuine reasons as such as cultural and historical traditions, translation and transliteration, reporting and recording variations, and typographical and phonetic errors (Borgman and Siegfried, 1992).

Figure 1. Hierarchy chart on the inputs, process, and outputs of the name verification task.



- Domain knowledge has to be incorporated into the entire process. Within the Australian context, the majority of names will be Anglo-Saxon but the minority will consist of many and very diverse groups of cultures and nationalities. Therefore the content of the name verification database has to include a significant number of popular Asian, African, Middle Eastern, and other names.

Figure 1 illustrates the input, process, and output sections. Input refers to the incoming names and those in the verification database (which acts like an external dictionary of legal names). Process/program refers to the possible four approaches for personal name analysis: exact-, phonetical-, similarity matching are existing and traditional approaches, while classification and hybrids are newer techniques on names-only data. Output refers to the insights correctly provided by the process. For simplicity, this paper uses first name to denote both first and middle names; and culture to represent culture and nationality. While the scope here explicitly seeks to extract first/last name and gender information from a personal name, culture can be inferred to a large extent (Levitt and Dubner, 2005), authenticity and age group can be inferred to a limited extent.

BACKGROUND

In this paper, we argue that there are four main explanations when the incoming first and last name does not match any name in the verification database exactly. First, the personal name is not authentic and should be manually checked. Second, it is most likely due to an incomplete white list. It is impossible to have a name verification database which has every possible name, especially rare ones. Third, the incoming name does not have any variant spelling of name(s) in the database (i.e. Western European last names). Fourth, there are virtually millions of potential name combinations or forms (i.e. East Asian first names).

The last three reasons are problems which prevent incoming personal names from being verified correctly by the database. Without finding an exact match in the name verification database, the personal name problem in this paper refers to scenario where ordering and gender (possibly culture, authenticity, and age group) cannot be determined correctly and automatically for every incoming personal name. Therefore, additional processing is required.

There are three different and broad application categories of related work in name matching (Borgman and Siegfried, 1992):

1. **Information retrieval:** Finding exact or variant form(s) of incoming name in verification database with no changes to the database. This present work is the most similar to ours where an incoming personal name is used as a search key to retrieve first/last name and gender information.
2. **Name authority control:** Mapping the incoming name upon initial entry to the most commonly used form in database. Current publications on author citation matching within the ACM (Association of Computing Machinery) portal database are examples of this (Feitelson, 2004). Unlike author names where the first names are usually abbreviated, many personal names in large databases have complete first and last names.
3. **Record linkage/duplication detection:** Detecting duplicates for incoming multiple data streams at input or during database cleanup. Recent publications focused on supervised learning on limited labelled data (Tejada *et al*, 2002) and on approximate string matching (Bilenko *et al*, 2003). Unlike their matching work which uses comparatively smaller data sets and has other informative address and phone data. Intelligently matching incoming names-only data with a comprehensive verification database seems like a harder problem.

Other specific applications of personal name matching include art history (Borgman and Siegfried, 1992), name entity extraction from free text (Cohen and Sarawagi, 2004; Patman and Thompson, 2003; Bikel *et al*, 1999), genealogy, law enforcement (Wang *et al*, 2004), law (Navarro *et al*, 2003; Branting, 2003), and registry identity resolution (Stanford ITS, 2005). Name matching has been explicitly or implicitly researched under databases, digital libraries, machine learning, natural language processing, statistics, and other research communities; and also known as identity uncertainty, identity matching, and name disambiguation.

MAIN FOCUS

In this section, the data sets, evaluation metrics, and computational resources are described. This is followed by an empirical comparison and discussion of results using four approaches for personal name analysis. The experimental Verification Data Set (VDS) has 99,570 unique names (examples) which are evenly distributed amongst gender, culture, and nationality. The original data set has 1 attribute (name component) and 3 class labels (first/last, gender, and culture). The Scoring Data Set (SDS) has 8,623 personal names/instances (each with first and last names) and is an assembly of four publicly available data sources which are multi-cultural and within the Australian context (all labelled with first/last and manually labelled with gender). To evaluate the effectiveness across all four approaches, this paper proposes a simple-to-use positive-valued Normalised Net Value (NNV) - to sum up all scores for each name component in the test set SDS.

Every name component is given a score s_i:

$$s_i = \begin{cases} 1 & \text{if correct match/prediction} \\ 0 & \text{if no match/prediction} \\ -1 & \text{if incorrect match/prediction} \end{cases}$$

Every approach on N number of names in the SDS is given an NNV:

$$\text{NNV} = \frac{\sum_{i=1}^{N} s_i + N}{2N}$$

Classifiers are also evaluated by F-measure (Witten and Frank, 2005):

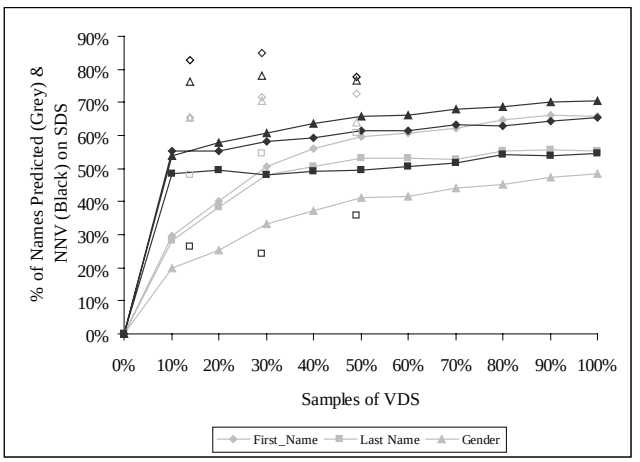
$$\text{F} - \text{measure} = \frac{2 \text{ x recall x precision}}{\text{recall } + \text{ precision}}$$

Exact-Matching Results

Each component in SDS is compared to every example in the VDS to find exact matches. For exact matching, phonetics, and simmetrics, when a match is found, its corresponding ordering and gender labels are counted, and the sum of candidate matches are returned. The label(s) with the highest count will be the final output. For example, if the name component "CLIFTON" is recognised in the VDS as both a first name and last name, the final prediction will be "F|L". But, it is important to note that in all subsequent experiments, predictions with conflicting outcomes such as "F|L" will be considered as a "no match/prediction" even though the correct class label is "F".

Figure 2 above shows the effect of having a larger random sample of VDS on the exact matching of first names, last names, and gender. Exact matching with the entire VDS can barely determine name authenticity, as it will involve manually checking 34.2% to 51.6%

Figure 2. Results of exact matching with different sample sizes and data selections of VDS on SDS



of the SDS which has no matches from the VDS. Its highest NNV is with the entire VDS: first names is 65.5%, of last names is 54.7%, and of gender is 70.6%. With larger data samples, the number of predictions (plotted lines in light grey) and normalised net value (plotted lines in dark grey) increase marginally. Interestingly, although the number of matches on gender is the lowest among the three, gender predictions are the most accurate.

In Figure 2, the hollow scatter points at 14%, 29%, and 49% are selected samples of the VDS which represent the choice of English (ENG) names only, Western European names only: ENG, French (FRE), German (GER), Dutch (DUT), Irish (IRI), Welsh (WEL); and Western European plus five other major name groups: Chinese (CHI), Indian (IND), Spanish (SPA), Arabic (ARA), Russian (RUS) accordingly. The dark grey hollow scatter points illustrate high accuracy for first name and gender probably because first names are repetitive and gender is determined from first names.

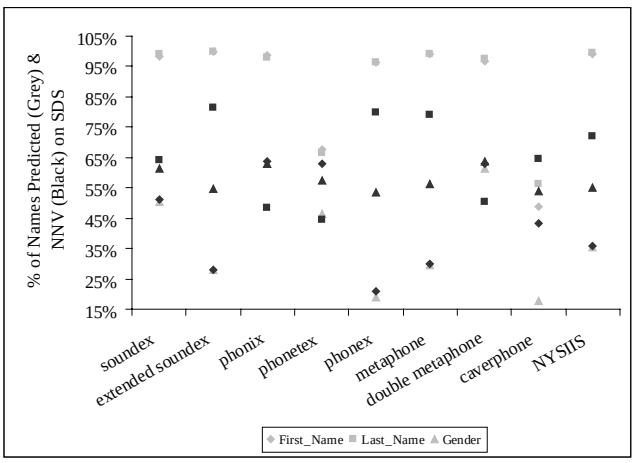
Phonetics Results

Phonetics (sounds-like algorithms) operate by encoding the SDS instance and then matching that against the encoded names from the VDS. The ones used in the experiments here are briefly described below:

1. **Soundex:** Soundex is the most widely used phonetic algorithm, has seven numerical codes and transforms the name into a four-letter code with the first letter of name preserved. Extended Soundex is a "relaxed" version of the original proposed by this paper: no preservation of the first letter of name, not restricted to a four-letter string, no trailing zeros to "pad" the four-letter code, and place "R" in the same numerical code group as "L".
2. **Soundex variants:** Phoni**x** applies more than a hundred string standardisation rules before a nine numerical code transformation (Zobel and Dart, 1996). Phonetex (Hodge and Austin, 2003) is a combination of Soundex and Phoni**x**. Phone*x* (Lait and Randell, 1993) is a combination of Soundex and Metaphone.
3. **Metaphone and extension:** Metaphone (Philips, 1990) reduces English words into sixteen consonant sounds and Double Metaphone (Philips, 2000) to twelve consonant sounds.
4. **Others:** Caverphone has more than fifty sequential rules and New York State Identification and Intelligence System (NYSIIS) uses five sets of rule sets to map name into code (Hood, 2002).

There are two obvious flaws in phonetics: Most of them were mainly designed for the Anglo-Saxon last names, yet many last names in most databases are of many different cultures. Also, many of them were designed for different purposes or were not general enough for widespread use. For example, Phonetex was designed for spell checkers; Phone*x* was adapted to British surnames, Caverphone was designed for New Zealand accents, and NYSIIS was mainly used for the New York city population.

Figure 3. Results of phonetics on first/last name and gender prediction on SDS



In Figure 3, there are phonetical matches to almost all SDS instances except for Phonetex and Caverphone. The highest NNV of first name is Phon**i**x at 63.9%, of last name is extended Soundex at 81.4%, and of gender is double Metaphone at 63.7%. The superior performance of extended Soundex against other more complex phonetical techniques for this problem is unexpected. The results confirm that phonetics were originally designed and, in comparison to simmetrics and classification, is still more effective for matching last names. In contrast, first names are neglected by phonetics.

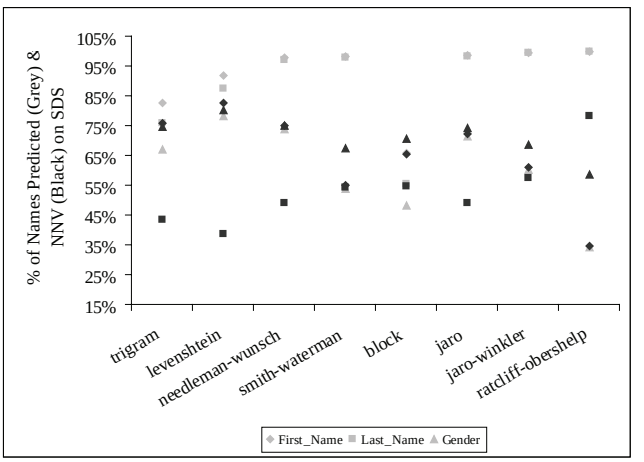
Simmetrics Results

While phonetics examine dissimilar groups of letters to identify similarities in pronunciation, simmetrics use similar or identical groups of letters. Simmetrics (looks-like algorithms, commonly known as edit distance algorithms) are character-based similarity metrics (Chapman, 2005; Cohen *et al*, 2003; Ratcliff and Metzener, 1998) which output the scaled similarity score (between 0 and 1) between two names components, where 0 represents totally different and 1 represents identical. Similarity measure = 1 - distance measure. Those used in the experiments here are briefly described below:

- **Edit distances:** Levenshtein calculates minimal number of single-character insertions, deletions, and substitutions to transform one string into another. Needleman-Wunsch is an extension of Levenshtein with a variable gap cost for insertions and deletions. Smith-Waterman is similar to Levenshtein but allows for context dependent gap costs.
- **Non-edit distances:** *N*-gram calculates the percentage of matches of all possible substrings of size n between two strings. Trigram is used in the experiments here. Block is the absolute difference of coordinates between two names. Jaro is dependent on number and order of common characters between two names. Jaro-Winkler, an extension of Jaro, takes in account the length of common prefix between two names. Ratcliff-Obershelp matches characters in the longest common subsequence, and recursively matching characters on the both sides of the longest common subsequence.

With similarity threshold set at 0.8, Figure 4 shows that simmetrics enables a very high match rate between VDS and SDS except for Trigram, Levenshtein, and Block. The highest NNV of first name is Levenshtein at 82.4%, of last name is Ratcliff-Obershelp at 78.1%, and of gender is Levenshtein at 80.3%. Like extended Soundex for last names, the basic Levenshtein produces the best NNV for first name and gender. It outperforms phonetics and classification because some first names are slight variants of the original. However, the percentage of names matched/predicted is relatively low at 91.7% and 78.2% respectively. Perhaps these names without matches/predictions should be manu-

Figure 4. Results of simmetrics (a group of string similarity metrics) on first/last name and gender prediction on SDS



ally investigated. There are other theoretically sound similarity metrics which have been experimented on VDS and SDS, but they are inefficient (Editex, Gotoh, and Monge-Elkan), or ineffective (Hirschberg and Ukkonen) for this problem.

Classification Results

Classifiers (discriminant functions) are trained with certain subsets of the VDS and score the SDS accordingly (it is the only approach which gives a ranked output). This is a hard problem because of the large numbers of nominal attribute values in the *n*-gram attributes. Due to this, typical decision trees (cannot handle identifier-like attributes) and support vector machines (extensive pre-processing required to convert data to numerical format) are not suited to this task. On the other hand, naïve Bayes is the only suitable classification algorithm which is extremely efficient and still comparable to other state-of-the-art algorithms.

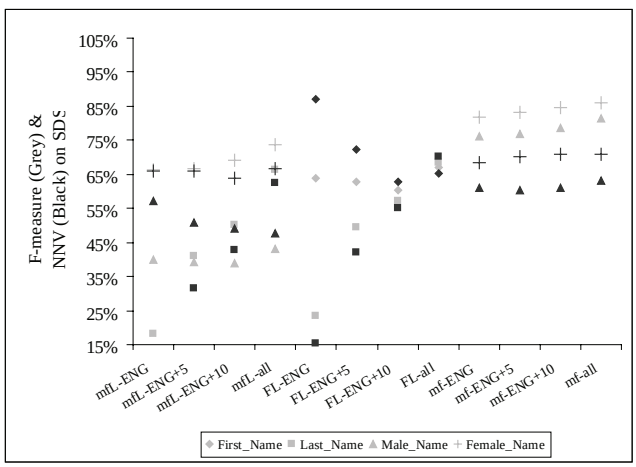
With reference to the x-axis of Figure 5 above, the classifiers are built from mfL which has a trinary class label (male, female, or last), FL which has a binary class label (first or last), and mf (from first names only) which has a binary class label (male or female). Finer-grained classifiers are built using selected samples of the VDS described before (ENG, ENG + 5, ENG + 10). The highest NNV of first name is FL-ENG at 87.0%, of last name is FL-all at 70.1%, of male name is mf-all at 63.0%, and of female name is mf-all at 71.0%. Although there is a conflict where the highest F-measure of first name is FL-all instead of FL-ENG, the latter is still preferred for SDS as most first names will be of English origin (even for different cultures). Also, it seems that results with binary class labels are slightly better than the trinary class label. The main disadvantage of classifiers, compared to the rest, is in the pre-processing effort required to transform data into a suitable format and the expertise needed to interpret the results.

Hybrid Results

Previous research claims that combination of results/evidence almost always improves performance (Hsiung, 2004; Hodge and Austin, 2003; Zobel and Dart, 1996), but this depends on the diversity of the individual results. First name and gender predictions are the best by combining results from simmetrics and classifiers where NNV is at 78.6% and 78.8% respectively. For last name, phonetics remain the single most important algorithm (combining results decreases NNV significantly here). The NNVs here are a few percentage points lower than the highest NNVs from other approaches but all the names from the SDS will now have a match/prediction to indicate whether a name component is a first or last (ordering), and/or male or female (gender) name.

There are three main lessons learnt from these experiments for personal name analysis. First, exact matching is inadequate. Second, more complex phonetical encoding and string-similarity algorithms often perform poorly in both accuracy and speed than the original ones. Therefore, there is no need to research more into this area. On the other hand, we also learnt that

Figure 5. Results of classification with different class labelling and data selection on SDS



the classification can play an essential part in personal name analysis, particularly when using hybridising it with simmetrics, to determine first name and gender.

FUTURE TRENDS

Personal name analysis is becoming more prevalent and important, especially in intelligence- and security-related research and applications:

1. **Research:** Author recognition in digital libraries, database marketing, fraud detection, homeland security, recommendation systems, and social network analysis.
2. **Private sector:** Account opening application; address change, payment activities in internet-based businesses; marketing in insurance, financial, and telecommunication businesses.
3. **Public sector:** Name verification activities in card issuing authorities, customs, electoral registers, health sectors, law enforcement, immigration, social security, and tax offices.

Opportunities for further research include more robust techniques to maintain individual privacy and confidentiality; use of other classification techniques, and experimentation with more test data sets; and application of the approaches discussed in this paper to extract culture, authenticity, and age group from personal names. As more personal name data with demographic information are become publicly available online (in the millions), this could well be a new data mining application area.

CONCLUSION

In this paper, personal name problem is defined for the case where the ordering and gender cannot be determined correctly and automatically for every incoming personal name. The recommended solution is to use the data from VDS with a set of techniques made up of phonetics (extended Soundex), simmetrics - string-similarity algorithms (Levenshtein), and classifiers (naïve Bayes algorithm). The combination of results/evidence from the above techniques improved performance, especially for predicting first names and gender. In addition, this paper emphasised the inadequacies of exact matching and scalability issues of more complex phonetical encoding and string-similarity algorithms.

KEY TERMS

Attribute Construction: Manual or automatic creation of derived attributes from existing attributes to increase predictiveness or performance results.

Classification: A statistical procedure in which examples are placed into groups based on quantitative information on one or more characteristics inherent in the items examples, and based on a training set of previously labeled items.

Data Cleaning: The process of improving the quality of the data by modifying its form/content.

Fraud Detection: The application of mathematical algorithms to tease out evidences of fraud or abuse from available data where only the most suspicious ones are manually investigated.

Personal Name Data: Commercial or security-related databases which contain important personal identifiers such as personal names.

Security and Intelligence Informatics: The study of the development and use of advanced information technologies and systems for national and international security-related applications.

Similarity/Deception/Alias Detection: The search for the same entity which is masked or disguised as something else, either accidentally or deliberately.

Perspectives and Key Technologies of Semantic Web Search

Konstantinos Kotis
University of the Aegean, Greece

INTRODUCTION

Current keyword-based Web search engines (e.g. Google[a]) provide access to thousands of people for billions of indexed Web pages. Although the amount of irrelevant results returned due to polysemy (one word with several meanings) and synonymy (several words with one meaning) linguistic phenomena tends to be reduced (e.g. by narrowing the search using human-directed topic hierarchies as in Yahoo[b]), still the uncontrolled publication of Web pages requires an alternative to the way Web information is authored and retrieved today. This alternative can be the technologies of the new era of the Semantic Web.

The Semantic Web, currently using OWL language to describe content, is an extension and an alternative at the same time to the traditional Web. A Semantic Web Document (SWD) describes its content with semantics, i.e. domain-specific tags related to a specific conceptualization of a domain, adding meaning to the document's (annotated) content. Ontologies play a key role to providing such description since they provide a standard way for explicit and formal conceptualizations of domains. Since traditional Web search engines cannot easily take advantage of documents' semantics, e.g. they cannot find documents that describe similar concepts and not just similar words, semantic search engines (e.g. SWOOGLE[c], OntoSearch[d]) and several other semantic search technologies have been proposed (e.g. Semantic Portals (Zhang et al, 2005), Semantic Wikis (Völkel *et al*, 2006), multi-agent P2P ontology-based semantic routing (of queries) systems (Tamma *et al*, 2004), and ontology mapping-based query/answering systems (Lopez *et al*, 2006; Kotis & Vouros, 2006, Bouquet *et al*, 2004). Within these technologies, queries can be placed as formally described (or annotated) content, and a semantic matching algorithm can provide the exact matching with SWDs that their semantics match the semantics of the query.

Although the Semantic Web technology contributes much in the retrieval of Web information, there are some open issues to be tackled. First of all, unstructured (traditional Web) documents must be semantically annotated with domain-specific tags (ontology-based annotation) in order to be utilized by semantic search technologies. This is not an easy task, and requires specific domain ontologies to be developed that will provide such semantics (tags). A fully automatic annotation process is still an open issue. On the other hand, SWDs can be semantically retrieved only by formal queries. The construction of a formal query is also a difficult and time-consuming task since a formal language must be learned. Techniques towards automating the transformation of a natural language query to a formal (structured) one are currently investigated. Nevertheless, more sophisticated technologies such as the mapping of several schemes to a formal query constructed in the form of an ontology must be investigated. The technology is proposed for retrieving heterogeneous and distributed SWDs, since their structure cannot be known a priory (in open environments like the Semantic Web).

This article aims to provide an insight on current technologies used in Semantic Web search, focusing on two issues: a) the automatic construction of a formal query (*query ontology*) and b) the querying of a collection of knowledge sources whose structure is not known a priory (distributed and semantically heterogeneous documents).

BACKGROUND

A keyword-based Web search mainly concerns search techniques that are based on string (lexical) matching of the query terms to the terms contained in Web documents. Traditionally, keyword-based search is used for unstructured Web documents' (text with no semantics

attached) retrieval, where retrieval is obtained when query terms are matched to terms found in documents. Several techniques for keyword-based Web search have been introduced (Alesso, 2004), with the most popular being the simple Boolean search, i.e. combination of keywords based on Boolean operators AND, OR, NOT. Other techniques include

- wildcard and proximity search (syntactic analysis of documents or query terms),
- fuzzy search (handles misspelling and plural variations of keywords),
- contextual search (analyse the content of Web pages and return the subject of the page),
- keyword location-based search (keywords occurring in the title tags of the Web page are more important than those in the body),
- human(or topic)-directed search (use of topic hierarchies, manually created, to help users to narrow the search and make search results more relevant),
- thesaurus-based search (use specific relations such as synonym to help retrieve relevant information even if keyword is not present in a document),
- and finally statistics-based search such as Google's PageRank[e] technology.

Keyword-based search technology has been also used to retrieve SWDs by matching NL query terms to terms that lexicalize concepts of a SWD (e.g. an ontology concept). Such technology, when used in semantic search engines (e.g. SWOOGLE), do not utilize the semantics of the SWD in the matching algorithm. Matching is based on lexical techniques (string matching of keywords with terms that lexicalize concepts of a an ontology) although the retrieved content is semantically described (i.e. SWDs). Generally, semantic matching is performed in extension to the lexical one and the syntactic similarity between terms is not of interest. In fact, what is important is the similarity of the meaning of two terms. For instance, a match between a query-term "book" and a document-term "reserve" may be correctly identified if the sense of concept "book" is "the reservation of a ticket" (synonymy). On the other hand, a match between the term "book" found in a query and an identical term found in a Web document, may be incorrectly identified if their senses are completely different i.e. the query-term "book", meaning a publication, and the document-term "book", meaning a reservation (polysemy).

Semantic matching requires that the semantics of both the query and the document must be known or uncovered prior their matching. If the query is formally specified, the semantics of each term can be explicitly defined. Thus, if a query is represented as an ontology (query ontology), the semantics of each term that lexicalizes an ontology concept can be revealed by the semantic relations between this concept and the other concepts of the ontology (structure of its neighborhood). Such semantic relations are not only subsumption (is-a) relations, but also others such as "part-of", "meronym", "synonym", etc. On the other hand, if the query is informally specified, i.e. in natural language, the semantics of each term in the query must be somehow uncovered. The issue here is how a machine can "guess" what the intended meaning of an informal query is, in order to retrieve the document that is closer to this meaning and therefore, more interesting to the user. Intelligent search engines such as AskJeeves[f] (Teoma technology) try to tackle this issue by analysing the terms and their relations in a sophisticated way using natural language processing techniques or by refining the query in collaboration with the users. An alternative technique map each term of a query to its intended meaning (sense found in lexicon), using a combination of vector space indexing techniques such as LSI (Deerwester et al, 1990) and a lexicon such as WordNet (Miler, 1995). Furthermore, to be able to execute a semantic matching, the document (in addition to the query) must also provide its semantics. In case of a SWD, the semantics of the document are formally and explicitly specified in an ontology. In case of unstructured documents, advanced ontology learning techniques are required in order to extract their semantics and use them to annotate the related documents.

Further related work has been also carried out and presented (Karanastasi & Christodoulakis, 2007), where an ontology-driven semantic ranking methodology for ontology concepts is used for natural language disambiguation. This work has been proposed in the context of OntoNL framework (Karanastasi et al, 2007). The methodology uses domain specific ontologies for the semantic disambiguation. The disambiguation procedure is automatic and quite promising.

There are several other proposals concerning the retrieval of SWDs. The majority of them assume that

the query is given in a structured way - using a formal language - and provide no advanced means for the (semantic) alignment of the query to the contents of distributed and heterogeneous SWDs. Querying such documents using a controlled language instead of a formal one to formulate a semantic query (Bernstein, 2005) still requires that users should learn a new language. Querying Semantic Web documents using formal queries requires that either the structure of SWDs is known a priory, (i.e. semantic homogeneity), and so use Semantic Web query languages such as OWL-QL (Fikes et al, 2003) and RQL (Karvounarakis, 2003) to query semantic portals, or the structure of SWDs is unknown (semantic heterogeneity) and so the querying is performed either by using a global schema (shared common ontology) to map queries on it or (in case of distributed settings i.e. p2p approaches) performing horizontal mappings across local schemas.

MAIN FOCUS

Latest research work (Lopez *et al*, 2006a; Kotis & Vouros, 2006) builds towards a method for a) automatically approximating the meaning of a simple NL query, reformulating it into an ontology (*query ontology*) that expresses the intended meaning of the query terms and of the query string as a whole, b) retrieving the most "relative" SWDs based on their similarity with the query ontology. The setting of such approaches is addressed to users with no background knowledge in formal languages and to SWDs that are heterogenous (capture different domain knowledge) and distributed (no centralized knowledge about their content exists).

An innovative technology to the transformation of an NL query to a query ontology is provided by the mapping of each query term to a sense in a semantic lexicon (e.g. WordNet) and by consulting the semantic relations between senses. Furthermore, the use of query ontologies to retrieve distributed and heterogeneous SWDs points to the need of measuring the similarity between the content of the query and that of SWDs. This is done by producing and comparing ontology mappings.

NL Query Reformulation for Ontology Construction

The mapping of terms to WordNet senses is performed by computing a semantic morphism that can be considered as a similarity function between terms and WordNet senses (Kotis *et al,* 2006). For the computation of this similarity the s-morphism takes into account the vicinity of each ontology term. Since this computation is based on the hypothesis that query terms are related to each other, the vicinity of a query term includes all the other terms in the query.

WordNet lexicon contains lexical and semantic information about nouns, verbs, adverbs, and adjectives, organized around the notion of a synset. A synset is a set of words with the same part-of-speech that can be interchanged in a certain context. A synset is often further described by a gloss. Semantic relations among synsets include among others the synonymy, hyper(hyp)onymy, meronymy and antonymy relations. WordNet contains thousands of words, synsets and links between concepts. Any semantic lexicon can be used for building a query ontology: For instance, prominent and well-agreed ontologies or thesauri that are known to the users of a retrieval service may be exploited for this purpose. However, this is only a conjecture that remains to be tested.

The s-morphism is computed by the Latent Semantic Indexing (LSI) method. LSI is a vector space technique originally proposed for information retrieval and indexing. It assumes that there is an underlying latent semantic space that estimates by means of statistical techniques using an association matrix (n×m) of term-document data (terms×WordNet senses in this case).

Each term in the initial NL query is being mapped to a WordNet sense through the computation of the s-morphism. Given the vicinity of the term (i.e. the other terms in the query) this sense is considered to express the meaning of the term, i.e. it reflects the intended meaning for the particular term in the context of the query. Given the computed mapping, the vicinity of each query term is being enriched by the set of the most important terms in the corresponding WordNet sense.

The reformulated enriched query can be used to retrieve unstructured documents using keyword-based search techniques, with higher precision than existing methods (Kotis, 2005). The length of the reformulated

query is rather important for the precision of the retrieval. However, to be able to retrieve SWDs, the query must be further processed towards the construction of the query ontology. The algorithm for this process is presented in (Kotis & Vouros, 2006).

Matching Queries Through Ontology Mapping

A variety of methods and tools have been proposed for solving the problem of ontology mapping, and although there is still much to be done, remarkable achievements have been made (Euzenat *et al*, 2006).

For the effective retrieval of SWDs an algorithm that computes the similarity of SWDs and the already constructed query ontology has been proposed. This similarity is being computed using an automatic ontology mapping tool called AUTOMS[g] that extends the HCONE-merge method for ontology mapping (Kotis et al, 2006) by combining lexical, semantic, and structural matching methods. The ranking of retrieved SWDs is computed based on how well they match to the query ontology: This is determined by the number of mappings (mapped concepts) between the query ontology and a SWD (Kotis and Vouros, 2006).

Lexical matching computes the matching of ontology concept names (labels at nodes), estimating the similarity among concepts using syntactic similarity measures. Structural matching computes the matching of ontology concepts by taking into account the similarity of concepts in their neighborhoods. The neighborhood of a concept includes those concepts that are related to it. Finally, semantic matching concerns the matching between the meanings of concept specifications. The computation of semantic matching may rely to external information found in lexicons, thesauri or reference ontologies, incorporating semantic knowledge (mostly domain-dependent) into the process.

AUTOMS tool, although in the experimental stage, achieves high precision and recall in mapping ontologies. Some first experiments and preliminary results of AUTOMS performance within a querying/answering SWDs approach can be found in (Kotis & Vouros, 2006).

Related Technologies

AquaLog (Lopez et al, 2005) is a fully implemented ontology-driven querying/answering system, which takes an ontology and a NL query as an input and returns answers drawn from semantic markup compliant with the input ontology. It is based on GATE infrastructure to obtain a set of syntactic annotations associated with the input query, extended by the use of JAPE grammars to identify terms, relations, question indicators, features, and to classify the query into a category. Knowing the category of the query and having the GATE annotations for the query, the system automatically creates query-triples. These query-triples are further processed and, using the structure and vocabulary of the input ontology, are mapped to ontology-compliant semantic markup or triples. An important limitation is that the system can be used to map a query only to one (shared organizational) ontology.

AquaLog is used in PowerAqua (Lopez et al 2006a), a novel querying/answering system which provides answers drawn from multiple, heterogeneous and distributed ontologies on the Web. Although promising technology, it is still in the phase of implementation, and currently no experiments have been given out any evaluation results. The core of this system is PowerMap (Lopez et al, 2006b) mapping algorithm which offers an alternative to current ontology mapping techniques by focusing on the real-time on-the-fly time-performance mapping of ontologies.

FUTURE TRENDS

We visualize querying/answering systems performing in a new Web, a unified Web of Knowledge (Kotis, 2005). Knowledge recorded in such a Web shall be *distributed* (querying more than one peer-source of knowledge), *heterogeneous* (querying knowledge with unknown structure), *personalized* (background knowledge extracted from already executed queries, predefined preferences on queries), *dynamic* (continuously evolving), and *open* (reached by anyone and from everywhere), providing a unified view of both structured and unstructured documents against simple natural language queries. New technologies should allow querying structured and unstructured documents in a unified way using keyword-based queries, as well as the querying of SWDs documents using both keywords and ontology queries.

Towards this vision, several issues must be further explored such as a) the impact of querying/answering history and/or the use of alternative (or combination

of) lexicons/thesauruses to the disambiguation of new queries, b) the degree of user involvement during the construction of query ontologies and/or the mapping of query ontologies to domain ones, and c) strategies for the maximization of performance (time, precision, recall) of ontology mapping algorithms.

CONCLUSIONS

The need to retrieve distributed and heterogeneous knowledge in open and dynamic environments such as the Semantic Web imposes the realization of new perspectives and the proposal of new approaches. These approaches accentuate the role of ontology mapping within Semantic Web search technology. Users must be empowered with new technologies to search the whole Semantic Web, technologies that will not require advanced skills, and at the same time that will ensure that all the query-related knowledge (and only that) will be promptly retrieved. Towards these targets, we have presented a review on latest related approaches, pointing also out the importance of such approaches to the success of Semantic Web.

KEY TERMS

Keyword-Based Web Search: Searching for Web documents that their content can be lexically matched (string similarity) with the content of a NL query.

Ontology Mapping: The mapping between two ontologies can be defined as a morphism from one ontology to the other i.e. a collection of functions assigning the symbols used in one vocabulary to the symbols of the other.

Ontology Matching: The computation of similarity functions in order to discover similarities between ontology concepts or/and properties pairs using combinations of lexical, structural, and semantic knowledge.

Query Ontology: An ontology automatically created by the mapping of NL query terms to a lexicon. The aim is to check its similarity against SWDs using ontology mapping techniques.

Semantic Knowledge: Knowledge that is captured by uncovering the human intended meaning of concepts, relying either on the computation of similarity functions that "translate" semantic relations (hyperonym, hyponym, meronym, part-of, etc) between the intension (the attribute set) of concepts or on the use of external information such as (the mappings of ontology concepts to) terms' meanings found in lexicons or thesauruses.

Semantic Search: Searching for SWDs with content that can be semantically matched (semantic similarity) with the content of a formal query

Semantic Web Document: Is a document represented as an RDF graph, written in RDF/XML syntax, allowing its content to be processable from machines. An ontology can be a special type of SWD (written in OWL syntax) that extends the semantics of RDF(S) language.

A Philosophical Perspective on Knowledge Creation

Nilmini Wickramasinghe
Stuart School of Business, Illinois Institute of Technology, USA

Rajeev K. Bali
Coventry University, UK

INTRODUCTION

Today's economy is increasingly based on knowledge and information (Davenport, & Grover 2001). Knowledge is now recognized as the driver of productivity and economic growth, leading to a new focus on the role of information, technology and learning in economic performance. Organizations trying to survive and prosper in such an economy are turning their focus to strategies, processes tools and technologies that can facilitate them to create knowledge. A vital and well respected technique in knowledge creation is data mining which enables critical knowledge to be gained from the analysis of large amounts of data and information. Traditional data mining and the KDD process (knowledge discovery in data bases) tends to view the knowledge product as a homogeneous product. Knowledge however, is a multifaceted construct, drawing upon various philosophical perspectives including Lockean/Leibnitzian and Hegelian/Kantian, exhibiting subjective and objective aspects as well as having tacit and explicit forms (Nonaka, 1994; Alavi & Leidner, 2001; Schultze & Leidner, 2002; Wickramasinghe et al, 2003). It is the thesis of this discussion that by taking a broader perspective of the resultant knowledge product from the KDD process; namely by incorporating both a people-based perspective and process-based perspective into the traditional KDD process, it will not only provide a more complete and macro perspective on knowledge creation but also a more balanced approach to knowledge creation which will in turn serve to enhance the extant knowledge base of an organization and facilitate the realization of superior decision making. The implications for data mining are clearly far reaching and are certain to help organizations more effectively realize the full potential of their knowledge assets, improve the likelihood of using/re-using the created knowledge and thereby enable them to be well positioned in today's knowledge economy.

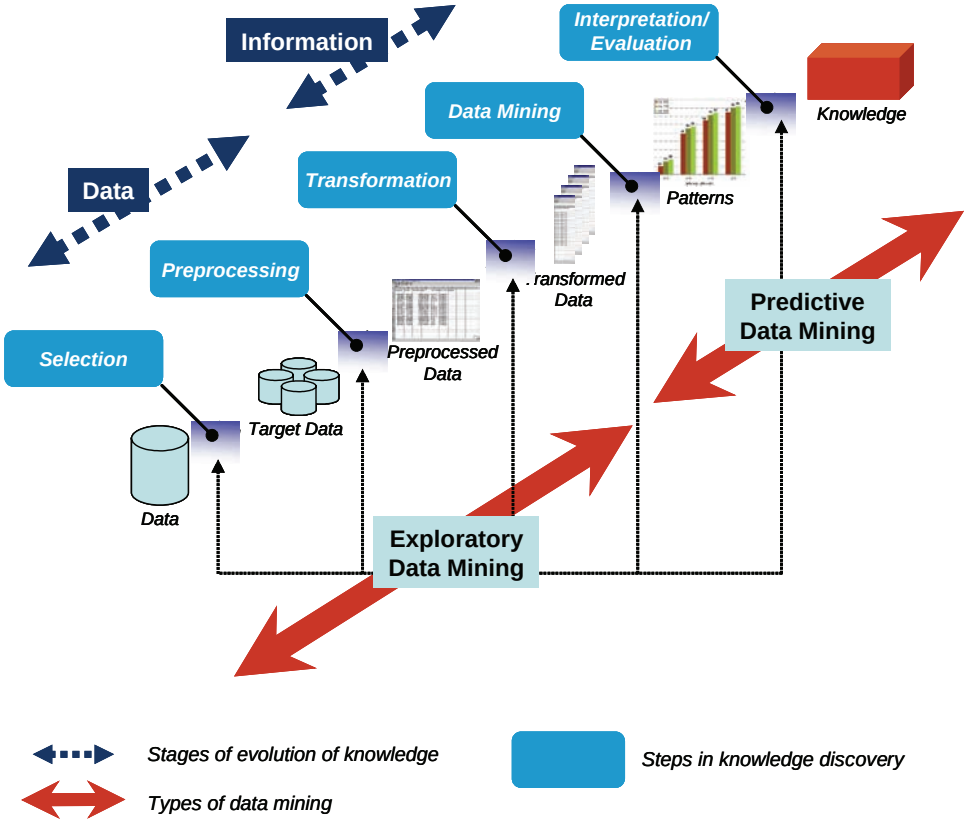
BACKGROUND: KNOWLEDGE CREATION

Knowledge Creation through Data Mining and the KDD Process

Knowledge discovery in databases (KDD), (and more specifically data mining) approaches knowledge creation from a primarily technology driven perspective. In particular, the KDD process focuses on how data is transformed into knowledge by identifying valid, novel, potentially useful, and ultimately understandable patterns in data (Spiegler, 2003; Fayyad et al., 1996). KDD is primarily used on data sets for creating knowledge through model building, or by finding patterns and relationships in data.

From an application perspective, data mining and KDD are often used interchangeably. Figure 1 presents a generic representation of a typical knowledge discovery process. This figure not only depicts each stage within the KDD process but also highlights the evolution of knowledge from data through information in this process as well as the two major types of data mining; namely, exploratory and predictive. whereas the last two steps (i.e., data mining and interpretation/evaluation) in the KDD process are considered predictive data mining. It is important to note in figure 1 that typically in the KDD process the knowledge component itself is treated as a homogeneous block. Given the well established multifaceted nature of the knowledge construct (Boland & Tenkasi, 1995; Malhotra, 2000; Alavi & Leidner, 2001; Schultze & Leidner, 2002; Wickramasinghe et al.,

Figure 1. Integrated view of the Knowledge Discovery Process (Adapted from Wickramasinghe et al, 2003)



2003) this would appear to be a significant limitation or over simplification of knowledge creation through data mining as a technique and the KDD process in general.

The Psycho-Social Driven Perspective to Knowledge Creation

Knowledge can exist as an object, in essentially two forms; explicit or factual knowledge and tacit or experiential i.e.," know how" (Polyani, 1958; 1966). Of equal significance is the fact that organizational knowledge is not static; rather it changes and evolves during the life time of an organization (Becerra-Fernandez, 2001; Bendoly, 2003; Choi & Lee, 2003). Furthermore, it is possible to change the form of knowledge; i.e., transform existing tacit knowledge into new explicit knowledge and existing explicit knowledge into new tacit knowledge or to transform the subjective form of knowledge into the objective form of knowledge (Nonaka & Nishiguchi, 2001; Nonaka, 1994). This process of transforming the form of knowledge, and thus increasing the extant knowledge base as well as the amount and utilization of the knowledge within the organization, is known as the knowledge spiral (Nonaka & Nishiguchi, 2001). In each of these instances the overall extant knowledge base of the organization grows to a new, superior knowledge base.

According to Nonaka (Nonaka & Nishiguchi, 2001): 1) Tacit to tacit knowledge transformation usually occurs through apprenticeship type relations where the teacher or master passes on the skill to the apprentice. 2) Explicit to explicit knowledge transformation usually occurs via formal learning of facts. 3) Tacit to explicit knowledge transformation usually occurs when there is an articulation of nuances; for example, as in healthcare if a renowned surgeon is questioned as to why he does a particular procedure in a certain manner, by his articulation of the steps the tacit knowledge becomes explicit and 4) Explicit to tacit knowledge transformation usually occurs as new explicit knowledge is internalized it can then be used to broaden, reframe and extend one's tacit knowledge. These transformations are often referred to as the modes of socializa-

tion, combination, externalization and internalization respectively (Nonaka, 1994). Integral to this changing of knowledge through the knowledge spiral is that new knowledge is created (Nonaka & Nishiguchi, 2001) and this can bring many benefits to organizations. Specifically, in today's knowledge-centric economy, processes that effect a positive change to the existing knowledge base of the organization and facilitate better use of the organization's intellectual capital, as the knowledge spiral does, are of paramount importance.

Two other primarily people driven frameworks that focus on knowledge creation as a central theme are Spender's and Blackler's respective frameworks (Newell et al, 2002; Swan et al, 1999). Spender draws a distinction between individual knowledge and social knowledge, each of which he claims can be implicit or explicit (Newell et al, 2002). From this framework we can see that Spender's definition of implicit knowledge corresponds to Nonaka's tacit knowledge. However, unlike Spender, Nonaka doesn't differentiate between individual and social dimensions of knowledge; rather he just focuses on the nature and types of the knowledge itself. In contrast, Blackler (Newell et al., 2002) views knowledge creation from an organizational perspective, noting that knowledge can exist as encoded, embedded, embodied, encultured and/or embrained. In addition, Blackler emphasized that for different organizational types, different types of knowledge predominate and highlighted the connection between knowledge and organizational processes (Newell et al., 2002).

Blackler's types of knowledge can be thought of in terms of spanning a continuum of tacit (implicit) through to explicit with embrained being predominantly tacit (implicit) and encoded being predominantly explicit while embedded, embodied and encultured types of knowledge exhibit varying degrees of a tacit (implicit) /explicit combination.

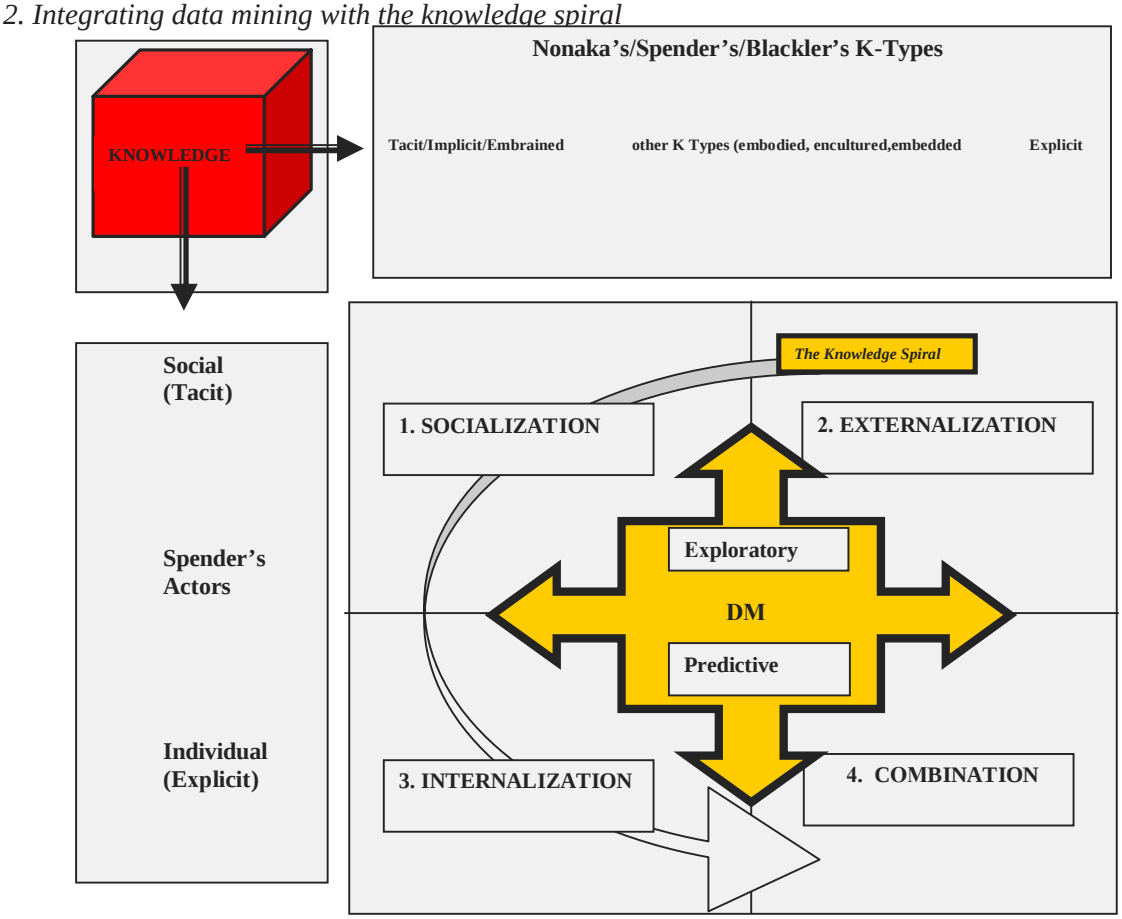
MAIN THRUST: ENRICHING DATA MINING WITH THE KNOWLEDGE SPIRAL

To conceive of knowledge as a collection of information seems to rob the concept of all of its life... Knowledge resides in the user and not in the collection. It is how the user reacts to a collection of information that matters. Churchman (1971, p. 10).

Churchman is clearly underscoring the importance of people in the process of knowledge creation. However, most formulations of information technology (IT) enabled knowledge management, and data mining in particular seem to have not only ignored the ignored the human element but also take a very myopic and homogenous perspective on the knowledge construct itself. Recent research that has surveyed the literature on KM indicates the need for more frameworks for knowledge management and particularly a meta framework to facilitate more successful realization of the KM steps (Wickramasinghe & Mills, 2001; Holsapple & Joshi, 2002; Alavi & Leidner, 2001; Schultze & Leidner, 2002). From a macro knowledge management perspective, the knowledge spiral is the cornerstone of knowledge creation. From a micro data mining perspective one of the key strengths of data mining as a technique is that it facilitates knowledge creation from data. Therefore, by integrating the algorithmic approach of knowledge creation (in particular data mining) with the psycho-social approach of knowledge creation (i.e., the people driven frameworks of knowledge creation, in particular the knowledge spiral) it is indeed possible to develop a meta framework for knowledge creation. By so doing, a richer and more complete approach to knowledge creation is realized. Such an approach not only leads to a deeper understanding of the knowledge creation process but also offers a knowledge creation methodology that is more customizable to specific organizational contexts, structures and cultures. Furthermore, it brings the human factor back into the knowledge creation process and doesn't over simplify the complex knowledge construct as a homogenous product.

Specifically, in figure 2 the knowledge product of data mining is broken into its constituent components based on the people driven perspectives (i.e., Blackler, Spender and Nonaka, respectively) of knowledge creation. On the other hand, the specific modes of transformation of the knowledge spiral discussed by Nonaka in his Knowledge Spiral should benefit from the algorithmic structured nature of both exploratory and predictive data mining techniques. For example, if we consider socialization which is described in (Nonaka & Nishiguchi, 2001, Nonaka, 1994) as the process of creating new tacit knowledge through discussion within groups, more specifically groups of experts, and we then incorporate the results of data mining techniques into this context this provides a structured forum and

Figure 2. Integrating data mining with the knowledge spiral



Specific Modes of Transformations and the Role of Data Mining in Realizing Them:

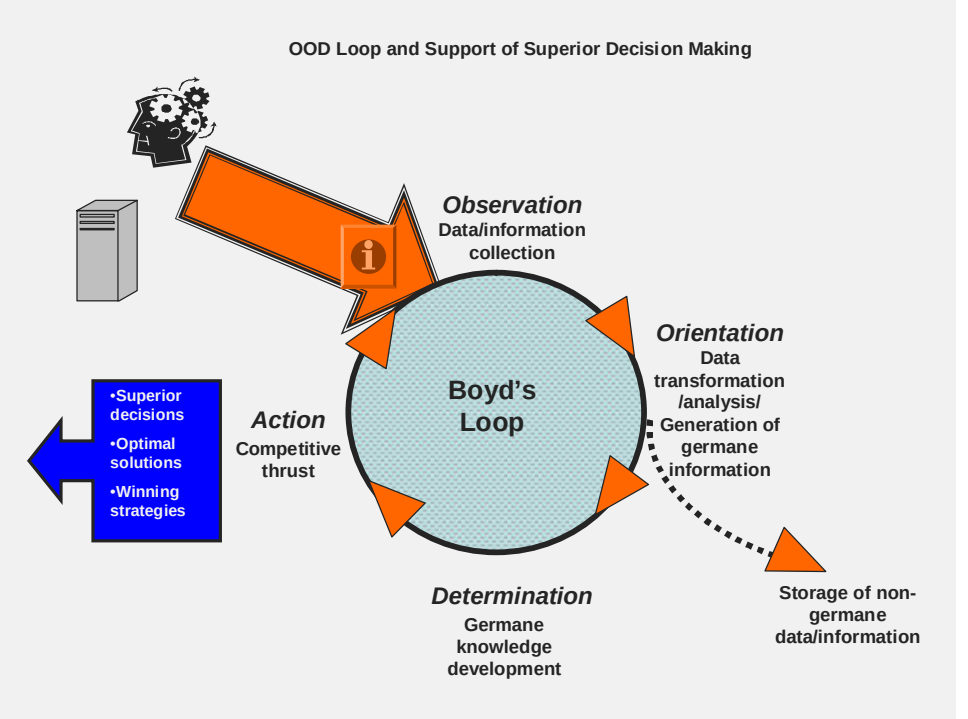
1. Socialization – experiential to experiential via practice group interactions on data mining results
2. Externalization – written extensions to data mining results
3. Internalization – enhancing experiential skills by learning from data mining results
4. Combination – gaining insights through applying various data mining visualization techniques

hence a "jump start" for guiding the dialogue and consequently knowledge creation. We note here though that this only enriches the socialization process without restricting the actual brainstorming activities, and thus not necessarily leading to the side effect of truncating divergent thoughts. This also holds for Nonaka's other modes of knowledge transformation.

Hierarchically, gathering of information precedes transformation of information into useable knowledge (Massey et al., 2002; Alavi & Leidner, 2001). Hence, the rate of information collection and the quality of the collected information will have a major impact on the quality (usefulness) of the generated knowledge (Chang et al., 2005). In dynamic and unstable environments, relative to the environment, the decision maker is in a position of tremendous information inferiority. In order to make effective decisions he/she must rapidly process seemingly irrelevant data and information into relevant and useable knowledge(Courtney, 2001; Drucker, 1993; Boyd, 1976; Award & Ghaziri, 2004; Newell et al., 2002, Schultz and Leidner, 2002; Wickramasinghe, 2006). This necessitates a process perspective to knowledge management (Wickramasinghe and von Lubitz, 2006; von Lubitz and Wickramasinghe, 2005b). The cornerstone of such a perspective is the OODA Loop (Figure 3) which provides formalized analysis of the processes involved in the development of a superior strategy (Boyd, 1976; 1987; von Lubitz & Wickramasinghe, 2006).

The Loop is based on a cycle of four interrelated stages revolving in time and space: Observation followed by Orientation, then by Decision, and finally

Figure 3. (Adapted from von Lubitz and Wickramasinghe, 2005ab)



Action. At the Observation and Orientation stages, multispectral implicit and explicit inputs are gathered (Observation) and converted into coherent information (Orientation). The latter determines the sequential Determination (knowledge generation) and Action (practical implementation of knowledge) steps. The outcome of the latter affects, in turn, the character of the starting point (Observation) of the next revolution in the forward progression of the rolling loop. The Orientation stage specifies the characteristics and the nature of the "center of thrust" at which the effort is to concentrate during the Determination and Action stages. Hence, the Loop implicitly incorporates the rule of "economy of force," i.e., the requirement that only minimum but adequate (containment) effort is applied to insignificant aspects of competitive interaction. The Loop exists as a network of simultaneous and intertwined events that characterize the multidimensional action space (competition space), and both influence and are influenced by the actor (e.g., an organization) at the centre of the network.

It is the incorporation of the dynamic aspect of the "action space" that makes the Loop particularly useful to environments that are inherently unstable and unpredictable i.e., medicine, business, war and emergency and disaster scenarios (von Lubitz and Wickramasinghe, 2005a; 2005b; 2006).

Thus as organizations strive to survive and thrive in today's competitive business environment incorporating people and process perspectives into their data mining initiatives will, through the extraction of germane knowledge, pertinent information and relevant data, serve to enable and support effective and superior decision making; a critical competitive necessity.

FUTURE TRENDS

The two significant ways to create knowledge are 1) synthesis of new knowledge through socialization with experts a primarily people dominated perspective 2) discovery by finding interesting patterns through observation and combination of explicit data, a primarily technology driven perspective (Becerra-Fernandez et al., 2004). In today's knowledge economy, knowledge creation and the maximization of an organization's knowledge and data assets is a key strategic necessity. Furthermore, we are seeing more techniques such as business intelligence and business analytics which have their foundations in traditional data mining being

embraced by organizations in order to try to facilitate the discovery of novel and unique patterns in data that will lead to new knowledge and maximization of an organization's data assets. Full maximization of an organization's data assets however will not be realized until the people perspective is incorporated into these data mining techniques to enable the full potential of knowledge creation to occur and even this is not sufficient for the ensuing decision to be most suitable. However, in addition, to taking such a socio-technical perspective, it is imperative to follow a systematic process in the extraction and application of the data, information and knowledge obtained, if indeed the consequent decision making is to be superior. As data warehouses and databases increase in volume and data mining and business intelligence capabilities increase in sophistication organizations that combine superior people centric and technology centric and most important the confluence of these two; i.e., socio-technical centric perspectives for knowledge creation will indeed have a sustainable competitive advantage in the current knowledge economy.

CONCLUSIONS

Sustainable competitive advantage is dependent on building and exploiting core competencies (Newell et al., 2002). In order to sustain competitive advantage, resources which are idiosyncratic (and thus scarce), and difficult to transfer or replicate are required (Grant, 1991). A knowledge-based view of the firm identifies knowledge as the organizational asset that enables sustainable competitive advantage especially in hyper competitive environments (Wickramasinghe, 2003; Davenport & Prusak, 1999; Zack,1999). This is attributed to the fact that barriers exist regarding the transfer and replication of knowledge (Wickramasinghe, 2003); thus making knowledge and knowledge management of strategic significance (Kanter, 1999). The key to maximizing the knowledge asset is in finding novel and actionable patterns and continuously creating new knowledge thereby increasing the extant knowledge base of the organization. It only becomes truly possible to support both major types of knowledge creation scenarios and thereby realize the synergistic effect of the respective strengths of these approaches in enabling superior decision making by embracing a holistic perspective to data mining; namely incorporating the people and process perspectives..

KEY TERMS

Combination: Knowledge transfer mode that involves new explicit knowledge being derived from existing explicit knowledge.

Explicit Knowledge: Or factual knowledge i.e. "know what" (Cabena et al, 1998), represents knowledge that is well established and documented.

Externalization: Knowledge transfer mode that involves new explicit knowledge being derived from existing tacit knowledge.

Internalization: Knowledge transfer mode that involves new tacit knowledge being derived from existing explicit knowledge.

Knowledge Spiral: The process of transforming the form of knowledge, and thus increasing the extant knowledge base as well as the amount and utilization of the knowledge within the organization

OODA Loop: Developed by Boyd, this framework traverses the decision maker through the critical steps of observation, orientation decision and action. At all times the access and extraction of germane knowledge, pertinent information and relevant data are key.

Socialization: Knowledge transfer mode that involves new tacit knowledge being derived from existing tacit knowledge.

Tacit Knowledge: Or experiential knowledge i.e.," know how" (Cabena et al, 1998) represents knowledge that is gained through experience and through doing.

Physical Data Warehousing Design

Ladjel Bellatreche
Poitiers University, France

Mukesh Mohania
IBM India Research Lab, India

INTRODUCTION

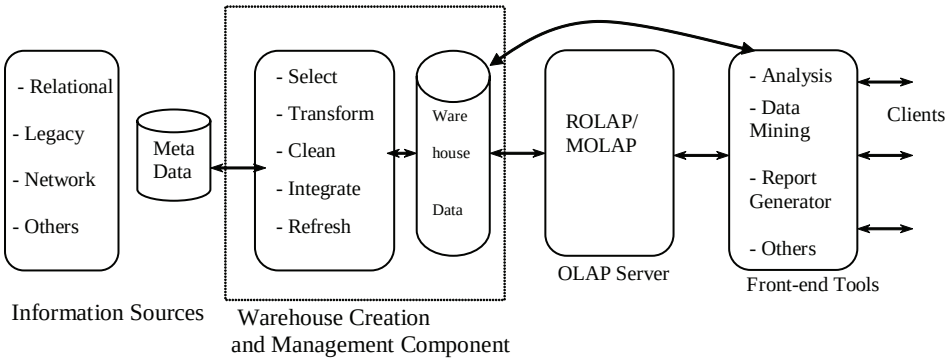
Recently, organizations have increasingly emphasized applications in which current and historical data are analyzed and explored comprehensively, identifying useful trends and creating summaries of the data in order to support high-level decision making. Every organization keeps accumulating data from different functional units, so that they can be analyzed (after integration), and important decisions can be made from the analytical results. Conceptually, a data warehouse is extremely simple. As popularized by Inmon (1992), it is a "subject-oriented, integrated, time-invariant, non-updatable collection of data used to support management decision-making processes and business intelligence". A data warehouse is a repository into which are placed all data relevant to the management of an organization and from which emerge the information and knowledge needed to effectively manage the organization. This management can be done using data-mining techniques, comparisons of historical data, and trend analysis. For such analysis, it is vital that (1) data should be accurate, complete, consistent, well defined, and time-stamped for informational purposes; and (2) data should follow business rules and satisfy integrity constraints. Designing a data warehouse is a lengthy, time-consuming, and iterative process. Due to the interactive nature of a data warehouse application, having fast query response time is a critical performance goal. Therefore, the physical design of a warehouse gets the lion's part of research done in the data warehousing area. Several techniques have been developed to meet the performance requirement of such an application, including materialized views, indexing techniques, partitioning and parallel processing, and so forth. Next, we briefly outline the architecture of a data warehousing system.

BACKGROUND

The conceptual architecture of a data warehousing system is shown in Figure 1. Data of a warehouse is extracted from operational databases (relational, object-oriented, or relational-object) and external sources (legacy data, other files formats) that may be distributed, autonomous, and heterogeneous. Before integrating this data into a warehouse, it should be cleaned to minimize errors and to fill in missing information, when possible, and transformed to reconcile semantic conflicts that can be found in the various sources. The cleaned and transformed data are integrated finally into a warehouse. Since the sources are updated periodically, it is necessary to refresh the warehouse. This component also is responsible for managing the warehouse data, creating indices on data tables, partitioning data, and updating meta-data. The warehouse data contain the detail data, summary data, consolidated data, and/or multi-dimensional data. The data typically are accessed and analyzed using tools, including OLAP query engines, data mining algorithms, information, visualization tools, statistical packages, and report generators.

The meta-data generally is held in a separate repository. The meta-data contain the informational data about the creation, management, and usage of tools (e.g., analytical tools, report writers, spreadsheets and data-mining tools) for analysis and informational purposes. Basically, the OLAP server interprets client queries (the client interacts with the front-end tools and passes these queries to the OLAP server) and converts them into complex SQL queries required to access the warehouse data. It also might access the data warehouse. It serves as a bridge between the users of the warehouse and the data contained in it. The warehouse data also are accessed by the OLAP server to present the data in a

Figure 1. A data warehousing architecture



multi-dimensional way to the front-end tools. Finally, the OLAP server passes the multi-dimensional views of data to the front-end tools, which format the data according to the client's requirements.

The warehouse data are typically modeled multi-dimensionally. The multi-dimensional data model has been proved to be the most suitable for OLAP applications. OLAP tools provide an environment for decision making and business modeling activities by supporting ad-hoc queries. There are two ways to implement a multi-dimensional data model: (1) by using the underlying relational architecture (star schemas, snowflake schemas) to project a pseudo-multi-dimensional model (example includes Informix Red Brick Warehouse); and (2) by using true multi-dimensional data structures such as, arrays (example includes Hyperion Essbase OLAP Server Hyperion). The advantage of MOLAP architecture is that it provides a direct multi-dimensional view of the data whereas the ROLAP architecture is just a multi-dimensional interface to relational data. On the other hand, the ROLAP architecture has two major advantages: (i) it can be used and easily integrated into other existing relational database systems; and (ii) relational data can be stored more efficiently than multi-dimensional data.

Data warehousing query operations include standard SQL operations, such as selection, projection, and join. In addition, it supports various extensions to aggregate functions, such as percentile functions (e.g., top 20th percentile of all products), rank functions (e.g., top 10 products), mean, mode, and median. One of the important extensions to the existing query language is to support multiple group-by, by defining roll-up, drill-down, and cube operators. Roll-up corresponds to doing further group-by on the same data object. Note that roll-up operator is order sensitive; that is, when it is defined in the extended SQL, the order of columns (attributes) matters. The function of a drill-down operation is the opposite of roll-up.

OLTP vs. OLAP

Relational database systems (RDBMS) are designed to record, retrieve, and manage large amounts of real-time transaction data and to keep the organization running by supporting daily business transactions (e.g., update transactions). These systems generally are tuned for a large community of users, and the user typically knows what is needed and generally accesses a small number of rows in a single transaction. Indeed, relational database systems are suited for robust and efficient Online Transaction Processing (OLTP) on operational data. Such OLTP applications have driven the growth of the DBMS industry in the past three decades and will doubtless continue to be important. One of the main objectives of relational systems is to maximize transaction throughput and minimize concurrency conflicts. However, these systems generally have limited decision support functions and do not extract all the necessary information required for faster, better, and intelligent decision making for the growth of an organization. For example, it is hard for an RDBMS to answer the following query: What are the supply patterns for product ABC in New Delhi in 2003, and how were they different from the year 2002? Therefore, it has become important to support analytical processing capabilities in organizations for (1) the efficient management of organizations, (2) effective marketing strategies, and (3) efficient and intelligent decision making. OLAP tools are well suited for complex data analysis, such as

Table 1. Comparison between OLTP and OLAP applications

Criteria	OLTP	OLAP
User	Clerk, IT Professional	Decision maker
Function	Day to day operations	Decision support
BD Design	Application-oriented	Subject-oriented
Data	Current	Historical, Consolidated
View	Detailed, flat relation	Summarized, multidimensional
Usage	Structured, Repetitive	Ad hoc
Unit of Work	Short, simple transaction	Complex query
Access	Read/Write	Append mostly
Records accessed	Tens	Millions
Users	Thousands	Tens
Size	MB-GB	GB-TB
Metric	Transaction throughput	Query throughput

multi-dimensional data analysis and to assist in decision support activities that access data from a separate repository called a data warehouse, which selects data from many operational legacies, and possibly heterogeneous data sources. The following table summarizes the differences between OLTP and OLAP.

MAIN THRUST

Decision-support systems demand speedy access to data, no matter how complex the query. To satisfy this objective, many optimization techniques exist in the literature. Most of these techniques are inherited from traditional relational database systems. Among them are materialized views (Bellatreche et al., 2000; Jixue et al., 2003; Mohania et al., 2000; Sanjay et al., 2000, 2001), indexing methods (Chaudhuri et al., 1999; Jügens et al., 2001; Stockinger et al., 2002), data partitioning (Bellatreche et al., 2000, 2002, 2004; Gopalkrishnan et al., 2000; Kalnis et al., 2002; Oracle, 2000; Sanjay et al., 2004), and parallel processing (Datta et al., 1998).

Materialized Views

Materialized views are used to precompute and store aggregated data, such as sum of sales. They also can be used to precompute joins with or without aggregations. So, materialized views are used to reduce the overhead associated with expensive joins or aggregations for a large or important class of queries. Two major problems related to materializing the views are (1) the view-maintenance problem, and (2) the view-selection problem. Data in the warehouse can be seen as materialized views generated from the underlying multiple data sources. Materialized views are used to speed up query processing on large amounts of data. These views need to be maintained in response to updates in the source data. This often is done using incremental techniques that access data from underlying sources. In a data-warehousing scenario, accessing base relations can be difficult; sometimes data sources may be unavailable, since these relations are distributed across different sources. For these reasons, the issue of self-maintainability of the view is an important issue in data warehousing. The warehouse views can be made self-maintainable by materializing some additional information, called auxiliary relations, derived from the intermediate results of the view computation. There are several algorithms, such as counting algorithm and exact-change algorithm, proposed in the literature for maintaining materialized views.

To answer the queries efficiently, a set of views that are closely related to the queries is materialized at the data warehouse. Note that not all possible views are materialized, as we are constrained by some resource like disk space, computation time, or maintenance cost. Hence, we need to select an appropriate set of views to materialize under some resource constraint. The view selection problem (VSP) consists in selecting a set of materialized views that satisfies the query response time under some resource constraints. All studies showed

that this problem is an NP-hard. Most of the proposed algorithms for the VSP are static. This is because each algorithm starts with a set of frequently asked queries (a priori known) and then selects a set of materialized views that minimize the query response time under some constraint. The selected materialized views will be a benefit only for a query belonging to the set of a priori known queries. The disadvantage of this kind of algorithm is that it contradicts the dynamic nature of decision support analysis. Especially for ad-hoc queries, where the expert user is looking for interesting trends in the data repository, the query pattern is difficult to predict.

Indexing Techniques

Indexing has been the foundation of performance tuning for databases for many years. It creates access structures that provide faster access to the base data relevant to the restriction criteria of queries. The size of the index structure should be manageable, so that benefits can be accrued by traversing such a structure. The traditional indexing strategies used in database systems do not work well in data warehousing environments. Most OLTP transactions typically access a small number of rows; most OLTP queries are point queries. B-trees, which are used in the most common relational database systems, are geared toward such point queries. They are well suited for accessing a small number of rows. An OLAP query typically accesses a large number of records for summarizing information. For example, an OLTP transaction would typically query for a customer who booked a flight on TWA 1234 on April 25, for instance; on the other hand, an OLAP query would be more like give me the number of customers who booked a flight on TWA 1234 in one month, for example. The second query would access more records that are of a type of range queries. B-tree indexing scheme is not suited to answer OLAP queries efficiently. An index can be a single-column or multi-column table (or view). An index either can be clustered or non-clustered. An index can be defined on one table (or view) or many tables using a join index. In the data warehouse context, when we talk about index, we refer to two different things: (1) indexing techniques and (2) the index selection problem. A number of indexing strategies have been suggested for data warehouses: value-list index, projection index, bitmap index, bit-sliced index, data index, join index, and star join index.

Data Partitioning and Parallel Processing

The data partitioning process decomposes large tables (fact tables, materialized views, indexes) into multiple (relatively) small tables by applying the selection operators. Consequently, the partitioning offers significant improvements in availability, administration, and table scan performance Oracle9i.

Two types of partitioning are possible to decompose a table: vertical and horizontal. In the vertical fragmentation, each partition consists of a set of columns of the original table. In the horizontal fragmentation, each partition consists of a set of rows of the original table. Two versions of horizontal fragmentation are available: primary horizontal fragmentation and derived horizontal fragmentation. The primary horizontal partitioning (HP) of a relation is performed using predicates that are defined on that table. On the other hand, the derived partitioning of a table results from predicates defined on another relation. In a context of ROLAP, the data partitioning is applied as follows (Bellatreche et al., 2002): it starts by fragmenting dimension tables, and then, by using the derived horizontal partitioning, it decomposes the fact table into several fact fragments. Moreover, by partitioning data of ROLAP schema (star schema or snowflake schema) among a set of processors, OLAP queries can be executed in a parallel, potentially achieving a linear speedup and thus significantly improving query response time (Datta et al., 1998). Therefore, the data partitioning and the parallel processing are two complementary techniques to achieve the reduction of query processing cost in data warehousing environments.

FUTURE TRENDS

It has been seen that many enterprises are moving toward building the Operational Data Store (ODS) solutions for real-time business analysis. The ODS gets data from one or more Enterprise Resource Planning (ERP) systems and keeps the most recent version of information for analysis rather than the history of data. Since the Client Relationship Management (CRM) offerings have evolved, there is a need for active integration of CRM with the ODS for real-time consulting and marketing (i.e., how to integrate ODS with CRM via messaging system for real-time business analysis).

Another trend that has been seen recently is that many enterprises are moving from data warehousing solutions to information integration (II). II refers to a category of middleware that lets applications access data as though they were in a single database, whether or not they are. It enables the integration of data and content sources to provide real-time read and write access in order to transform data for business analysis and data warehousing and to data placement for performance, currency, and availability. That is, we envisage that there will more focus on integrating the data and contents rather than only integrating structured data, as done in the data warehousing.

CONCLUSION

The data warehousing design is quite different from those of transactional database systems, commonly referred as Online Transaction Processing (OLTP) systems. A data warehouse tends to be extremely large, and the information in a warehouse usually is analyzed in a multi-dimensional way. The main objective of a data warehousing design is to facilitate the efficient query processing and maintenance of materialized views. For achieving this objective, it is important that the relevant data is materialized in the warehouse. Therefore, the problems of selecting materialized views and maintaining them are very important and have been addressed in this article. To further reduce the query processing cost, the data can be partitioned. That is, partitioning helps in reducing the irrelevant data access and eliminates costly joins. Further, partitioning at a finer granularity can increase the data access and processing cost. The third problem is index selection. We found that judicious index selection does reduce the cost of query processing, but we also showed that indices on materialized views improve the performance of queries even more. Since indices and materialized views compete for the same resource (storage), we found that it is possible to apply heuristics to distribute the storage space among materialized views and indices so as to efficiently execute queries and maintain materialized views and indexes.

It has been seen that enterprises are moving toward building the data warehousing and operational data store solutions.

KEY TERMS

Bitmap Index: Consists of a collection of bitmap vectors, each of which is created to represent each distinct value of the indexed column. A bit i in a bitmap vector, representing value x, is set to 1, if the record i in the indexed table contains x.

Cube: A multi-dimensional representation of data that can be viewed from different perspectives.

Data Warehouse: An integrated decision support database whose content is derived from the various operational databases. A subject-oriented, integrated, time-variant, non-updatable collection of data used in support of management decision-making processes.

Dimension: A business perspective useful for analyzing data. A dimension usually contains one or more hierarchies that can be used to drill up or down to different levels of detail.

Dimension Table: A table containing the data for one dimension within a star schema. The primary key is used to link to the fact table, and each level in the dimension has a corresponding field in the dimension table.

Fact Table: The central table in a star schema, containing the basic facts or measures of interest. Dimension fields are also included (as foreign keys) to link to each dimension table.

Horizontal Partitioning: Distributing the rows of a table into several separate tables.

Join Index: Built by translating restrictions on the column value of a dimension table to restrictions on a large fact table. The index is implemented using one of two representations: row id or bitmap, depending on the cardinality of the indexed column.

Legacy Data: Data that you already have and use. Most often, this takes the form of records in an existing database on a system in current use.

Measure: A numeric value stored in a fact table or cube. Typical examples include sales value, sales volume, price, stock, and headcount.

Star Schema: A simple database design in which dimensional data are separated from fact or event data. A dimensional model is another name for star schema.

Positive Unlabelled Learning for Document Classification

Xiao-Li Li
Institute for Infocomm Research, Singapore

See-Kiong Ng
Institute for Infocomm Research, Singapore

INTRODUCTION

In traditional supervised learning, a large number of labeled positive and negative examples are typically required to learn an accurate classifier. However, in practice, it is costly to obtain the class labels for large sets of training examples, and oftentimes the negative examples are lacking. Such practical considerations motivate the development of a new set of classification algorithms that can learn from a set of labeled positive examples *P* augmented with a set of unlabeled examples *U* (which contains both hidden positive and hidden negative examples). That is, we want to build a classifier using *P* and *U* in the absence of negative examples to classify the data in *U* as well as future test data. This problem is called the Positive Unlabelled learning problem or PU learning problem.

For instance, a computer scientist may want to build an up-to-date repository of machine learning (ML) papers. Ideally, one can start with an initial set of ML papers (e.g., a personal collection) and then use it to find other ML papers from related online journals or conference series, e.g., Artificial Intelligence journal, AAAI (National Conference on Artificial Intelligence), IJCAI (International Joint Conferences on Artificial Intelligence), SIGIR (ACM Conference on Research & Development on Information Retrieval), and KDD (ACM International Conference on Knowledge Discovery and Data Mining) etc. With the enormous volume of text documents on the Web, Internet news feeds, and digital libraries, finding those documents that are related to one's interest can be a real challenge.

In the application above, the class of documents that one is interested in is called the **positive documents** (i.e. the ML papers in the online sources). The set of known positive documents are represented as *P* (namely, the initial personal collection of ML papers). The unlabelled set *U* (papers from AAAI Proceedings etc) contains two groups of documents. One group contains documents of class *P*, which are the hidden positive documents in *U* (e.g., the ML papers in an AAAI Proceedings). The other group, which comprises the rest of the documents in *U*, are the **negative documents** (e.g., the non-ML papers in an AAAI Proceedings) since they do not belong to positive class. Given a positive set *P*, **PU learning** aims to identify a particular class *P* of documents from *U* or classify the future test set into positive and negative classes. Note that collecting unlabeled documents is normally easy and inexpensive, especially those involving online sources.

BACKGROUND

A theoretical study of PAC learning from positive and unlabeled examples under the statistical query model was first reported in (Denis, 1998). It assumes that the proportion of positive instances in the unlabeled set is known. Letouzey *et al.* (Letouzey, Denis, & Gilleron, 2000; Denis, Gilleron, & Letouzey, 2005) presented a learning algorithm based on a modified decision tree algorithm in this model. Muggleton (Muggleton, 1997) followed by studying the problem in a Bayesian framework where the distribution of functions and examples are assumed known. (Liu, Lee, Yu, & Li, 2002) reported sample complexity results and provided theoretical elaborations on how the problem may be solved.

A number of practical algorithms, S-EM, PEBL and Roc-SVM (Liu et al., 2002; Yu, Han, & Chang, 2002; Li & Liu, 2003) have also been proposed. They all conformed to the theoretical results in (Liu et al., 2002), following a two-step strategy: (1) identifying a set of reliable negative documents *RN* from the unlabeled set (called *strong negative documents* in PEBL), and (2) building a classifier using *P* (positive set), *RN* (negative set) and *U-RN*

(unlabelled set) through applying an existing learning algorithm (such as EM or SVM) once or iteratively. Their specific differences are described in the next subsection "Existing Techniques S-EM, PEBL and Roc-SVM".

Other related works include: Lee and Liu's weighted logistic regression technique (Lee & Liu, 2003) and Liu et al.'s biased SVM technique (Liu, Dai, Li, Lee, & Yu, 2003). Both required a performance criterion to determine the quality of the classifier. In (Fung, Yu, Lu, & Yu, 2006), a method called PN-SVM was proposed to deal with the case when the positive set is small where it assumes that the positive examples in *P* and the hidden positives in *U* were all generated from the same distribution. More recently, PU learning was used to identify unexpected instances in the test set (Li, Liu, & Ng, 2007b). PU learning was also useful for extracting relations, identifying user preferences and filtering junk email, etc (Agichtein, 2006; Deng, Chai, Tan, Ng, & Lee., 2004; Schneider, 2004; Zhang & Lee., 2005).

MAIN FOCUS

We will first introduce state-of-art techniques in PU learning for document classification, namely, S-EM (Liu et al., 2002), PEBL (Yu et al., 2002) and Roc-SVM (Li & Liu, 2003). Then, we will describe a document classification application which requires PU learning with only a small positive training set.

Existing Techniques S-EM, PEBL and Roc-SVM

As mentioned earlier, the existing techniques (S-EM, PEBL and Roc-SVM) all use a two-step strategy. We will focus on discussing the first step (negative example extraction) of the three methods (Spy, 1DNF, Rocchio respectively), since the second step of the three methods is essentially similar.

The main idea of S-EM is to use a spy technique to identify some *reliable negative documents* from the unlabeled set *U*. S-EM works by sending some "spy" documents from the positive set *P* to the unlabeled set *U*. The technique makes the following assumption: since the spy documents from *P* and the hidden positive documents in *U* are positive documents, the spy documents should behave identically to the hidden positive documents in *U* and can thus be used to reliably infer the behavior of the unknown positive documents.

S-EM randomly samples a set *S* of positive documents from *P* and puts them in *U*. Next, it runs the naïve Bayesian (NB) technique using the set $P - S$ as positive and the set $U \cup S$ as negative. The NB classifier is then applied to classify each document *d* in $U \cup S$, i.e., to assign it a probabilistic class label Pr(+|*d*), where "+" represents the positive class. Finally, it uses the probabilistic labels of the spies to decide which documents are most likely to be positive (the remaining documents are thus the reliable negative). S-EM sets a threshold using the probabilistic labels of spies which controls to extract most (85%) of spies from *U*, indicating that it can also extract out most of the other hidden positives from *U* since they behave identically.

In comparison, PEBL (Positive Example Based Learning) tries to extract reliable (strong) negative documents by using 1DNF method. Those documents in *U* that do not contain any positive features are regarded as reliable negative documents. 1DNF method first builds a positive feature set *PF* containing words that occur in the positive set *P* more frequently than in the unlabeled set *U*. Then it tries to filter out possible positive documents from *U*. A document in *U* that does not contain any positive feature in *PF* is regarded as a reliable negative document.

Unlike S-EM and PEBL, Roc-SVM performs negative data extraction using the Rocchio method. Roc-SVM uses the positive set *P* as positive training data and *U* as negative training data to build a Rocchio classifier where positive and negative prototype vectors $\vec{c}^{+}$ and $\vec{c}^{-}$ are constructed. In classification, for each document $\vec{d}'$ in unlabelled set U, it simply uses the cosine measure (Salton & McGill, 1986) to compute the similarity of $\vec{d}'$ with each prototype vector. The class whose prototype vector is more similar to $\vec{d}'$ is assigned to the document. Those documents classified as negative form the reliable negative set *RN*.

Let us compare the above three methods for extracting reliable negative documents. Although S-EM is not sensitive to noise, it can be problematic when the EM's assumptions (the data is generated by a mixture model, and there is a one-to-one correspondence between mixture components and classes) do not hold (Liu et al., 2002). PEBL is sensitive to the number of positive documents. When the positive data

is small, the results are often very poor (Li & Liu, 2003) (Fung et al., 2006). In contrast, Roc-SVM is robust and performs consistently well under a variety of conditions (Li & Liu, 2003; Fung et al., 2006). However, these current methods do not perform well when the size of the positive examples is small.

LPLP

In this section, we consider a problem of learning to classify documents with only a small positive training set. The work was motivated by a real-life business intelligence application of classifying web pages of product information. For example, a company that sells digital cameras may want to do a product comparison among the various cameras currently available in the market. One can first collect sample digital camera pages by crawling through all product pages from a consolidated e-commerce web site (e.g., amazon.com) and then hand-label those pages containing digital camera product information to construct the set *P* of positive examples. Next, to get more product information, one can then crawl through all the product pages from other web sites (e.g., cnet.com) as *U*. Ideally, PU learning techniques can then be applied to classify all pages in *U* into digital camera pages and non-digital camera pages. However, we found that while the digital camera product pages from two websites (say, amazon.com and cnet.com) do indeed share many similarities, they can also be quite distinct as the different web sites invariably present their products in different styles and have different focuses. As such, directly applying existing methods would give very poor results because 1) the small positive set *P* obtained from one site typically contains only tens of web pages (usually less than 30) and therefore do not adequately represent the whole positive class *P*, and 2) the features from the positive examples in *P* and the hidden positive examples in *U* are usually not generated from the same distribution because they were from different web sites.

The LPLP (Learning from Probabilistically Labeling Positive examples) method is designed to perform well for this task (Li, Liu, & Ng, 2007a). It consists of three steps. 1) Selecting a set of representative keywords from *P*; 2) Identifying likely positive set *LP* from *U* and probabilistically labeling the documents in *LP*; 3) Performing the classification algorithm. Note that LPLP is significantly different from current existing PU learning techniques since it focuses on extracting a set of likely positive documents from *U* instead of reliable negatives.

Selecting a Set of Representative Keywords From P

Notice that while the positive documents in *P* and the hidden positive documents in *U* were not drawn from the same distribution, they should still be similar in some underlying feature dimensions given that they belonged to the same class. For example, the digital camera pages from two different sites, say amazon.com and cnet.com, would share the representative keywords such as "resolution", "pixel", "lens", "shutter", "zoom", etc, even if their respective distributions may be quite different.

A set *RW* of representative keywords can be extracted from the positive set *P* which contains the top *k* words with the highest $s(w_i)$ scores. The scoring function $s()$ is based on TFIDF method (Salton & McGill, 1986) which gives high scores to those words that occur frequently in the positive set *P* and not in the whole corpus $P \cup U$ since *U* contains many other unrelated documents.

After removing the stop words and performing stemming (Salton & McGill, 1986), the LPLP algorithm computes the accumulated word frequency for each word feature w_i in the positive set *P*. The score of w_i is then computed by considering both w_i's probabilities of belonging to a positive class and its inverted document frequency in $P \cup U$. After ranking the scores for all the features into the rank list *L*, those word features with top *k* scores in *L* are stored into *RW*.

Identifying *LP* and Probabilistically Labeling the Documents

Once the set *RW* of representative keywords is determined, we can regard them together as a representative document (*rd*) of the positive class. The next objective is to identify the likely positive set *LP*, since the current positive set *P* is small.

The similarity of each document d_i in *U* with *rd* can be computed by using the cosine similarity metric (Salton & McGill, 1986). For any document d_i in *U*, if $sim(rd, d_i)>0$, it is stored into a set *LP* assigned with a probability $Pr(+|d_i)$ based on the ratio of the similarity $sim(rd, d_i)$ and *m* (the maximal similarity). Otherwise,

d_i is included in *RU* instead. The documents in *RU* have zero similarity with *rd* and can be considered as a "purer" negative set than *U*.

The hidden positive examples in *LP* will be assigned high probabilities $Pr(+|d_i)$ while the negative examples in *LP* will be assigned very low probabilities $Pr(+|d_i)$. This is because the representative keywords in *RW* were chosen based on those words that occurred frequently in *P* but not in the whole corpus $P \cup U$. As such, the hidden positive examples in *LP* should also contain many of the features in *RW* while the negative examples in *LP* would contain few of the features in *RW*.

Performing the Classification Algorithm

Finally, the proposed LPLP algorithm will build a NB classifier using *RU* as negative training set. As the positive set *PS*, there are two possible choices: either (1) combine *LP* and *P* as *PS*, or (2) use only *LP* as *PS*, depending on the situation. The initial NB classifier is then applied to the documents in ($LP \cup RU$) to obtain the posterior probabilities ($Pr(+|d_i)$ and $Pr(-|d_i)$) for each document. An EM algorithm can then iteratively employ the revised posterior probabilities to build a new NB classifier until the parameters of the NB classifier converge.

The LPLP algorithm was evaluated with experiments performed using actual product Web pages (Notebook, Digital Camera, Mobile Phone, Printer and TV) collected from 5 commercial Web sites: Amazon, CNet, PCMag, J&R and ZDnet. As expected, LPLP was found to perform significantly better than the three existing methods S-EM, PEBL and Roc-SVM. Its ability to handle probabilistic labels makes it better equipped to take advantage of the probabilistic *LP* set than the SVM-based approaches. As for the choices of two different *PS* sets, if there were only a small number of positive documents available, it was found that using combined *PS* for constructing the classifier is better since likely positive set *LP* can help represent the whole positive class better. Interestingly, if there is a large number of positive documents, using only *LP* is superior (Li et al., 2007a).

FUTURE TRENDS

We have described four techniques S-EM, PEBL, Roc-SVM, and LPLP that can be used in PU learning for document classification. One important empirical observation is that when the positive set is sufficiently large, all the PU learning techniques can achieve good classification results. However, when a small positive set is available, only the LPLP method can perform well. PU learning with small positive set *P* is a challenging problem since the small positive examples in *P* does not adequately represent the documents of whole positive class.

Current search engines are keyword-based instead of example-based, assuming that a user can always articulate what he/she is looking for with a few keywords. For complex information retrieval tasks, it may be useful for a user to provide a few positive examples that he/she is interested in. Given that the positive examples would provide more descriptive power than the keywords, PU learning with small positive set could potentially improve the accuracy of search engines further. This is one of the future directions of PU learning.

CONCLUSION

We have presented the PU learning problem and some existing techniques for it. Particularly, S-EM, PEBL and Roc-SVM, have been proposed to address the lack of negative examples by attempting to identify potential negative examples from the unlabelled set *U*. However, such PU learning methods would not work well in some real-world classification applications where the size of positive examples is small.

LPLP method was designed to address this oft-overlooked issue. Instead of identifying a set of reliable negative documents from the unlabeled set *U*, LPLP focuses on extracting a set of likely positive documents from *U*. This addresses the limited size of *P* and its potential distribution differences with the overall positive examples. With the augmentation of the extracted probabilistic *LP* set, the LPLP algorithm can build a much more robust classifier than those algorithms that rely only on the small positive set *P*.

Key Terms

1DNF: A technique is used to extract the strong negative documents that do not contain any positive feature.

Likely Positive Set: Based on the representative document (*rd*) from the positive set *P*, a set *LP* of likely positive documents can be extracted out from unlabelled set *U*, by computing the similarities between the documents in *U* and *rd*.

Positive Set: A set *P* of positive documents which we are interested in. It is possible that *P* contains the documents from multiple classes.

PU Learning: Given *P* and *U*, a classifier is built to identify positive documents in *U* or in a separate test set *T*. In other words, the objective of PU learning is to accurately classify the documents in *U* or *T* into documents from *P* and documents not from *P*.

Spy: S-EM works by sending some "spy" documents from the positive set *P* to the unlabeled set *U*. Since spy documents should behave identically to the hidden positive documents in *U* and hence allows to reliably infer the behavior of the unknown positive documents.

Two-Step Strategy of PU Learning: (1) given positive set *P* and unlabelled set *U*, the first step is to identify a set of reliable negative documents from the unlabeled set *U*; and second step is to build a classifier using EM or SVM once or iteratively.

Unlabeled Set: A set *U* of the mixed set which contains both positive documents from positive class *P* and also other types of negative documents.

Predicting Resource Usage for Capital Efficient Marketing

INTRODUCTION

A structural conflict exists in businesses which sell services whose production costs are discontinuous and whose consumption is continuous but variable. A classic example is in businesses where capital-intensive infrastructure is necessary for provisioning service, but the capacity resulting from capital outlay is not always fully and efficiently utilized. Marketing departments focus on initiatives which increase infrastructure usage to improve both customer retention and on-going revenue. Engineering and operations departments focus on the cost of service provision to improve the capital efficiency of revenue dollar received. Consequently, a marketing initiative to increase infrastructure usage may be resisted by engineering if its introduction would require great capital expense to accommodate that increased usage. This conflict is exacerbated when a usage-enhancing initiative tends to increase usage variability so that capital expenditures are triggered with only small increases in total usage.

A data warehouse whose contents encompass both these organizational functions has the potential to mediate this conflict, and data mining can be the tool for this mediation. Marketing databases typically have customer data on rate plans, usage and past response to marketing promotions. Engineering databases generally record infrastructure locations, usages and capacities. Other information is often available from both general domains to allow for the aggregation, or clustering of customer types, rate plans and marketing promotions so that marketing proposals and their consequences can be systematically evaluated to aid in decision making. These databases generally contain such voluminous or complicated data that classical data analysis tools are inadequate. In this chapter, we look at a case study where data mining is applied to predicting capital-intensive resource or infrastructure usage, with the goal of guiding marketing decisions to enable capital efficient marketing. Although the data mining models developed in this chapter do not provide conclusive positions on specific marketing initiatives and their engineering consequences, the usage revenues and infrastructure performance predicted by these models provide systematic, sound, and quantitative input for making balanced and cost-effective business decisions.

BACKGROUND

In this business context, applying data mining (Berry and Linoff, 2004; Abramowicz and Zurada, 2000; Han and Kamber, 2006; Kantardzic and Zurada, 2005) to capital efficient marketing is illustrated here by a study from wireless telephony (Green, 2000) where marketing plans introduced to utilize excess off-peak network capacity (see Figure 1) could potentially result in requiring fresh capital outlays by indirectly driving peak demand to levels beyond current capacity.

We specifically consider marketing initiatives—e.g., specific rate plans with free nights and weekends—that are aimed at stimulating off-peak usage. Given a rate plan with a fixed peak minute allowance, availability of extra off-peak minutes could potentially increase peak usage. The quantification of this effect is complicated by the corporate reality of myriad rate plans and geographically extensive and complicated peak usage patterns. In this study, we use data mining methods to analyze customer, call detail, rate plan and cell-site location data to predict the effect of marketing initiatives on busy hour network utilization. This will enable forecasting

Figure 2. Flowchart describing data sources and data mining operations used in predicting busy hour impact of marketing initiatives

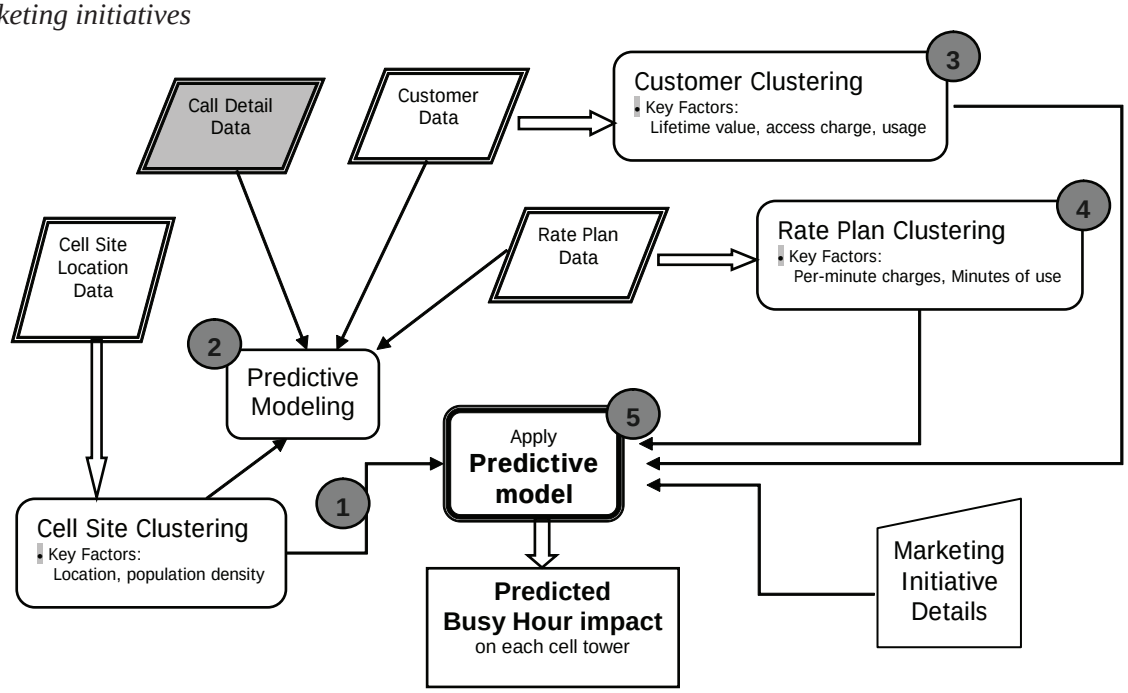

Figure 1. Marketing initiatives to boost average demand can indirectly increase peak demand to beyond capacity.

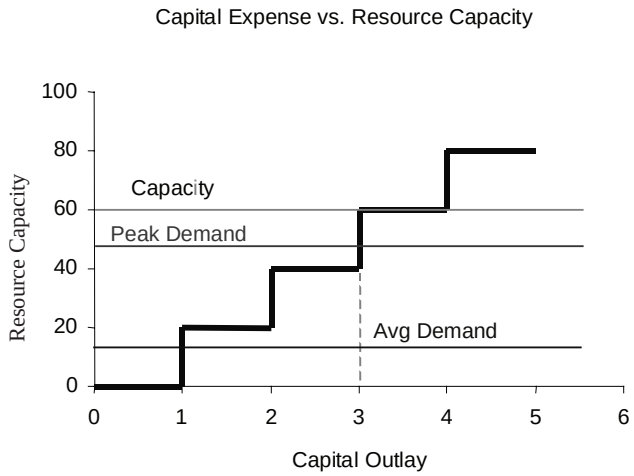


network cost of service for marketing initiatives thereby leading to optimization of capital outlay.

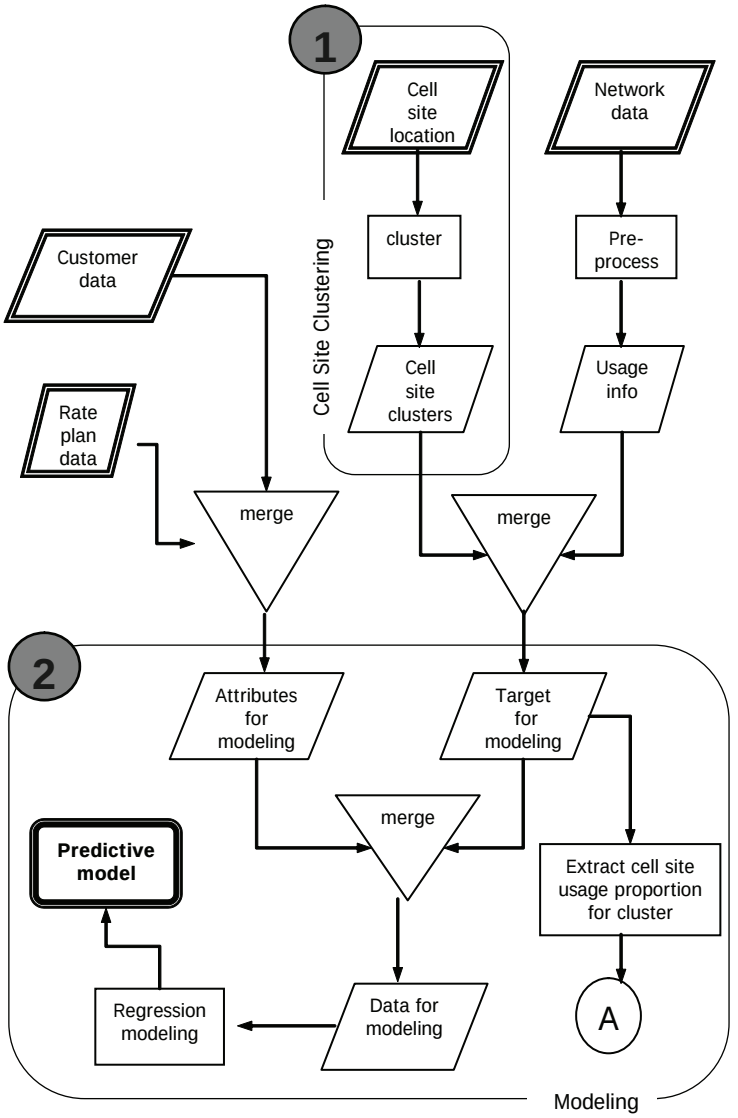
MAIN THRUST OF THE CHAPTER

Ideally, the capital cost of a marketing initiative is obtained by determining the existing capacity, the increased capacity required under the new initiative, and then factoring the cost of the additional capital; and data for a study like this would come from a corporate data warehouse (Berson and Smith, 1997) that integrates data from relevant sources. Unfortunately, such detailed cost data are not available in most corporations and businesses—in fact in many situations, the connection between promotional marketing initiatives and capital cost is not even recognized. In this case study, we therefore need to assemble relevant data from different and disparate sources in order to predict the busy hour impact of marketing initiatives.

Data

The parallelograms in the flowchart in Figure 2 indicate essential data sources for linking marketing initiatives to busy hour usage. *Customer Data* characterizes the customer by indicating a customer's mobile phone number(s), lifetime value, access charge, subscribed rate plan, peak and off-peak minutes used. *Rate Plan Data* provides details for a given rate plan including monthly charges, allowed peak, off-peak and weekend minutes of use, per-minute charges for excess use, long distance and roaming charges, etc. *Call Detail Data* provides, for every call placed in a given time period, the originating and terminating phone numbers

Figure 3. Steps 1 and 2 in the data mining process outlined in Figure 2



(and hence originating and terminating customers), cell sites used in handling the call, call duration and other call details. *Cell Site Location Data* indicates the geographic location of cell sites, capacity of each cell site, and details about the physical and electromagnetic configuration of the radio towers.

Data Mining Process

Figure 2 provides an overview of the analysis and data mining process. The numbered processes are described in more detail to illustrate how the various components are integrated into an exploratory tool that allows marketers and network engineers to evaluate the effect of proposed initiatives.

Cell-Site Clustering

Clustering cell sites using the geographic location (latitude, longitude) results in cell site clusters that capture the underlying population density, with cluster area generally inversely proportional to population. This is a natural consequence of the fact that heavily populated urban areas tend to have more cell towers to cover the large call volumes and provide good signal coverage. The flowchart for cell site clustering is included in

Figure 3 with results of *k*-means clustering (Hastie, Tibshirani and Friedman, 2001; Cios et. al., 2007) for the San Francisco area shown in Figure 4. The cell sites in the area are grouped into four clusters, each cluster approximately circumscribed by an oval.

Predictive Modeling

The predictive modeling stage, shown in Figure 3, merges customer and rate plan data to provide the data attributes (features) used for modeling. The target for modeling is obtained by combining cell site clusters with network usage information. Note that the sheer volume of call detail data makes its summarization and merging with other customer and operational data a daunting one. See, for example, Berry and Linoff (2000) for a discussion. The resulting dataset has, for every customer, related customer characteristics and rate plan details, matched up with that customer's actual network usage and the cell sites providing service for that customer. This data can then be used to build a predictive model. Feature selection (Liu and Motoda, 1998) is performed based on correlation to target, with grouped interactions taken into account. The actual predictive model is based on linear regression (Hastie, Tibshirani and Friedman, 2001; Hand, Mannila and Smyth, 2001)—which for this application performs similar to neural network models (Haykin, 1998; Duda, Hart and Stork, 2000). Note that the sheer number of customer and rate plan characteristics requires the variable reduction capabilities of a data mining solution.

For each of the 4 cell site clusters shown in Figure 4, Figure 5 shows the actual versus predicted busy hour usage, for calls initiated during a specific month in the San Francisco region. With statistically significant R^2 correlation values ranging from about 0.31 to 0.67, the models, while not perfect, are quite good at predicting cluster-level usage.

Figure 4. Clustering cell sites in the San Francisco area, based on geographic position. Each spot represents a cell site, with the ovals showing approximate location of cell site clusters

Customer and Rate Plan Clustering

Using *k*-means clustering to cluster customers based on their attributes, and rate plans based on their salient features, results in categorizing customers and rate plans into a small number of groups. Without such clustering, the complex data combinations and analyses needed to predict busy hour usage will result in very little predictive power. Clusters ameliorate the situation by providing a small set of representative cases to use in the prediction.

As in cell site clustering, based on empirical exploration, we decide on using four clusters for both customers and rate plans. Results of the clustering for customers and applicable rate plans in the San Francisco area are shown in Figure 6 and 7.

Integration and Application of the Predictive Model

Stringing all the pieces together, we can start with a proposed rate plan and an inwards projection of the expected number of customers who would subscribe to the plan, and predict the busy hour usage on targeted cell sites. The process is outlined in Figure 8. Inputs labeled A, B and C come from the respective flowcharts in Figures 2, 6 and 7.

Validation

Directly evaluating and validating the analytic model developed would require data summarizing capital cost of a marketing initiative. This requires determining the existing capacity, the increased capacity required under the new initiative, and then factoring the cost of the additional capital. Unfortunately, as mentioned earlier,

Figure 5. Regression modeling results showing predicted versus actual busy hour usage for the cell site clusters shown in Figure 4

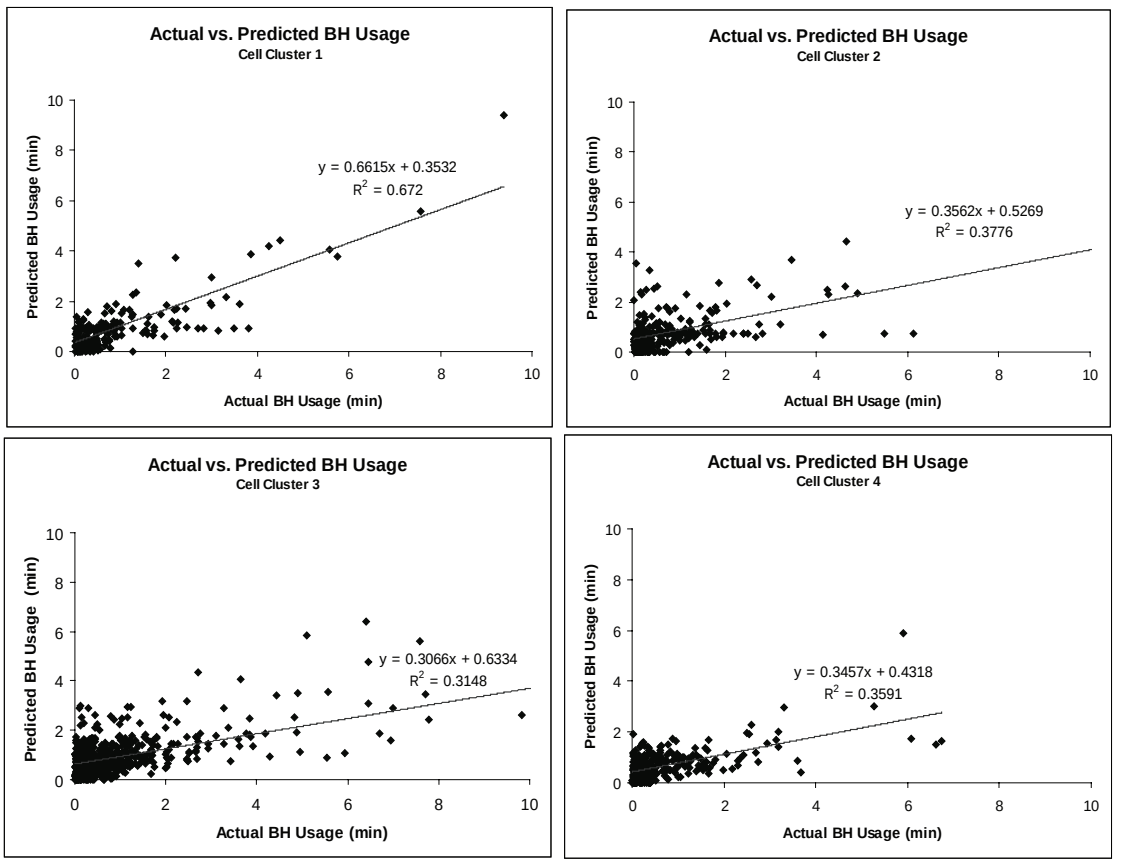


Figure 6. Customer clustering flowchart and results of customer clustering. The key attributes identifying the four clusters are access charge (ACC_CHRG), lifetime value (LTV_PCT), peak minutes of use (PEAK_MOU) and total calls (TOT_CALL)

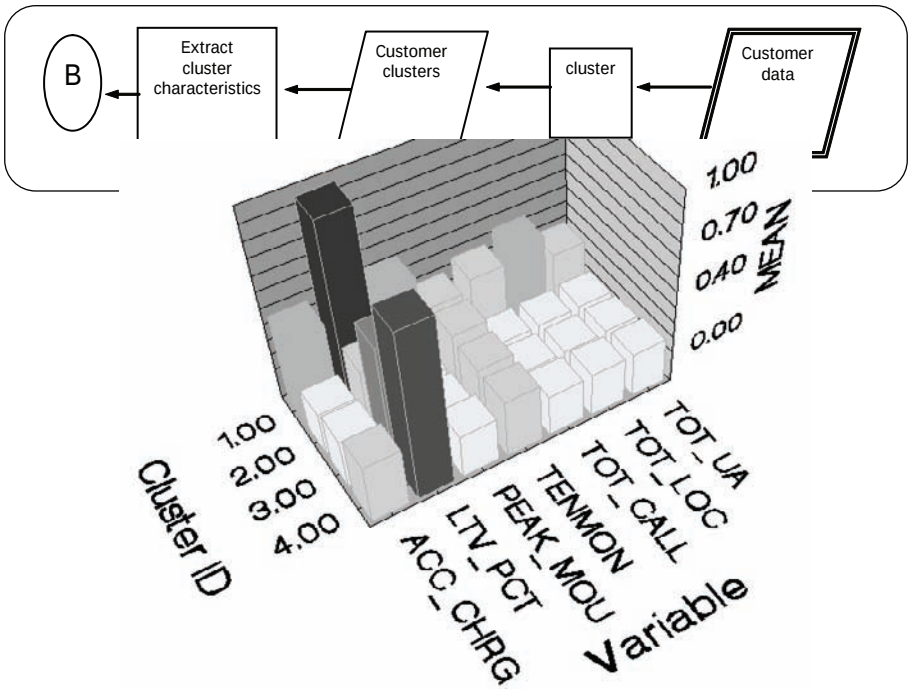

Figure 7. Rate plan clustering flowchart and clustering results. The driving factor that distinguish rate plan clusters include per-minute charges (intersystem, peak and off-peak), and minutes of use

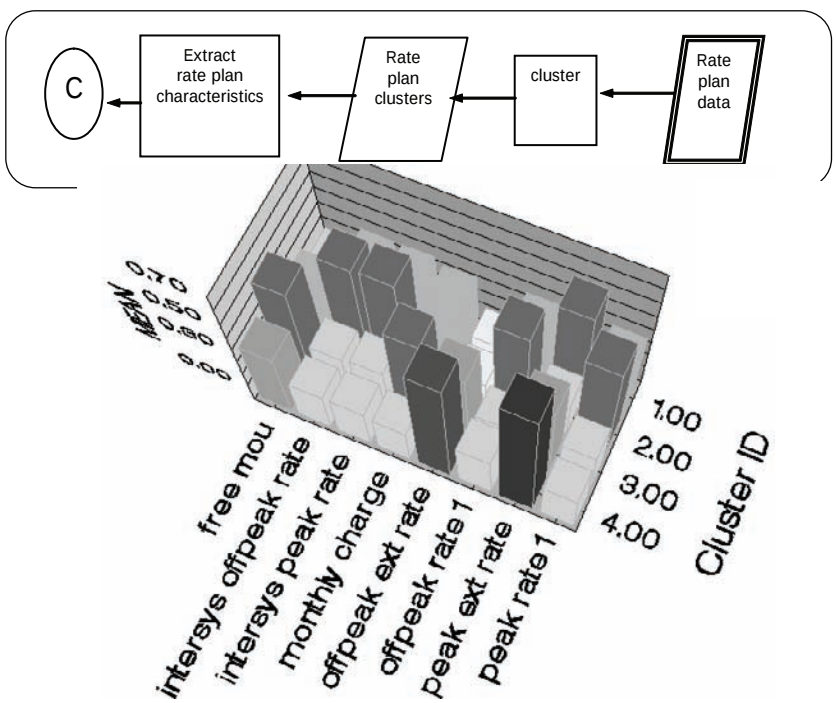

Figure 8. Predicting busy hour usage at a cell site for a given marketing initiative

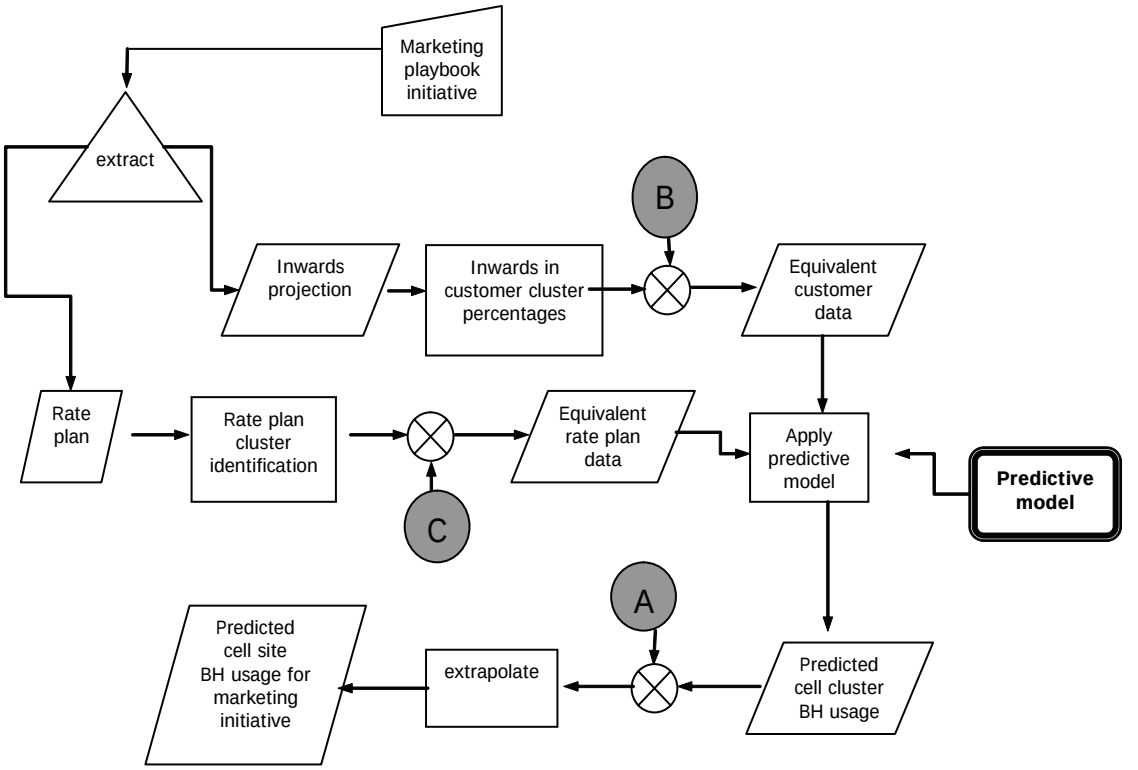


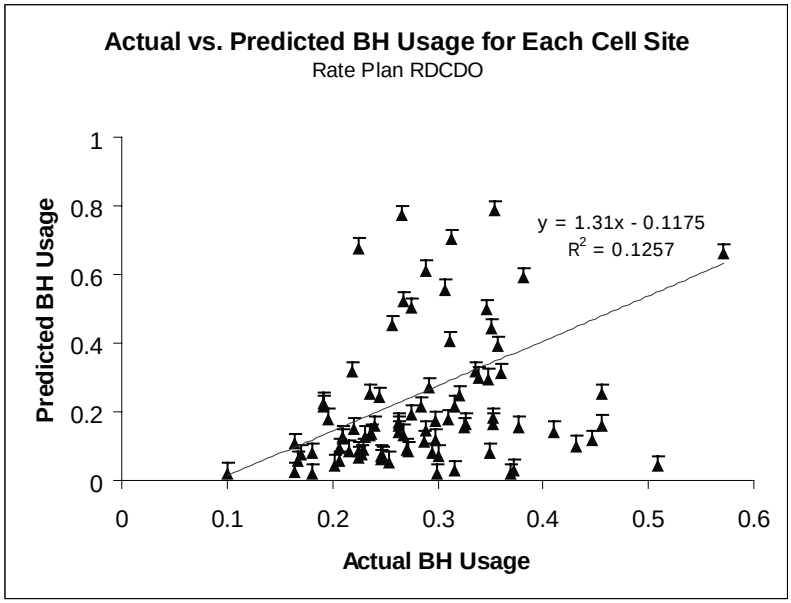
such detailed cost data are generally unavailable. We therefore validate the analytic model by estimating its impact and comparing the estimate with known parameters.

We began this estimation by identifying the ten most frequent rate plans in the data warehouse. From this list we selected one rate plan for validation. Based on marketing area and geographic factors, we assume an equal inwards projection for each customer cluster. Of course, our approach allows for, but does not require, different inward projections for the customer clusters. This flexibility could be useful, for example, when price elasticity data suggest inward projection differences by cluster.

Starting at the cluster level, we applied the predictive model to estimate the average busy hour usage for each customer on each cell tower. These cluster-level predictions were disaggregated to the cellular-tower level by assigning busy-hour minutes proportionate to total minutes for each cell tower within the respective cellular-tower cluster. Following this, we then calculated the actual busy hour usage per customer of that rate plan across the millions of call records. In Figure 9, a scatter plot of actual busy hour usage against predicted busy hour usage, with individual cell tower now the unit of analysis, reveals an R^2 correlation measure of 0.13.

The estimated model accuracy dropped from R^2s in the mid 0.30s for cluster-level data (Figure 5) to about 0.13 when the data were disaggregated to the cellular tower level (Figure 9). In spite of the relatively low R^2 value, the correlation is statistically significant, indicating that this approach can make contributions to the capital estimates of marketing initiatives. However, the model accuracy on disaggregated data was certainly lower than the effects observed at the cluster level. The reasons for this loss in accuracy could probably be attributed to the fine-grained disaggregation, the large variability among the cell sites in terms of busy hour usage, the proportionality assumption made in disaggregating, and model sensitivity to inward projections. These data point up both an opportunity (that rate plans can be intelligently targeted to specific locations with excess capacity) and a threat (that high busy hour volatility would lead engineering to be cautious in allowing usage-increasing plans).

Figure 9. Scatter plot showing actual versus predicted busy hour usage for each cell site, for a specific rate plan



Business Insights

In the context of the analytic model, the data can also reveal some interesting business insights. First, observe the customer lifetime value density plots as a function of strain they place on the network. The left panel in Figure 10 shows LTV density for customers with below average total usage and below average busy-hour usage. The panel on the right shows LTV density for customers with above average total usage and above average busy hour usage. Although the predominant thinking in marketing circles is that "higher LTV is always better," the data suggest this reasoning should be tempered by whether the added value in revenue offsets the disproportionate strain on network resources. This is the basis for a fundamental tension between marketing and engineering functions in large businesses.

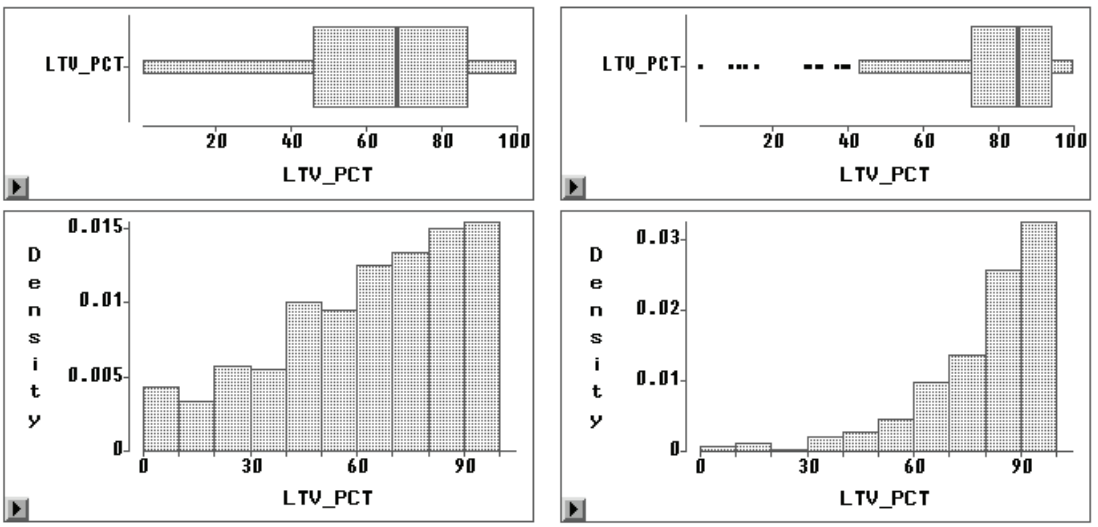
Looking at busy hour impact by customer cluster and rate plan cluster is also informative, as shown in Figure 11. For example, if we define "heavy BH users" as customers who are above average in total minutes as well as busy hour minutes, we can see main effect differences across the customer clusters (Figure 11a).

This is not entirely surprising, as we have already seen that LTV was a major determinant of customer cluster and heavy BH customers also skewed towards having higher LTV. There was, however, an unexpected crossover interaction of rate plan cluster by customer cluster when "heavy BH users" was the target (Figure 11b). The implication is that controlling for revenue, certain rate plan types are more network-friendly depending on the customer cluster under study. Capital-conscious marketers could in theory tailor their rate plans to minimize network impact by more precisely tuning rate plans to customer segments.

FUTURE TRENDS

The proof of concept case study sketched above describes an analytical effort to optimize capital costs of marketing programs, while promoting customer satisfaction and retention by utilizing the business insights gained to tailor marketing programs to better match the needs and requirements of customers (see, for example, Lenskold, 2003). Even as this linkage of marketing innovation and engineering capacity will remain an important business goal well into the foreseeable future, there are practical aspects to the updating of the analysis and models as the industry evolves. Although rate plans, calling areas and customer

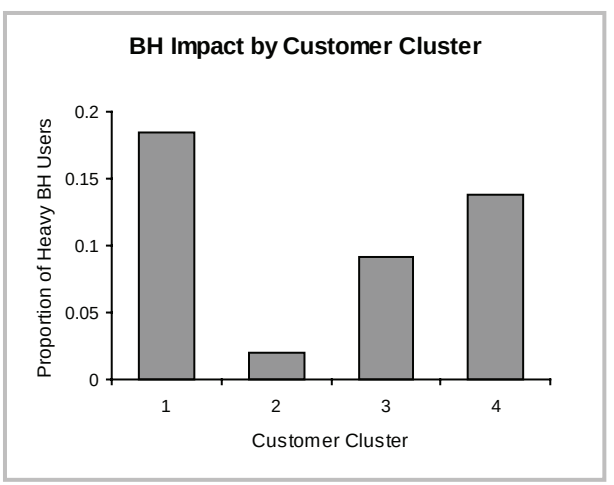
Figure 10. Life-time value (LTV) distributions for customers with below and above average usage and BH usage indicates that high-LTV customers also impact the network with high BH usage



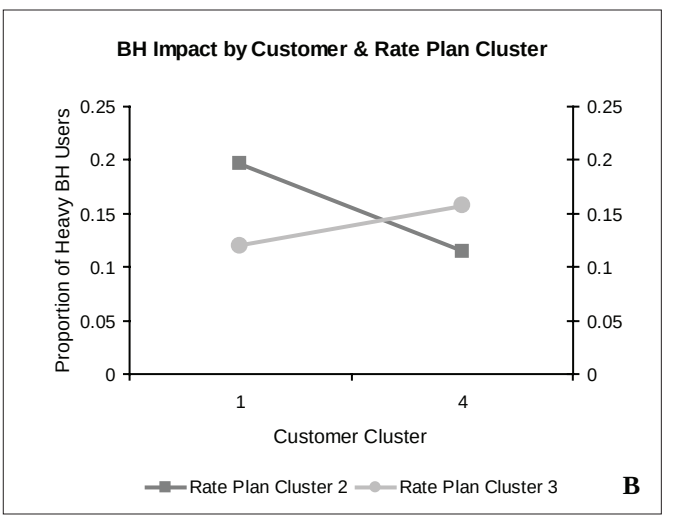
LTV distribution for customers with **less** than average usage and BH usage

LTV distribution for customers with **more** than average usage and BH usage

Figure 11. Exploring customer clusters and rate plan clusters in the context of BH usage shows that customers in a cluster who subscribe to a class of rate plans impact BH usage differently from customers in a different cluster



A



B

characteristics change continuously, the coefficients of the models above should change much less frequently. New plans with new characteristic levels appear, and customer characteristics change as cell phones become ubiquitous, but their effects can be predicted in the same way as the older characteristics. When the models' predictions become too inaccurate, as they eventually must, a series of changes, from simple to complex, can be built into the models. For instance, the intercept or offset of the usage model can easily be changed to accommodate more of the same mix of customers, and later, intercepts for individual clusters can be similarly tuned. This kind of simple modification may allow the essential models to be useful for long periods. Ultimately, though, we expect database systems to incorporate data mining engines (e.g., Oracle Data Mining, Oracle, 2007) and future software and customer relationship management applications to automatically incorporate such analysis to extract timely and optimal recommendations and business insights for maximizing business return on investment and customer satisfaction—leading to effective and profitable one-to-one customer relationship management (Greenberg, 2001; Brown, 2000; Gilmore and Pine, 2000).

CONCLUSION

We have made the general argument that a comprehensive company data warehouse and broad sets of models analyzed with modern data mining techniques can resolve tactical differences between different organizations within the company, and provide a systematic and sound basis for business decision making. The role of data mining in so doing has been illustrated here in mediating between the marketing and engineering functions in a wireless telephony company, where statistical models are used to target specific customer segments with rate plan promotions to increase overall usage (and hence retention) while more efficiently using, but not exceeding, network capacity. A further practical advantage of this data mining approach is that all of the customer groups, cell site locations and rate plan promotions are simplified through clustering to simplify their characteristic representation facilitating productive discussion among upper management strategists.

We have sketched several important practical business insights that come from this methodology. A basic concept to be demonstrated to upper management is that busy hour usage, the main driver of equipment capacity needs, varies greatly by customer segment, and by general cell site grouping (see Figure 9), and that usage can be differently volatile over site groupings (see Figure 5). These differences point out the potential need for targeting specific customer segments with specific rate plan promotions in specific locations. One interesting example is illustrated in Figure 11, where two customer segments respond differently to each of two candidate rate plans—one group decreasing its BH usage under one plan, while the other decreasing it under the other plan. This leads to the possibility that certain rate plans should be offered to specific customer groups in locations where there is little excess equipment capacity, but others can be offered with there is more slack in capacity.

There are, of course, many organizational, implementation and deployment issues associated with this integrated approach. All involved business functions must accept the validity of the modeling and its results, and this concurrence requires the active support of upper management overseeing each function. Secondly, these models should be repeatedly applied and occasionally rerun to assure their relevance in a dynamic business environment, as wireless telephony is in our illustration. Thirdly, provision should be made for capturing the sales and engineering consequences of the decisions made from this approach, to be built into future models. Despite these organizational challenges, business decision makers informed by these models may hopefully resolve a fundamental business rivalry.

KEY TERMS

Capital-Efficient Marketing: Marketing initiatives that explicitly take into account, and optimize if possible, the capital cost of provisioning service for the introduced initiative or promotion.

Marketing Plan: Also referred to as *marketing initiatives*, these are promotions and incentives, mediated through a *rate plan*—a mobile calling plan that specifies minute usage allowances at peak and off-peak times, monthly charge, cost of extra minutes, roaming and long-distance charges,etc.

Capacity: The maximum number of simultaneous calls that can be handled by the wireless network at any given time. Times during the day when call volumes are higher than average are referred to as *peak hours*; *off-peak hours* entail minimal call traffic—like nights and weekends.

Busy Hour: The hour at which a mobile telephone network handles the maximum call traffic in a 24 hour period. It is that hour during the day or night when the product of the average number of incoming calls and average call duration is at its maximum.

Inwards Projection: Estimating the expected number of customers that would sign on to a marketing promotion, based on customer characteristics and profiles.

Lifetime Value: A measure of the profit generating potential, or value, of a customer, and is a composite of expected tenure (how long the customer stays with the business provider) and expected revenue (how much does a customer spend with the business provider).

Predictive Modeling: Use of statistical or data mining methods to relate attributes (input features) to targets (outputs) using previously existing data for training, in such a manner that the target can be predicted for new data based on the input attributes alone.

***k*-Means Clustering:** A clustering method that groups items that are close together—based on a distance metric (like Euclidean distance)—to form clusters. The members in each of the resulting *k* clusters can be

described succinctly using the mean (or centroid) of the respective cluster.

Feature Selection: The process of identifying those input attributes that significantly contribute to building a predictive model for a specified output or target.

Preference Modeling and Mining for Personalization

Seung-won Hwang
Pohang University of Science and Technology (POSTECH), Korea

INTRODUCTION

As near-infinite amount of data are becoming accessible on the Web, it becomes more important to support intelligent personalized retrieval mechanisms, to help users identify the results of a manageable size satisfying user-specific needs. Example case studies include major search engines, such as Google and Yahoo, recently released personalized search, which adapts the ranking to the user-specific search context. Similarly, e-commerce sites, such as Amazon, are providing personalized product recommendation based on the purchase history and user browsing behaviors. To achieve this goal, it is important to model user preference and mine user preferences from user behaviors (e.g., click history) for personalization. In this article, we discuss recent efforts to extend mining research to preference and identify goals for the future works.

BACKGROUND

Traditional modeling for user preference can be categorized into (1) quantitative and (2) qualitative approaches. In the quantitative approach, given a set of data objects *D*, a utility function *F* assigns a numerical score *F(o)* for an object *o* in *D*. This utility score may aggregate scores on one (i.e., uni-attribute model) or more (i.e., multi-attribute model) *attributes* $F(a_1, \ldots, a_n)$, when $o = (a_1, \ldots, a_n)$. For instance, the utility of a house with *price = 100k* and *size = 100 square foot* can be quantified by a user-specific utility function, e.g., *F = size/price*, into a score, such that houses maximizing the scores, e.g., with largest size per unit price, can be retrieved.

Alternatively, in the qualitative approach, the preference on each object is stated in comparison to other objects. That is, given two objects *x* and *y*, instead of quantifying preferences into numerical scores, users simply state which one is more preferred, denoted as $x > y$ or $y > x$. Alternatively, users may state indifference $x \quad y$. Compared to quantitative modeling requiring users to quantify numerical scores of all objects, qualitative modeling is considered to be more intuitive to formulate (Payne, Bettman, & Johnson, 1993), while less efficient for evaluating the absolute utility of the specific object, as such evaluation requires relative comparisons to all other objects. Meanwhile, qualitative approach may also aggregate multiple orderings. Optimal results from such aggregation is formally defined as pareto-optimality as stated below.

Definition 1 (Pareto-optimality). A tuple *x* dominates another tuple *y* if and only if as $x > y$ or $x \quad y$ in all the given orderings.

MAIN FOCUS

Major components of enabling personalized retrieval can be identified as (1) preference modeling, (2) preference mining, and (3) personalization, each of which will be discussed in the following three subsections.

Preference Modeling

As discussed in the prior section, preferences are modeled typically as (1) quantitative utility function (Fishburn, 1970; Keeney & Raiffa, 1976) or (2) qualitative utility orderings (Payne et al., 1993). Personalization is guided by preferences represented in these two models, to retrieve ideal data results that maximize the utility. To maximize quantitative utility, *ranking query* (Guentzer, Balke, & Kiessling, 2000; Fagin, Lotem, & Naor, 2003) of returning few highly preferred results has been studied, while to maximize qualitative utility, *skyline query* (Börzsönyi, Kossmann, & Stocker, 2001; Godfrey, Shipley, & Gryz, 2007) of returning pareto-optimal objects not less preferred to (or "dominated" by) any other object based on the given

qualitative orderings, as we will discuss in detail in the personalization section.

Preference Mining

While user preference can be explicitly stated, in the form of a utility function or total orderings, such formulation can be too complicated for most end-users. Most applications thus adopt the approach of mining preferences from implicit feedbacks. In particular, preference mining from user click logs has been actively studied. Intuitively, items clicked by users can be considered as preferred items, over the items not clicked, which suggests *qualitative preference* of the specific user. More recently, the problem of using such qualitative reference information to infer *quantitative preference* utility function has been studied (Joachims, 2002; Radlinski & Joachims, 2005). These works adopt machine-learning approach to use qualitative orderings as training data to mine an underlying utility function.

Alternatively to *offline mining* of preferences from user logs, system may support dynamic and incremental preference elicitation procedures to collect additional user preference information and revise the result ranking. For *quantitative preference*, Yu, Hwang, and Chang (2005) studied adopting selective sampling to provide users with sample objects to provide feedbacks on, based on which the system collects information on user preferences and applies it in the retrieval process. To enable *online mining*, such sampling was designed to maximize the learning effectiveness such that the desired accuracy can be reached with the minimal user feedbacks. More recently, Joachims and Radlinski (2007) proposed to augment offline mining with online user elicitation procedure. For *qualitative preference*, Balke, Guentzer, and Lofi (2007) studied this online mining process to incrementally revise the skyline results, which was later extended to discuss a sophisticated user interface to assist users in the cooperative process of identifying partial orderings (Balke, Guentzer, & Lofi, 2007b).

Personalization

Once the preference is identified, we use it to retrieve the personalized results with respect to the preference.

For *quantitative preference*, the problem of efficient processing of ranking queries, which retrieve the results with the maximal utility score has been actively studied, pioneered by Algorithm FA (Fagin, 1996). Following works can be categorized into the two categories. First, more works followed to FA to be optimal in a stronger sense, by improving the stopping condition such that the upper bounds of the unseen objects can be more tightly computed, as presented in (Fagin et al., 2003). Second, another line of works follows to propose algorithms for various access scenarios, beyond FA assuming the sorted accesses over all predicates (Bruno, Gravano, & Marian, 2002; Hwang & Chang, 2005).

For *qualitative preference*, skyline queries are first studied as maximal vectors in (Kung, Luccio, & Preparata, 1975) and later adopted for data querying in (Börzsönyi et al., 2001) which proposes three basic skyline computation algorithms such as block nested loop (BNL), divide-and-conquer (D&C), and B-tree-based algorithms. Tan, Eng, and Ooi (2001) later study progressive skyline computation using auxiliary structures such as bitmap and sorted list. Kossmann, Ramsak, and Rost (2002) next propose nearest neighbor (NN) algorithm for efficiently pruning out dominated objects by iteratively partitioning the data space based on the nearest objects in the space. Meanwhile, Papadias, Tao, Fu, and Seeger (2003) develop branch and bound skyline (BBS) algorithm with I/O optimality property and Chomicki, Godfery, Gryz, and Liang (2003) develop sort-filter-skyline (SFS) algorithm leveraging pre-sorted lists for checking dominance condition efficiently. More recently, Godfrey, Shipley, and Gryz (2005) propose linear elimination-sort for skyline (LESS) algorithm with attractive average-case asymptotic time complexity, i.e., $O(d \cdot n)$ for d-dimensional data of size n.

More recently, there have been research efforts to combine the strength of these two query semantics. While skyline queries are highly intuitive to formulate, this intuitiveness comes with price of returning too many results especially when the dimensionality d of data is high, i.e., "curse of dimensionality" problem (Bentley, Kung, Schkolnick, & Thompson, 1978; Chaudhuri, Dalvi, & Kaushik, 2006; Godfrey, 2004) Recent efforts address this problem by narrowing down the skylines by ranking them and identifying the top-k results, which can be categorized into the following two groups of approaches: First, *user-oblivious ranking approach* leverages skyline frequency metric (Chan et al., 2006) which ranks each tuple in the decreasing order of the number of subspaces and in which the tuple is a skyline and k-dominances (Chan et al., 2006) which identifies k-dominant skylines as the common skyline

objects in all *k*-dimensional subspaces and ranks the tuples in the increasing order of *k*. Second, *personalized ranking approach* studies how to annotate skylines with different characteristics, as a basis for user-specific personalized ranking of skyline objects (Pei, Fu, Lin, & Wang, 2007; Pei, Jin, Ester, & Tao, 2005;Pei et al., 2006; Lee, You, & Hwang, 2007).

FUTURE TRENDS

While personalization has been actively studied when preferences are fully specified, more theories and techniques need to be developed in the near future for exploiting partial preferences. For instance, even when the preference of the specific user is only partially specified, a query on the preferences of prior users can retrieve the users with the similar taste, based on which we can complete the preference elicitation. For this purpose, scalable storage/query systems for user preferences is essential, which has not yet been actively studied, while such systems for data itself has been well studied.

CONCLUSION

As more and more data are getting accessible, it is getting more and more important to provide personalized results tailored for user-specific preference. Toward the goal, we identify preference modeling, mining, and personalization as major challenges: First, preference modeling enables to present user preference, collected from (1) offline mining of logs or (2) online mining of online user behaviors to guide the preference formulation. Once the preference is identified, the ultimate goal of this line of research is to enable effective and efficient personalization, to provide optimal results for the user-specific preference.

KEY TERMS

Online Preference Mining: Data mining process to identify preferences online from runtime user behaviors.

Personalized Retrieval: Procedures of tailoring retrieval to individual users' preferences.

Preference Elicitation: Procedures that support the expression of user-specific preferences, typically through the recommendations of data items.

Preference Mining: Data mining process to identify preferences from implicit user feedbacks.

Preference Modeling: Formal presentation of preferences in human and machine understandable forms.

Ranking Query: Query that supports the retrieval of data objects in the descending order of quantitative utility scores.

Skyline Query: Query that supports the retrieval of pareto-optimal results, not less preferred by any other object.

Privacy Preserving OLAP and OLAP Security

Alfredo Cuzzocrea

Vincenzo Russo
University of Calabria, Italy

INTRODUCTION

The problem of ensuring the *privacy* and *security* of OLAP data cubes (Gray et al., 1997) arises in several fields ranging from advanced *Data Warehousing* (DW) and *Business Intelligence* (BI) systems to sophisticated *Data Mining* (DM) tools. In DW and BI systems, decision making analysts aim at avoiding that malicious users access perceptive ranges of multidimensional data in order to infer *sensitive knowledge*, or *attack* corporate data cubes via violating user rules, grants and revokes. In DM tools, domain experts aim at avoiding that malicious users infer *critical-for-the-task knowledge* from authoritative DM results such as frequent item sets, patterns and regularities, clusters, and discovered association rules. In more detail, the former application scenario (i.e., DW and BI systems) deals with both the privacy preservation and the security of data cubes, whereas the latter one (i.e., DM tools) deals with *privacy preserving OLAP issues* solely. With respect to security issues, although security aspects of information systems include a plethora of topics ranging from *cryptography* to *access control* and *secure digital signature*, in our work we particularly focus on *access control techniques* for data cubes, and remand the reader to the active literature for the other orthogonal matters.

Specifically, privacy preservation of data cubes refers to the problem of ensuring the privacy of data cube cells (and, in turn, that of queries defined over collections of data cube cells), i.e. hiding sensitive information and knowledge during data management activities, according to the general guidelines drawn by Sweeney in her seminar paper (Sweeney, 2002), whereas access control issues refer to the problem of ensuring the security of data cube cells, i.e. restricting the access of unauthorized users to specific sub-domains of the target data cube, according to well-known concepts studied and assessed in the context of DBMS security. Nonetheless, it is quite straightforward foreseeing that these two even distinct aspects should be meaningfully *integrated* in order to ensure both the privacy and security of complex data cubes, i.e. data cubes built on top of complex data/knowledge bases.

During last years, these topics have became of great interest for the Data Warehousing and Databases research communities, due to their exciting theoretical challenges as well as their relevance and practical impact in modern real-life OLAP systems and applications. On a more conceptual plane, theoretical aspects are mainly devoted to study how *probability* and *statistics schemes* as well as rule-based models can be applied in order to efficiently solve the above-introduced problems. On a more practical plane, researchers and practitioners aim at integrating convenient privacy preserving and security solutions within the core layers of commercial OLAP server platforms.

Basically, to tackle deriving privacy preservation challenges in OLAP, researchers have proposed models and algorithms that can be roughly classified within two main classes: *restriction-based techniques*, and *data perturbation techniques*. First ones propose limiting the number of query kinds that can be posed against the target OLAP server. Second ones propose perturbing data cells by means of random noise at various levels, ranging from schemas to queries. On the other hand, access control solutions in OLAP are mainly inspired by the wide literature developed in the context of controlling accesses to DBMS, and try to adapt such schemes in order to control accesses to OLAP systems.

Starting from these considerations, in this article we propose a survey of models, issues and techniques in a broad context encompassing privacy preserving and security aspects of OLAP data cubes.

BACKGROUND

Handling sensitive data, which falls in privacy preserving issues, is common in many real-life application scenarios. For instance, consider a government agency that collects information about client applications/users for a specific *e*-government process/task, and then makes this information available for a third-party agency willing to perform market analysis for business purposes. In this case, preserving sensitive data of client applications/users and protecting their utilization from malicious behaviors play a leading role. It should be taken into account that this scenario gets worse in OLAP systems, as the interactive nature of such systems *naturally* encourages malicious users to retrieve *sensitive knowledge* by means of *inference techniques* (Wang et al., 2004a; Wang et al., 2004b) that, thanks to the wide availability of OLAP tools and operators (Han & Kamber, 2000), can reach an high degree of effectiveness and efficiency.

Theoretical background of privacy preserving issues in OLAP relies on research experiences in the context of *statistical databases* (Shoshani, 1997), where these issues have been firstly studied. In statistical databases, this problem has been tackled by means of *Statistical Disclosure Control* (SDC) techniques (Domingo-Ferrer, 2002), which propose achieving the privacy preservation of data via *trade-offing the accuracy and privacy of data*. The main idea of such an approach is that of admitting the need for data provisioning while, at the same time, the need for privacy of data. In fact, *full data hiding* or *full data camouflaging* are both useless, as well as publishing *completely-disclosed data sets*. Therefore, balancing accuracy and privacy of data is a reasonable solution to this challenge. In this context, two meaningful measures for evaluating the accuracy and privacy preservation capabilities of an arbitrary method/technique have been introduced. The first one is referred as *Information Loss* (IL). It allows us to estimate the lost of information (i.e., the accuracy decrease) due to a given privacy preserving method/technique. The second one is the *Disclosure Risk* (DR). It allows us to estimate the risk of disclosing sensitive data due to a given privacy preserving method/technique.

Duncan *et al.* (2001) introduce two metrics for probabilistically evaluating IL and DR. Given a numerical attribute A that can assume a value w with probability P_w, such that $\mathcal{D}(w)$ is the domain of w (i.e., the set of *all* the values that A can assume), a possible metrics of IL is given by the *Data Utility* (DU), which is defined as follows:

$$DU(w) = \frac{|\mathcal{D}(w)|}{\sum_{\mathrm{w}} P_w \cdot (w-1)^2} \tag{1}$$

where $|\mathcal{D}(w)|$ denotes the cardinality of $\mathcal{D}(w)$. It should be noted that DU and IL are inversely proportional, i.e. the more is IL the less is DU, and, conversely, the less is IL the more is DU.

Different formulations exist. For instance, Sung *et al.* (2006) introduce the so-called *accuracy factor* $F_{a,Q}$ of a given query Q against a data cube D, i.e. the relative accuracy decrease of the *approximate answer* to Q, denoted by $\tilde{A}(Q)$, which is evaluated on the *synopsis data cube* $\tilde{D}$ obtained from D by means of *perturbation-based techniques* (presented next), with respect to the *exact answer* to Q, denoted by $A(Q)$, which is evaluated on the original data cube D. $F_{a,Q}$ is defined as follows:

$$F_{a,Q} = 2^{-\left|\frac{\tilde{A}(Q)-A(Q)}{A(Q)}\right|} \tag{2}$$

With regards to DR, Duncan *et al.* (2001) consider the *probability with respect to the malicious user* that A can assume the value w, denoted by P_w^U, and introduce the following metrics that models DR in terms of the reciprocal of the *information entropy*, as follows:

$$DR(w) = \frac{1}{-\sum_{\mathrm{w}} P_w^U \cdot \log(P_w^U)} \tag{3}$$

Indeed, being impossible to estimate the value of P_w^U, as one should know *all* the information/knowledge held by the malicious user, in (Duncan et al., 2001) the *conditional* version of (3) is proposed as follows:

$$DR(w) = \frac{1}{-\sum_{\mathrm{w}} p(w \mid u) \cdot \log_2 p(w \mid u)} \tag{4}$$

such that $p(w|u)$ denotes the *conditional probability* that the actual value of A is w while the value known by the malicious user is u.

Just like for IL, different formulations for measuring DR exist. Sung *et al.* (2006) introduce the so-called *privacy factor* $F_{p,D}$ of a given data cube D with respect to the corresponding perturbation-based synopsis data cube $\tilde{D}$. $F_{p,D}$ is defined as follows:

$$F_{p,D} = \frac{1}{N} \cdot \sum_{i=1}^{N} \frac{\left|\tilde{C}_i - C_i\right|}{\left|C_i\right|} \quad (5)$$

such that C_i denotes a data cell of the data cube D, and $\tilde{C}$ the corresponding perturbed data cell $\tilde{C}$ of the synopsis data cube $\tilde{D}$.

According to research results presented in (Duncan et al., 2001), accuracy and privacy of a privacy preserving technique are related and must be traded-off. Intuitively enough, an increase of one of these properties causes a correlated decrease of the other one. Also, it is a matter to notice that having maximum accuracy implies a very high DR while, conversely, minimum accuracy implies minimum DR. On the other hand, accuracy cannot be minimized, and DR cannot be maximized. As we will describe in next section, most of privacy preserving OLAP techniques of the active literature are based on this terminology, and on the fundamental idea of trading-off accuracy and privacy.

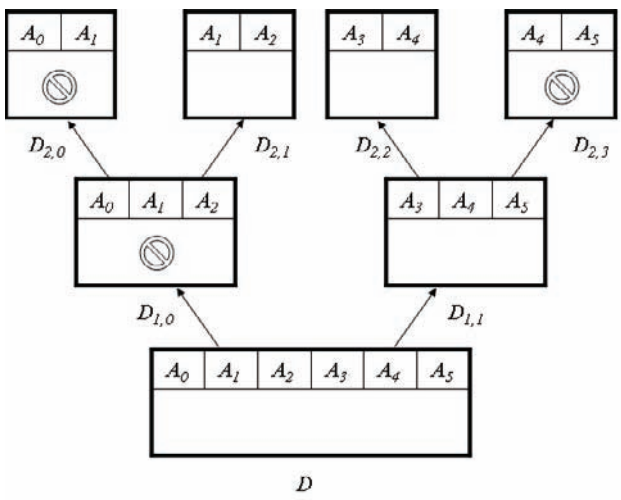
For what regards the background of security issues, actual literature focuses on access control techniques, as discussed above. Access control has a quite long history in DBMS, where the goal is protecting data objects from unauthorized accesses. In this context, an *authorization* is modeled as a triple: ⟨*Object*, *Subject*, +/-*Action*⟩, such that (*i*) *Object* is the data object to be protected, (*ii*) *Subject* is the user/application accessing the object *Object*, and (*iii*) *Action* is the operation that the user/application *Subject* can or cannot (i.e., +/-) perform on the object *Object*. Typically, read-only operations are controlled, since data updates are indeed allowed to few users/user-groups only.

Because of (very) different data models, the main difference between access control issues in DBMS and OLAP systems is represented by the nature of data objects. In DBMS, an object can be a data table, a query or a record. This allows us to achieve very precise authorization mechanisms, as singleton records or partitions of data tables (they may be vertical or horizontal) can be handled. Indeed, we can claim that access control techniques take great advantages from the *flexibility* of DBMS models and schemas. When OLAP systems are considered, models and schemas are characterized by *dimensionality and multi-resolution of data*, and access control mechanisms need to become more sophisticated in order to prevent malicious user attacks. Target data objects are represented by data cubes, which can be generally thought as collections of *cuboids*, one for each combination of hierarchy levels. Also, dimensional hierarchies pose additional challenges, as malicious users can successfully exploit the multi-resolution data models defined by dimensional hierarchies in order to devise very effective *knowledge inference techniques* able to hierarchically browse the structure of the cube with the goal of discovering aggregations computed over sensitive ranges of data. Also, rich OLAP tools and operators (Han & Kamber, 2000), such as *roll-up*, *drill-down* and *slice & dice*, represent "sophisticate instruments" in the hands of malicious users, as they can be used to extract sensitive knowledge from a secured cuboid at a given level ℓ starting from disclosed cuboids at levels different from ℓ.

To overcome security breaches like those described above, access control techniques for OLAP data cubes usually apply a restriction-based approach, and limit the set of cuboids that can be accessed by external applications/users. Nevertheless, even in this case a trade-off strategy must be devised, as securing a large number of cuboids can become useless in real-life OLAP scenarios. All considering, as studied by Wang *et al.* in (Wang et al., 2004a; Wang et al., 2004b), the *inference problem* in OLAP introduces more probing issues rather than precursor scientific areas related to inference issues in statistical databases (Denning & Schlorer, 1983).

To give an example on a simple access control mechanism in *Relational OLAP* (ROLAP) data cubes (i.e., data cubes stored in form of tables of a RDBMS in Han & Kamber, 2000), consider Figure 1, where a

Figure 1. Access control mechanism on a ROLAP data cube



data cube D with the related *cuboid lattice* is depicted. In this case, the cuboids $D_{1,0}$, $D_{2,0}$, and $D_{2,3}$ are secured to authorized applications/users only and forbidden to unauthorized ones.

PRIVACY PRESERVING TECHNIQUES IN OLAP

Privacy Preserving OLAP (PPOLAP) (Agrawal et al., 2005) is a specialized case of *Privacy Preserving Data Mining* (PPDM) (Agrawal et al., 2000). While PPDM concerns with the privacy of data during DM activities (e.g., clustering, classification, pattern discovery, association rule discovery etc), PPOLAP deals with the problem of preserving the privacy of data cells of a given data cube during typical OLAP activities such as performing classical operators (e.g., roll-up and drill-down) or evaluating complex OLAP queries (e.g., *range-* (Ho et al., 1997), *top-k* (Xin et al., 2006), and *iceberg* (Fang et al., 1998) queries). With respect to PPDM, PPOLAP introduces more *semantics* into the privacy preservation due to its well-known knowledge-intensive tools such as multidimensionality and multi-resolution of data, and hierarchies.

In the following, we review the two kinds of privacy preserving techniques in OLAP (i.e., restriction-based and perturbation-based techniques) introduced in the previous Section.

Restriction-based techniques limit the queries that can be posed to the OLAP server in order to preserve the privacy of data cells. This problem is related to the issue of *auditing queries in statistical databases*, which consists in analyzing the past (answered) queries in order to determine whether these answers can be composed by a malicious user to infer sensitive knowledge in the form of answers to forbidden queries. Therefore, in order to understand which kinds of queries must be forbidden, a restriction-based technique needs to audit queries posed to the target data (e.g., OLAP) server during a given interval of time. Auditing queries in statistical databases is the conceptual and theoretical basis of auditing queries in OLAP systems.

Interesting auditing techniques for queries against statistical databases have been proposed by Dobkin *et al.* (1979), which introduce a model for auditing average and median queries, and Chin and Ozsoyoglu (1982), which propose a technique for handling the past history of SUM queries in order to reduce the sequence of answered queries to privacy preservation purposes. Also, Chin and Ozsoyoglu (1982) describe how to check the *compromisability* of the underlying statistical database when using the reduced sequence. The proposed auditing technique is called *Audit Expert*.

More recently, few approaches focusing on the problem of auditing techniques for OLAP data cubes and queries appeared. Among all, we recall: (*i*) the work of Zhang *et al.* (2004), which propose an interesting *information theoretic approach* that simply counts the number of cells already covered to answer previous queries in order to establish if a *new* query should be answered or not; (*ii*) the work of Malvestuto *et al.* (2006), which introduce a novel notation for auditing range-SUM queries (i.e., an OLAP-like class of queries) against statistical databases making use of *Integer Linear Programming* (ILP) tools for detecting if a *new* range-sum query can be answered safely.

Perturbation-based techniques add random noise at various levels of the target database, ranging from schemas, like in (Schlorer, 1981), to query answers, like in (Beck, 1980).

Agrawal *et al.* (2005) first propose the notion of PPOLAP. They define a PPOLAP model over data partitioned across multiple clients using a *randomization approach* on the basis of which (*i*) clients perturb tuples which with they participate to the partition in order to gain *row-level privacy*, and (*ii*) server is capable of evaluating OLAP queries against perturbed tables via reconstructing original distributions of attributes involved by such queries. In (Agrawal et al., 2005), authors demonstrate that the proposed approach is safe against privacy breaches.

Hua *et al.* (2005) propose a different approach to preserve the privacy of OLAP data cubes. They argue that hiding parts of data that could cause inference of sensitive cuboids is enough in order to achieve the notion of "secure" data cubes. While a strengthness point of the proposed approach is represented by its simplicity, authors do not provide sufficient experimental analysis to prove in which measure the data hiding phase affects the target OLAP server.

Sung *et al.* (2006) propose a *random data distortion* technique, called *zero-sum method*, for preserving secret information of *individual* data cells while providing accurate answers to range-queries over original aggregates. Roughly speaking, data distortion consists in iteratively altering the values of individual data cells of the target data cube in such a way as to maintain the

marginal sums of data cells along rows and columns of the data cube equal to zero. This ensures the privacy of individual data cells, and the correctness of answers to range-queries.

Due to different, specific motivations, both restriction-based and perturbation-based techniques are ineffective in OLAP. Specifically, restriction-based techniques cannot be applied to OLAP systems since the nature of such systems is intrinsically *interactive*, and based on a wide set of operators and query classes. On the other hand, perturbation-based techniques cannot be applied in OLAP systems since they introduce excessive computational overheads when executed on massive data cubes.

SECURITY TECHNIQUES IN OLAP

The problem of security control methods has been widely studied in the context of statistical databases, and it has produced a wide and consolidate literature (Adam & J.C. Wortmann, 1989) that, in turn, is inspiring actual initiatives for securing OLAP data cubes, i.e. limiting their access to authorized applications/users only.

As stated in the background Section, the main idea of these approaches is devising *access control schemes* that establish how applications/users must access multidimensional data on the basis of *grants* and *revokes* (Griffiths & Wade, 1976), *roles* (Sandhu et al., 1996), and *authorization rules* (Jajodia et al., 2001).

Following the above-mentioned pioneristic approaches, some preliminary, sporadic studies in the context of securing data warehouses (Bhargava, 2000) and data cubes (Pernul & Priebe, 2000) have been appeared in literature subsequently. While these works are clearly in their initial stages, they have inspired most part of actual research effort in the context of access control schemes for OLAP data cubes.

(Wang et al., 2004a; Wang et al., 2004b) represent the state-of-the-art for access control schemes in OLAP. They propose a novel technique for limiting inference breaches in OLAP systems via detecting *cardinality-based* sufficient conditions over cuboids, in order to make data cubes safe with respect to malicious users. Specifically, the proposed technique combines access control and inference control techniques (Denning & Schlorer, 1983), being (*i*) first one based on the hierarchical nature of data cubes in terms of cuboid lattice and multi-resolution of data, and (*ii*) second one based on directly applying restriction to *coarser aggregations* of data cubes, and then removing remaining inferences that can be still derived.

FUTURE TRENDS

Privacy preserving and security issues in OLAP will play more and more a significant role in Data Warehousing research. Actually, it seems that the following topics will decisively capture the attention from the research communities:

- *Low-Complexity Solutions*: since OLAP data cubes are massive in size, the problem of devising efficient solutions requiring low spatio-temporal complexity is a challenge of great interest.
- *Enhancing the Semantics of Privacy Preserving Data Cubes*: semantics of data cube models is richer and attracting than semantics of database models; this offers noteworthy extensions of the actual privacy preserving schemes towards the integration of such schemes with innovative paradigms such as *flexibility* and *adaptivity*.
- *Scaling-Up Access Control Models*: with regards to access control issues, devising models able to scale-up on complex data cubes (i.e., data cubes with complex dimensions, hierarchies and measures) represents the next work to be accomplished.
- *Integration with Real-Life Data Warehouse Servers*: after their complete assessment, both privacy preserving and security models need to be integrated and put-at-work within the core layer of real-life Data Warehouse servers, in order to precisely evaluate their effectiveness in realistic settings and operational environments.

CONCLUSION

Inspired by privacy preserving and security issues in statistical databases, privacy preserving and secure OLAP data cubes are a leading topic in Data Warehousing research. Despite this, researchers have not devoted a great attention to this area so far. As a consequence, privacy preservation and security of data cubes is a relatively adolescent research context, which needs to be further developed during next years. Under such

a futuristic vision, this article has presented a survey of state-of-the-art models, issues and techniques in a broad context encompassing privacy preserving and security aspects of OLAP data cubes, with critical analysis of benefits and limitations coming from these initiatives.

KEY TERMS

Access Control Scheme: A scheme that establishes the constraints under which a data object must be accessed.

Disclosure Risk: A measure of the amount of disclosed information due to a privacy preserving technique.

Inference: A methodology for extracting sensitive knowledge from disclosed information.

Information Loss: A measure of the information lost due to a privacy preserving technique.

On-Line Analytical Processing (OLAP): A methodology for representing, managing and querying massive DW data according to multidimensional and multi-resolution abstractions of them.

Privacy Preservation: A property that describes the capability of data management techniques in preserving the privacy of processed data.

Security: A property that describes the capability of data representation models in ensuring the security of portions of data whose access is forbidden to unauthorized applications/users.

Privacy-Preserving Data Mining

Stanley R. M. Oliveira
Embrapa Informática Agropecuária, Brazil

INTRODUCTION

Despite its benefits in various areas (e.g., business, medical analysis, scientific data analysis, etc), the use of data mining techniques can also result in new threats to privacy and information security. The problem is not data mining itself, but the way data mining is done. "Data mining results rarely violate privacy, as they generally reveal high-level knowledge rather than disclosing instances of data" (Vaidya & Clifton, 2003). However, the concern among privacy advocates is well founded, as bringing data together to support data mining projects makes misuse easier. Thus, in the absence of adequate safeguards, the use of data mining can jeopardize the privacy and autonomy of individuals.

Privacy-preserving data mining (PPDM) cannot simply be addressed by restricting data collection or even by restricting the secondary use of information technology (Brankovic & V. Estivill-Castro, 1999). Moreover, there is no exact solution that resolves privacy preservation in data mining. In some applications, solutions for PPDM problems might meet privacy requirements and provide valid data mining results (Oliveira & Zaïane, 2004b).

We have witnessed three major landmarks that characterize the progress and success of this new research area: *the conceptive landmark*, *the deployment landmark*, and *the prospective landmark*. *The Conceptive landmark* characterizes the period in which central figures in the community, such as O'Leary (1995), Piatetsky-Shapiro (1995), and others (Klösgen, 1995; Clifton & Marks, 1996), investigated the success of knowledge discovery and some of the important areas where it can conflict with privacy concerns. The key finding was that knowledge discovery can open new threats to informational privacy and information security if not done or used properly.

The Deployment landmark is the current period in which an increasing number of PPDM techniques have been developed and have been published in refereed conferences. The information available today is spread over countless papers and conference proceedings. The results achieved in the last years are promising and suggest that PPDM will achieve the goals that have been set for it.

The Prospective landmark is a new period in which directed efforts toward standardization occur. At this stage, there is no consensus on privacy principles, policies, and requirements as a foundation for the development and deployment of new PPDM techniques. The excessive number of techniques is leading to confusion among developers, practitioners, and others interested in this technology. One of the most important challenges in PPDM now is to establish the groundwork for further research and development in this area.

BACKGROUND

Understanding privacy in data mining requires understanding how privacy can be violated and the possible means for preventing privacy violation. In general, one major factor contributes to privacy violation in data mining: the misuse of data.

Users' privacy can be violated in different ways and with different intentions. Although data mining can be extremely valuable in many applications (e.g., business, medical analysis, etc), it can also, in the absence of adequate safeguards, violate informational privacy. Privacy can be violated if personal data are used for other purposes subsequent to the original transaction between an individual and an organization when the information was collected (Culnan, 1993).

Defining Privacy for Data Mining

In general, privacy preservation occurs in two major dimensions: users' personal information and information concerning their collective activity. We refer to the former as individual privacy preservation and the latter

as collective privacy preservation, which is related to corporate privacy in (Clifton et al., 2002).

- **Individual privacy preservation:** The primary goal of data privacy is the protection of personally identifiable information. In general, information is considered personally identifiable if it can be linked, directly or indirectly, to an individual person. Thus, when personal data are subjected to mining, the attribute values associated with individuals are private and must be protected from disclosure. Miners are then able to learn from global models rather than from the characteristics of a particular individual.
- **Collective privacy preservation:** Protecting personal data may not be enough. Sometimes, we may need to protect against learning sensitive knowledge representing the activities of a group. We refer to the protection of sensitive knowledge as collective privacy preservation. The goal here is quite similar to that one for statistical databases, in which security control mechanisms provide aggregate information about groups (population) and, at the same time, prevent disclosure of confidential information about individuals. However, unlike as is the case for statistical databases, another objective of collective privacy preservation is to protect sensitive knowledge that can provide competitive advantage in the business world.

MAIN FOCUS

A Taxonomy of existing PPDM Techniques

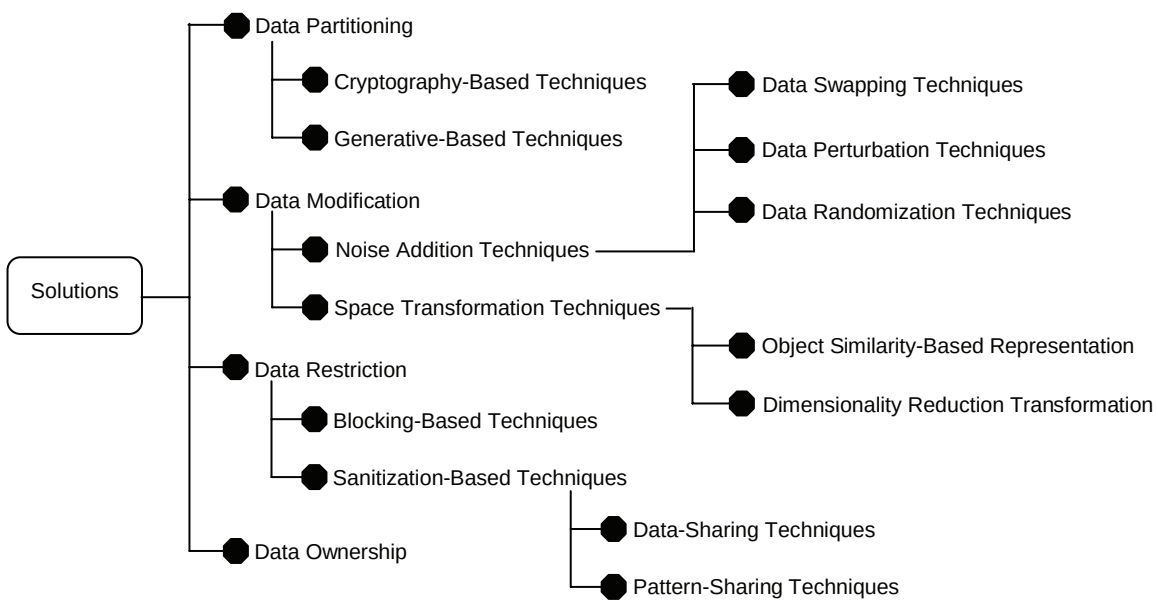
The existing PPDM techniques in the literature can be classified into four major categories: data partitioning, data modification, data restriction, and data ownership as can be seen in Figure 1.

Data Partitioning Techniques

Data partitioning techniques have been applied to some scenarios in which the databases available for mining are distributed across a number of sites, with each site only willing to share data mining results, not the source data. In these cases, the data are distributed either horizontally or vertically. In a horizontal partition, different entities are described with the same schema in all partitions, while in a vertical partition the attributes of the same entities are split across the partitions. The existing solutions can be classified into Cryptography-Based Techniques and Generative-Based Techniques.

- **Cryptography-based techniques:** In the context of PPDM over distributed data, cryptography-based techniques have been developed to solve problem of the following nature: two or more

Figure 1. A taxonomy of PPDM techniques.



parties want to conduct a computation based on their private inputs. The issue here is how to conduct such a computation so that no party knows anything except its own input and the results. This problem is referred to as the secure multiparty computation (SMC) problem (Goldreich, Micali, & Wigderson, 1987). The technique proposed in (Lindell & Pinkas, 2000) address privacy-preserving classification, while the techniques proposed in (Kantarcioğlu & Clifton, 2002; Vaidya & Clifton, 2002) address privacy-preserving association rule mining, and the technique in (Vaidya & Clifton, 2003) addresses privacy-preserving clustering.

- **Generative-based techniques:** These techniques are designed to perform distributed mining tasks. In this approach, each party shares just a small portion of its local model which is used to construct the global model. The existing solutions are built over horizontally partitioned data. The solution presented in (Veloso et al., 2003) addresses privacy-preserving frequent itemsets in distributed databases, whereas the solution in (Meregu & Ghosh, 2003) addresses privacy-preserving distributed clustering using generative models.

Data Modification Techniques

Data modification techniques modify the original values of a database that needs to be shared, and in doing so, privacy preservation is ensured. The transformed database is made available for mining and must meet privacy requirements without losing the benefit of mining. In general, data modification techniques aim at finding an appropriate balance between privacy preservation and knowledge disclosure. Methods for data modification include noise addition techniques and space transformation techniques.

- **Noise addition techniques:** The idea behind noise addition techniques for PPDM is that some noise (e.g., information not present in a particular tuple or transaction) is added to the original data to prevent the identification of confidential information relating to a particular individual. In other cases, noise is added to confidential attributes by randomly shuffling the attribute values to prevent the discovery of some patterns that are not supposed to be discovered. We categorize noise addition techniques into three groups: (1) data swapping techniques that interchange the values of individual records in a database (Estivill-Castro & Brankovic, 1999); (2) data distortion techniques that perturb the data to preserve privacy, and the distorted data maintain the general distribution of the original data (Liu, Kargupta, & Ryan, 2006; Agrawal & Srikant, 2000); and (3) data randomization techniques which allow one to perform the discovery of general patterns in a database with error bound, while protecting individual values. Like data swapping and data distortion techniques, randomization techniques are designed to find a good compromise between privacy protection and knowledge discovery (Evfimievski et al., 2002; Rizvi & Haritsa, 2002; Zang, Wang, & Zhao, 2004).
- **Space transformation techniques:** These techniques are specifically designed to address privacy-preserving clustering. These techniques are designed to protect the underlying data values subjected to clustering without jeopardizing the similarity between objects under analysis. Thus, a space transformation technique must not only meet privacy requirements but also guarantee valid clustering results. The solution proposed in (Oliveira & Zaïane, 2007a; Oliveira & Zaïane, 2007b) relies on dimensionality reduction-based transformation. The idea behind such a solution is that by reducing the dimensionality of a dataset to a sufficiently small value, one can find a trade-off between privacy, communication cost, and accuracy. Once the dimensionality of a database is reduced, the released database preserves (or slightly modifies) the distances between data points.

Data Restriction Techniques

Data restriction techniques focus on limiting the access to mining results through either generalization or suppression of information (e.g., items in transactions, attributes in relations), or even by blocking the access to some patterns that are not supposed to be discovered. Such techniques can be divided into two groups: Blocking-based techniques and Sanitization-based techniques.

- **Blocking-based techniques:** These techniques aim at hiding some sensitive information when

data are shared for mining. The private information includes sensitive association rules and classification rules that must remain private. Before releasing the data for mining, data owners must consider how much information can be inferred or calculated from large databases, and must look for ways to minimize the leakage of such information. In general, blocking-based techniques are feasible to recover patterns less frequent than originally since sensitive information is either suppressed or replaced with unknowns to preserve privacy (Saygin, Verykios, & Clifton, 2001).

- **Sanitization-based techniques:** Unlike blocking-based techniques that hide sensitive information by replacing some items or attribute values with unknowns, sanitization-based techniques hide sensitive information by strategically suppressing some items in transactional databases, or even by generalizing information to preserve privacy in classification. These techniques can be categorized into two major groups: (1) data-sharing techniques in which the sanitization process acts on the data to remove or hide the group of sensitive association rules that contain sensitive knowledge. To do so, a small number of transactions that contain the sensitive rules have to be modified by deleting one or more items from them or even adding some noise, i.e., new items not originally present in such transactions (Verykios et al., 2004; Oliveira & Zaïane, 2006); and (2) pattern-sharing techniques in which the sanitizing algorithm acts on the rules mined from a database, instead of the data itself. The existing solution removes all sensitive rules before the sharing process and blocks some inference channels (Oliveira, Zaïane, & Saygin, 2004a).

Data Ownership Techniques

Data ownership techniques can be applied to two different scenarios: (1) to protect the ownership of data by people about whom the data were collected (Felty & Matwin, 2002). The idea behind this approach is that a data owner may prevent the data from being used for some purposes and allow them to be used for other purposes. To accomplish that, this solution is based on encoding permissions on the use of data as theorems about programs that process and mine the data. Theorem proving techniques are then used to guarantee that these programs comply with the permissions; and (2) to identify the entity that receives confidential data when such data are shared or exchanged (Mucsi-Nagy & Matwin, 2004). When sharing or exchanging confidential data, this approach ensures that no one can read confidential data except the receiver(s). It can be used in different scenarios, such as statistical or research purposes, data mining, and on-line business-to-business (B2B) interactions.

FUTURE RESEARCH TRENDS

Preserving privacy on the Web has an important impact on many Web activities and Web applications. In particular, privacy issues have attracted a lot of attention due to the growth of e-commerce and e-business. These issues are further complicated by the global and self-regulatory nature of the Web.

Privacy issues on the Web are based on the fact that most users want to maintain strict anonymity on Web applications and activities. The ease access to information on the Web coupled with the ready availability of personal data, also made it easier and more tempting for interested parties (e.g., businesses and governments) to willingly or inadvertently intrude on individuals' privacy in unprecedented ways.

Clearly, privacy issues on Web data is an umbrella that encompasses many Web applications such as e-commerce, stream data mining, multimedia mining, among others. In this work, we focus on issues toward foundation for further research in PPDM on the Web because these issues will certainly play a significant role in the future of this new area. In particular, a common framework for PPDM should be conceived, notably in terms of definitions, principles, policies, and requirements. The advantages of a framework of that nature are as follows: (a) a common framework will avoid confusing developers, practitioners, and many others interested in PPDM on the Web; (b) adoption of a common framework will inhibit inconsistent efforts in different ways, and will enable vendors and developers to make solid advances in the future of research in PPDM on the Web.

CONCLUSION

The area of data mining has received special attention since the 1990s. The fascination with the promise of analysis of large volumes of data has led to an increasing number of successful applications of data mining in recent years. Despite its benefits in various areas, the use of data mining techniques can also result in new threats to privacy and information security. The problem is not data mining itself, but the way data mining is done. Thus, in the absence of adequate safeguards, the use of data mining can jeopardize the privacy and autonomy of individuals.

This chapter emphasizes issues concerning privacy-preserving data mining (PPDM), which has posed challenges for novel uses of data mining technology. These technical challenges indicate a pressing need to rethink mechanisms to address some issues of privacy and accuracy when data are either shared or exchanged before mining. Such mechanisms can lead to new privacy control methods to convert a database into a new one that conceals private information while preserving the general patterns and trends from the original database.

KEY TERMS

Collective Privacy: Is concerned with the protection of *sensitive knowledge* representing the activities of a group.

Data Sanitization: Is the process of hiding *sensitive rules* in transactional databases. The sanitization is achieved by modifying some transactions. In some cases, a number of items are deleted from a group of transactions with the purpose of hiding the sensitive rules derived from those transactions. In doing so, the support of such sensitive rules is decreased below a certain disclosure threshold defined by the data owner.

Disclosure Threshold: The process of hiding some *sensitive rules* satisfies a disclosure threshold controlled by the database owner.

Individual Privacy: Is concerned with the protection of personally identifiable information. In general, information is considered personally identifiable if it can be linked, directly or indirectly, to an individual person.

Privacy-Preserving Data Mining: Encompasses the dual goal of meeting privacy requirements and providing valid data mining results.

Sensitive Knowledge: Is described as the knowledge that can provide competitive advantage in the business world.

Sensitive Rules: Are a special group of association rules which represent the *sensitive knowledge* mined from databases.

Process Mining to Analyze the Behaviour of Specific Users

Laura Măruşter

Niels R. Faber
University of Groningen, The Netherlands

INTRODUCTION

As the on-line services and Web-based information systems proliferate in many domains of activities, it has become increasingly important to model user behaviour and personalization, so that these systems will appropriately address user characteristics. In this sense, particular topics are addressed by research in human-computer interaction (HCI), such as the discovering of user behaviour or navigation styles (Balajinath & Raghavan, 2001; Herder & Juvina, 2005; Juvina & Herder, 2005b; Mensalvas et al., 2003; Obendorf, et al., 2007), developing metrics involved in modelling and assessing web navigation (Herder, 2002; McEneany, 2001; Spiliopoulou & Pohle, 2001), and cognitive models for improving the redesign of information systems (Bollini, 2003; Ernst & Story, 2005; Juvina & Herder, 2005a; Juvina et al., 2005b; Lee & Lee, 2003).

Various methods have been developed to model web navigation in case of generic users (Eirinaki &Vazirgiannis, 2003). The existence of systems and/or interfaces neglecting specific user groups results into low performance of these systems, which requires further redesign. By investigating navigational patterns of specific user groups, and combining with their specific characteristics, the (re)design of the systems can be made more effectively. In this chapter, farmers have been considered as a specific user group. However, the methodology discussed in this chapter can be used also in case of other specific user groups.

Focusing on farmers as a specific IT user group, becomes an important research issue (Thysen, 2000). Farmers show a low rate of management software adoption (Alvarez & Nuthall, 2006). Different projects have been initiated to support farmers, to pursue their decision-making activities with the aid of Information Systems (see Fountas, Wulfsohn, Blackmore, Jacobsen, & Pederson, 2006; US North Central Research in Farm Information Systems, 2000). Kuhlmann & Brodersen (2001) and Hayman (2003) express their pessimism about the fast diffusion of complex information technology tools and decision support systems (DSS) among farmers. Various studies aimed to find factors that hamper adoption of DSSs in agriculture (Faber, Jorna, Van Haren, & Maruster, 2007; Kerr, 2004; Kuhlmann & Brodersen, 2001). Alvarez & Nuthall (2006) conclude that "software developers must work with farmers, both in design, and training and support, and the system must be configurable to suit a range of farmer characteristics". Therefore, there seems to be a real need to personalize these systems, such that they address farmers' characteristics.

Personalization of website design that supports DSS systems, to incorporate user characteristics, enhances effectiveness and usage of these systems. "The goal of personalization is to provide users with what they want or need without requiring them to ask for it explicitly" (Mulvenna, Anand, & Buchner, 2000).

The enhancement of website effectiveness is especially relevant in case a website offers access to underlying systems that aim to provide support and advice to its users. For instance, Jensen (2001) analyzed the usage of a web-based information system for variety selection in field crops. He compared four user groups by constructing measures based on logged information. This analysis reveals interesting similarities and differences in behaviour concerning the four groups. However, no insights could be given about the most typical sequence of behaviour/navigation patterns, such that it could support the redesign of the system.

In this chapter, a methodology of investigating user behaviour/navigation patterns by employing process mining technique is presented (Maruster & Faber, 2007). This methodology consists of (i) obtaining user groups considering some performance criteria, (ii) determining navigational patterns for all users and

for each user group, and (iii) deriving implications for redesign. In the following section, this methodology is presented, using an example involving starch potato farmers. We conclude this chapter with future trends and conclusions.

PROCESS MINING FOR PERSONALIZATION

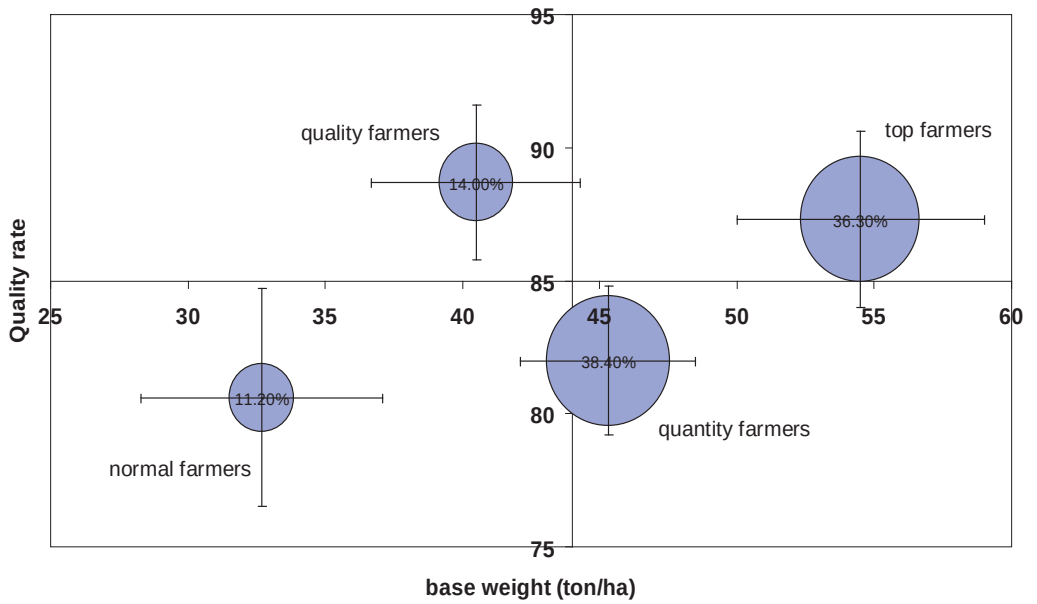
Web Usage Mining by exploiting web access logs targets General Access Pattern Tracking and Customized Usage Tracking. *General Access Pattern Tracking* is using KDD (Knowledge Discovery in Data) techniques to understand general access patterns and trends of web usage, while *Customized Usage Tracking* analyses access patterns of each user at a time (see Zaïane, 2007). Customized Usage Tracking can be used to provide recommendations to web users via personalization. Personalization can be done by distinguishing between different users or group of users, which is called *User profiling* (Eirinaki &Vazirgiannis, 2003).

Developing User Groups

Farmers are considered as a specific group of professional users, characterized by a modest use of IT. In the context of using applications (e.g. decision support systems) developed on Web-service platforms, personalization decisions are not straightforward and have to be based on knowledge about the user. Applications developed for farmers such as decision support systems (DSS) cannot consider them either as generic users (they have low experience with IT, lack of interest to use IT), or individual users (because DSS are complex systems that are hardly customizable for individual users).

Clustering is a common technique used in user profiling (Eirinaki &Vazirgiannis, 2003). Using two-step clustering method[1], Dutch starch potato farmers have been split up into four groups based on performance characteristics, where quantity and quality of a farmer's yield are the used dimensions for cluster analysis, both averaged over the last three years (Faber, Peters & Jorna, 2006). The found clusters have been labelled

Figure 1. Farmer clusters



respectively normal farmers, quality farmers, quantity farmers, and top farmers. In Figure 1, the size of the circles refers to the contribution of the respective clusters to the total production of starch (also indicated with the mentioned percentages).

Determining Navigational Patterns with Process Mining

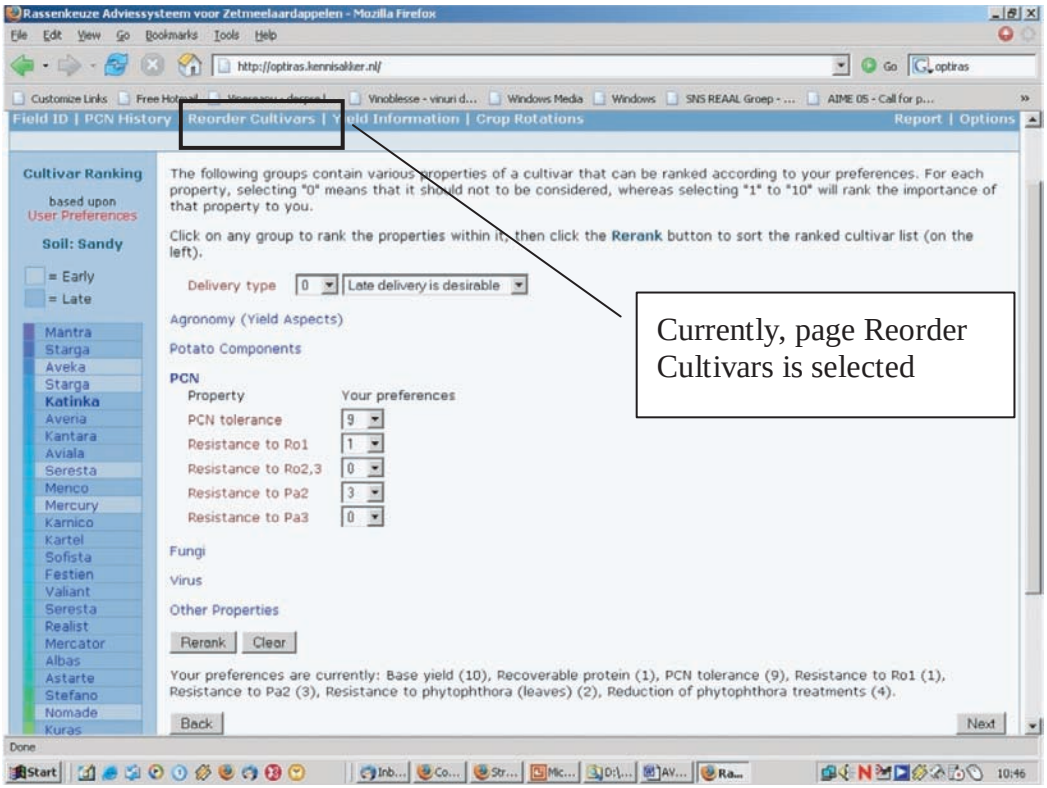
Different methods have been used to investigate the navigation patterns of users, by using logged data. For instance, Herder (2002) developed a technique based on aggregated measures, McEneany (2001) employed graphical and numerical methods, and Spiliopoulou & Pohle (2001) developed a mining query language for depicting navigational patterns.

Data mining techniques are used to develop navigation patterns (or to model user behaviour), such as Clustering, Classification, Association Rule Discovery, Sequential pattern Discovery, Markov models, hidden (latent) variable models, and hybrid models (Mobasher, 2006).

In this chapter, navigational patterns exhibited by farmers are determined using a technique called process mining. *Process mining* techniques allow for extracting information from event logs: for instance, transaction logs of an enterprise resource planning system can be used to discover models describing processes, organisations, and products (Van der Aalst et al., 2007). While navigational patterns developed with the above-mentioned data mining techniques are sequential, process mining may discover also parallel patterns. Moreover, it is possible to use process mining to monitor deviations (e.g. comparing the observed events with predefined models) (Rozinat & Van der Aalst, 2006)[2].

Maruster & Faber (2007) used process mining employing the logs resulted from using a decision support system called OPTIRas™, a DSS that aids starch potato farmers in their cultivar selection activities (Agrobio-

Figure 2. OPTIRas™ screenshot



kon, 2007). The interface of OPTIRas™ DSS consists on seven main pages: Field ID, PCN History, Reorder Cultivars, Yield Information, Crop Rotation, Report and Option (see Figure 2).

Farmers can login in OPTIRas registering with their e-mails, but they can register also with an anonymous ID. This manner of anonymousness provides advantages for the users, but brings disadvantages to the analysis. A user may login first time with his/her e-mail, the second time anonymously using computer A, and the third time again anonymously using computer B; in the analysis, these three sessions will count as sessions belonging to three separate users, and we cannot see anymore how a user eventually changes his behaviour in time.

Table 1 shows an excerpt from the log, which contains information concerning the movement from one 'source' page to a 'destination' page, such as time stamp, name of source page, name of destination page. The final log file consists on 763 user sessions, belonging to 501 individual users.

Navigational patterns are obtained with the aid of an algorithm called *genetic process mining* available as a plug-in the process mining ProM framework (ProM, 2007). Genetic based algorithms for process mining provide good heuristics that can tackle relevant structural constructs (i.e. sequences, parallelism, choices, loops). Moreover, these algorithms are equipped with analysis metrics that assess how complete, precise and folded the resulting process representations are (Medeiros, 2006).

First, the navigational patterns of all users are determined. In Figure 3 is shown the result of genetic process mining on the log including the sessions of all farmers. The focus is to grasp the patterns of navigation from one page to another ('FromPage' field was considered for mining, see Table 1). The rectangles in Figure 3 refer to transitions or activities, in our case to page names, such as Field, Order, etc. There are two special activity names, ArtificialStartTask and ArtificialEndTask that refer to a generic start or end page. The term 'complete' refers to a finished action. The number inside the rectangle shows how many times a page has been invoked. The arcs (associated with a number) between rectangles represent the occurrence of two pages and how often it happens. For instance in Figure 3, Pcn page occurred 526 times after Field page.

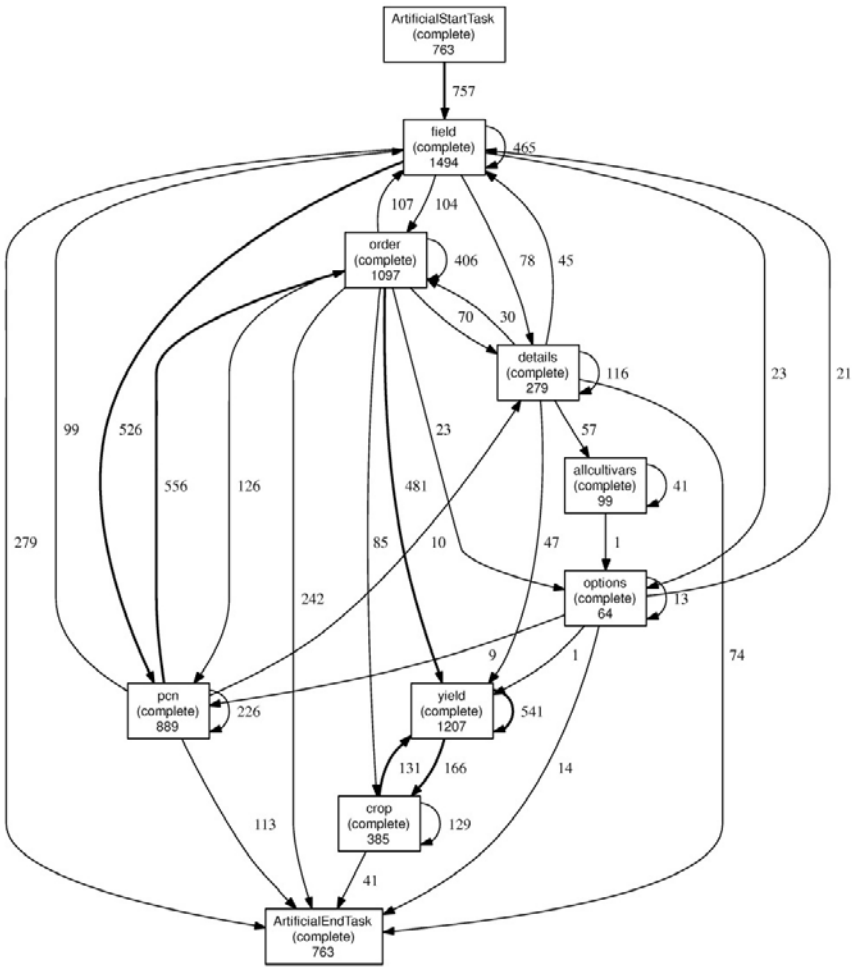
In Figure 3 we can determine "the most common navigational pattern" (represented with bold arrows) which consists of ArtificialStartTask→Field (757), Field→Pcn (526), Pcn→Order (556), Order→Yield (481), Yield→ Crop (166), Yield→ Yield (541), Crop→ Yield (131). The sequence Field → Pcn → Order → Yield → Crop is actually the "prescribed" order of pages in OPTIRas, e.g. the order in which pages are presented in OPTIRas.

Second, the ProM genetic process mining is used on the logs including 22 sessions of top-farmers, 8 belonging to quality farmers, and 8 to quantity farmers (there were not sessions belonging to normal farmers).

Table 1. Excerpt from a log file

Time stamp	**FromPage**	**ToPage**
2004-12-22 22:13:29	field	Pcn
2004-12-22 22:13:35	pcn	Order
2004-12-22 22:14:00	order	Yield
2004-12-22 22:14:26	yield	Crop
2004-12-22 22:16:16	crop	Yield
2004-12-22 22:16:25	yield	Crop
2004-12-22 22:16:53	crop	details (katinka_l)
2004-12-22 22:17:54	details	Allcultivars

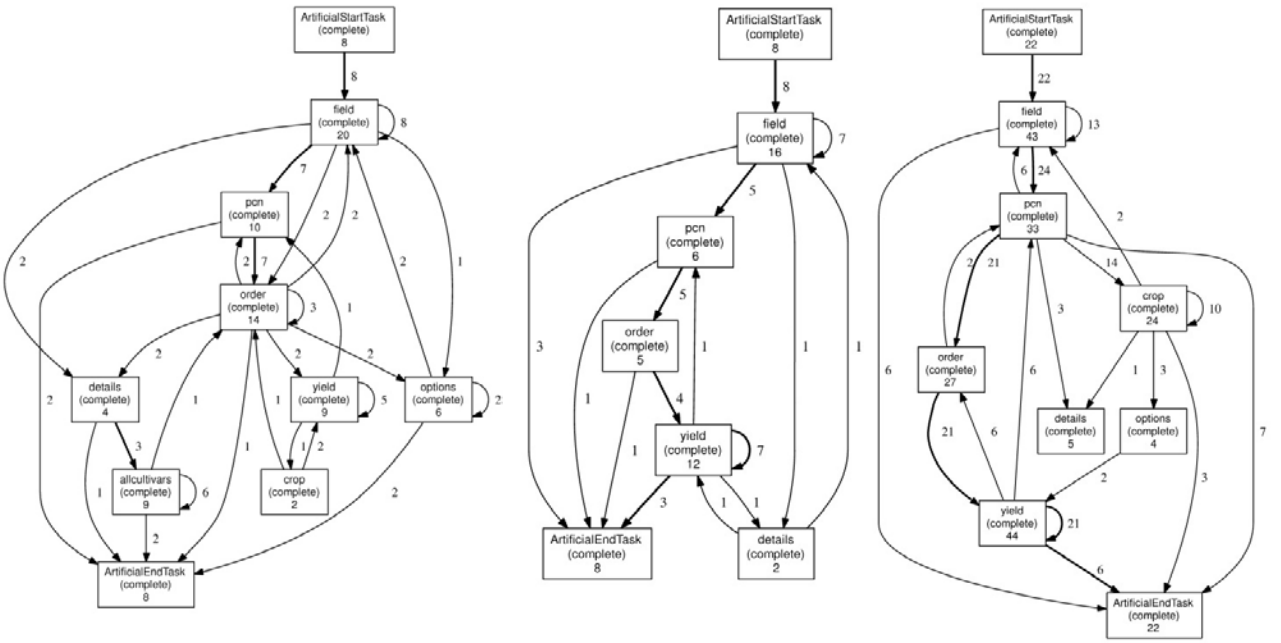
Figure 3. The mined behaviour of all farmers (run of the genetic algorithm)



This analysis shows a distinction of three types of users (see Figure 4). Quality farmers show "spread" behaviour, without clear defined patterns (Figure 4a). Top farmers are seeking information and looping (Field→ Pcn→Field, Pcn→Order→Pcn, Order→Yield→Order, Pcn→Crop→Field) (Figure 4b). Quantity farmers seem to follow in majority the prescribed order of pages (emphasized with bold arrows), e.g. ArtificialStartTask → Field → Pcn → Order → Yield→ ArtificialEndTask (Figure 4c).

This methodology shows how to combine navigational patterns with already identified user groups, which allows for the construction of navigational patterns for specific groups of users. Top-farmers show the most complex behavioural pattern of usage, visiting webpages in a non-linear order and backtracking their steps. In contrast, quality farmers have navigational patterns that simply comply with the prescribed sequence of pages of the website.

Figure 4. The mined behaviour for 'quality farmers' (a), 'top farmers' (b) and 'quantity farmers' (c), using genetic process mining



(a) *(b)* *(c)*

Implications for Redesign

The combination of navigational patterns and user characteristics can be used to redesign websites. In Maruster & Faber (2007), based on the identified behaviours of top, quantity, and quality farmers, three distinct behaviours regarding the DSS have been identified. Because these are preliminary findings, a detailed redesign cannot be made yet. However, from current findings two possibilities for redesign are inferred. First, because quantity farmers show navigational behaviour aligned with the current design of the website, no redesign seems to be needed for this particular group. Second, because top farmers shows more complex behaviour, a possibility for redesign is to group more information and functions on one page (Faber, Peters, & Jorna, 2006). In this manner, users in this group will be able to see the consequences of their actions directly, without having to go back and forth through various webpages.

FUTURE TRENDS

Although research in personalization results in many successful contributions, various challenges still lie ahead. Modelling user context and interests, is one of challenges existing in the domain of personalization (Mobasher, 2006). Determining the cognitive models and learning styles of users will provide the necessary information to understand better the users, their decision-making process, interests and needs, which subsequently will lead to improvements of user models. Pieters (2005) found that farmer clusters differ significantly on the motivation scales extrinsic value and self-efficacy and on the skills scales peer learning

and help seeking. Top farmers appear to have better learning attitudes relative to other farmer clusters. Quality oriented farmers seem to stay behind with respect to their learning skills, especially on the scales of peer learning, and help seeking. These farmers might perform better when their learning skills are addressed properly. The normal farmers rank very high regarding extraversion and openness. This opens the possibility that these farmers are not highly interested in improving starch potato cultivation but have their interests in other aspects of their farm or life. Learning styles and personality have impact on use of DSS's; especially anxiety is one of the scales, which blocks effectively the usage of DSS's. All these factors may be taken into account when redesigning and/or personalizing a DSS.

CONCLUSION

Mining user behaviour for personalization enables the redesign for personalization of existing websites, resulting in websites that are aligned with actual usage behaviour. The split up of users based on their characteristics results in an initial identification of different user groups. In the domain of crop selection, application users are farmers. History has shown that farmers cannot be treated as one homogeneous group, and instead should be treated individually. However, decision support systems for these farmers are complex systems, making the tailoring of these systems to individual farmers difficult. Therefore, the population of farmers has been split up into various groups based on performance characteristics, resulting in four different groups.

Process mining techniques are used to construct navigational patterns from user logs. The level of detail of user behaviour that can be mined depends on the granularity of the logs. From the user logs individual and aggregated behavioural patterns can be constructed. Combining navigational patterns with already identified user groups allows for the construction of navigational patterns for specific groups of users. Ultimately, the combination enables the redesign of the existing application, tailored for each user group. The application can be tailored to fit specific characteristics of the different user groups and their particular behaviour.

KEY TERMS

Decision Support System: An application, possibly accessible through a website that informs its user regarding a specific domain, enabling the user to effectively make decisions in relation to his tasks.

Human-Computer Interaction: Human-computer interaction is a discipline concerned with the design, evaluation and implementation of interactive computing systems for human use and with the study of major phenomena surrounding them.

Navigational Pattern: Represent the manner in which a user or a group of users are navigating through a web site.

Process Mining: Allow for extracting information from event logs. These techniques can be used to discover models describing processes, organisations, and products. Moreover, it is possible to use process mining to monitor deviations (e.g., comparing the observed events with predefined models or business rules).

Specific User Group: A cluster of people that is identified based on one or more characteristics that the people of the cluster have in common (for instance, growers can be split into various clusters based on yield performance measures).

System Redesign: Altering the design of an existing software application or part thereof, by revising a function or the appearance of the application or by making a new design for the application.

User Behaviour: The observable result of the reasoning of a human-being who uses a computer application that is logged.

User Profiling: Distinguishing between users or group of users, by creating an information base that contains the preferences, characteristics, and activities of the users.

Profit Mining

Senqiang Zhou
Simon Fraser University, Canada

Ke Wang
Simon Fraser University, Canada

INTRODUCTION

A major obstacle in data mining applications is the gap between the statistic-based pattern extraction and the value-based decision-making. "Profit mining" aims to reduce this gap. In profit mining, given a set of past transactions and pre-determined target items, we like to build a model for recommending target items and promotion strategies to new customers, with the goal of maximizing profit. Though this problem is studied in the context of retailing environment, the concept and techniques are applicable to other applications under a general notion of "utility". In this short article, we review existing techniques and briefly describe the profit mining approach recently proposed by the authors. The reader is referred to (Wang, Zhou & Han, 2002) for the details.

BACKGROUND

It is a very complicated issue whether a customer buys a recommended item. Consideration includes items stocked, prices or promotions, competitors' offers, recommendation by friends or customers, psychological issues, conveniences, etc. For on-line retailing, it also depends on security consideration. It is unrealistic to model all such factors in a single system. In this article, we focus on one type of information available in most retailing applications, namely past transactions. The belief is that shopping behaviors in the past may shed some light on what customers like. We try to use patterns of such behaviors to recommend items and prices.

Consider an on-line store that is promoting a set of *target items*. At the cashier counter, the store likes to recommend one target and a promotion strategy (such as a price) to the customer based on *non-target items* purchased. The challenge is determining an item interesting to the customer at a price affordable to the customer and profitable to the store. We call this problem *profit mining* (Wang, Zhou & Han, 2002).

Most statistics-based rule mining, such as association rules (Agrawal, Imilienski & Swami, 1993; Agrawal & Srikant, 1994), considers a rule as "interesting" if it passes certain statistical tests such as support/confidence. To an enterprise, however, it remains unclear how such rules can be used to maximize a given business object. For example, knowing "Perfume→ Lipstick" and "Perfume→Diamond", a store manager still cannot tell which of Lipstick and Diamond, and what price should be recommended to a customer who buys Perfume. Simply recommending the most profitable item, say Diamond, or the most likely item, say Lipstick, does not maximize the profit because there is often an inverse correlation between the likelihood to buy and the dollar amount to spend. This inverse correlation reflects the general trend that the more dollar amount is involved, the more cautious the buyer is when making a purchase decision.

MAIN THRUST OF THE CHAPTER

Related Work

Profit maximization is different from the "hit" maximization as in classic classification because each hit may generate different profit. Several approaches existed to make classification *cost-sensitive*. (Domingos, 1999) proposed a general method that can serve as a wrapper to make a traditional classifies cost-sensitive. (Zadrozny & Elkan, 2001) extended the error metric by allowing the cost to be example dependent. (Margineantu & Dietterich, 2000) gave two bootstrap methods to estimate the average cost of a classifier. (Pednault, Abe & Zadrozny, 2002) introduced a method to make sequential cost-sensitive decisions, and the goal is to maximize the total

benefit over a period of time. These approaches assume a given error metric for each type of misclassification, which is not available in profit mining.

Profit mining is related in motivation to *actionability* (or *utility*) of patterns: a pattern is interesting in the sense that the user can act upon it to her advantage (Silberschatz & Tuzhilin, 1996). (Kleinberg, Papadimitriou & Raghavan, 1998) gave a framework for evaluating data mining operations in terms of utility in decision-making. These works, however, did not propose concrete solutions to the actionability problem. Recently, there were several works applying association rules to address business related problems. (Brijs, Swinnen, Avanhoof & Wets, 1999; Wong, Fu & Wang, 2003; Wang & Su, 2002) studied the problem of selecting a given number of items for stocking. The goal is to maximize the profit generated by selected items or customers. These works present one important step beyond association rue mining, i.e., addressing the issue of converting a set of individual rules into a single actionable model for recommending actions in a given scenario.

There were several attempts to generalize association rules to capture more semantics, e.g., (Lin, Yao & Louie, 2002; Yao, Hamilton & Butz, 2004; Chan, Yang & Shen, 2003). Instead of a uniform weight associated with each occurrence of an item, these works associate a general weight with an item and mine all itemsets that pass some threshold on the aggregated weight of items in an itemset. Like association rule mining, these works did not address the issue of converting a set of rules or itemsets into a model for recommending actions.

Collaborative filtering (Resnick & Varian, 1997) makes recommendation by aggregating the "opinions" (such as rating about movies) of several "advisors" who share the taste with the customer. Built on this technology, many large commerce web sites help their customers to find products. For example, Amazon.com uses "Book Matcher" to recommend books to customers; Moviefinder.com recommends movies to customers using "We Predict" recommender system. For more examples, please refer to (Schafer, Konstan & Riedl, 1999). The goal is to maximize the hit rate of recommendation. For items of varied profit, maximizing profit is quite different from maximizing hit rate. Also, collaborative filtering relies on carefully selected "item endorsements" for similarity computation, and a good set of "advisors" to offer opinions. Such data are not easy to obtain. The ability of recommending prices, in addition to items, is another major difference between profit mining and other recommender systems.

Another application where data mining is heavily used for business targets is *direct marketing*. See (Ling & Li, 1998**;** Masand & Shapiro, 1996; Wang, Zhou, Yeung & Yang, 2002), for example. The problem is to identify buyers using data collected from previous campaigns, where the product to be promoted is usually fixed and the best guess is about who are likely to buy. The profit mining, on the other hand, is to guess the best item and price for a given customer. Interestingly, these two problems are closely related to each other. We can model the direct marketing problem as profit mining problem by including customer demographic data as part of her transactions and including a special target item NULL representing no recommendation. Now, each recommendation of a non-NULL item (and price) corresponds to identifying a buyer of the item. This modeling is more general than the traditional direct marketing in that it can identify buyers for more than one type of item and promotion strategies.

Profit Mining

We solve the profit mining by extracting patterns from a set of past transactions. A transaction consists of a collection of sales of the form (item, price). A simple price can be substituted by a "promotion strategy", such as "buy one get one free" or "X quantity for Y dollars", that provides sufficient information for derive the price. The transactions were collected over some period of times and there could be several prices even for the same item if sales occurred at different times. Given a collection of transactions, we find *recommendation rules* of the form $\{s_1, \ldots, s_k\} \rightarrow \langle I,P \rangle$, where I is a target item and P is a price of I, and each s_i is a pair of non-target item and price. An example is (*Perfume, price=$20*)→(*Lipstick, price=$10*). This recommendation rule can be used to recommend Lipstick at the price of $10 to a customer who bought Perfume at the price of $20. If the recommendation leads to a sale of Lipstick of quantity Q, it generates $(10\text{-}C)*Q$ profit, where C is the cost of Lipstick.

Several practical considerations would make recommendation rules more useful. First, items on the left-hand side in s_i can be item categories instead to capture category-related patterns. Second, a customer may have paid a higher price if a lower price was not available at the shopping time. We can incorporate the

domain knowledge that paying a higher price implies the willingness of paying a lower price (for exactly the same item) to search for stronger rules at lower prices. This can be done through multi-level association mining (Srikant and Agrawal, 1995; Han and Fu, 1995), by modeling a lower price as a more general category than a higher price. For example, the sale {<*chicken, $3.8*>} in a transaction would match any of the following more general sales in a rule: <*chicken, $3.8*>, <*chicken, $3.5*>, <*chicken, $3.0*>, *chicken, meat, food.* Note that the last three sales are generalized by climbing up the category hierarchy and dropping the price.

A key issue is how to make a set of individual rules work as a single recommender. Our approach is ranking rules the *recommendation profit*. The recommendation profit of a rule *r* is defined as the average profit of the target item in r among all transactions that match *r*. Note that the rank by average profit implicitly takes into account of both confidence and profit because a high average profit implies that both confidence and profit are high. Given a new customer, we pick up the highest ranked matching rule to make recommendation.

Before making recommendation, however, "over-fitting" rules that work only for observed transactions, but not for new customers, should be pruned because our goal is to maximize profit on new customers. The idea is as follows. Instead of ranking rules by observed profit, we rank rules by *projected profit,* which is based on the *estimated error* of a rule adapted for pruning classifiers (Quinlan, 1993). Intuitively, the estimated error will increase for a rule that matches a small number of transactions. Therefore, over-fitting rules tend to have a larger estimated error, which translates into a lower projected profit, and a lower rank.

For a detailed exposure and experiments on real life and synthetic data sets, the reader is referred to (Wang, Zhou & Han, 2002).

FUTURE TRENDS

The profit mining proposed is only the first, but important, step in addressing the ultimate goal of data mining. To make profit mining more practical, several issues need further study. First, it is quite likely that the recommended item tends to be the item that the customer will buy independently of the recommendation. Obviously, such items need not be recommended, and recommendation should focus on those items that the customer may buy if informed, but may not otherwise. Recommending such items likely brings in *additional* profit. Second, the current model maximizes only the profit of "one-shot selling effect," therefore, a sale in a large quantity is favored. In reality, a customer may regularly shop the same store over a period of time, in which case a sale in a large quantity will affect the shopping frequency of a customer, thus, profit. In this case, the goal is maximizing the profit for reoccurring customers over a period of time. Another interesting direction is to incorporate the feedback whether a certain recommendation is rejected and accepted to improve future recommendations.

This current work has focused on the information captured in past transactions. As pointed out in Introduction, other things such as competitors' offers, recommendation by friends or customers, consumer fashion, psychological issues, conveniences, etc. can affect the customer's decision. Addressing these issues requires additional knowledge, such as competitors' offers, and computers may not be the most suitable tool. One solution could be suggesting several best recommendations to the domain expert, the store manager or sales person in this case, who makes the final recommendation to the customer after factoring the other considerations.

CONCLUSION

Profit mining is a promising data mining approach because it addresses the ultimate goal of data mining. In this article, we study profit mining in the context of retailing business, but the principles and techniques illustrated should be applicable to other applications. For example, "items" can be general actions and "prices" can be a notion of utility resulted from actions. In addition, "items" can be used to model customer demographic information such as Gender, in which case the price component is unused.

KEY TERMS

Association Rule: An association has the form $I_1 \rightarrow I_2$, where I_1 and I_2 are two itemsets. The support of an association rule is the support of the itemset $I_1 \cup I_2$, and the *confidence* of a rule is the ratio of support of $I_1 \cup I_2$ and the support of I_1.

Classification: Given a set of training examples in which each example is labeled by a class, build a model, called a classifier, to predict the class label of new examples that follow the same class distribution as training examples. A classifier is accurate if the predicted class label is the same as the actual class label.

Cost Sensitive Classification: The error of a misclassification depends on the type of the misclassification. For example, the error of misclassifying Class 1 as Class 2 may not be the same as the error of misclassifying Class 1 as Class 3.

Frequent Itemset: The support of an itemset refers to as the percentage of transactions that contain all the items in the itemset. A frequent itemset is an itemset with support above a pre-specified threshold.

Over-fitting Rule: A rule has high performance (e.g. high classification accuracy) on observed transaction(s) but performs poorly on future transaction(s). Hence, such rules should be excluded from the decision-making systems (e.g. recommender). In many cases over-fitting rules are generated due to the noise in data set.

Profit Mining: In a general sense, profit mining refers to data mining aimed at maximizing a given objective function over decision making for a targeted population (Wang, Zhou & Han, 2002). Finding a set of rules that pass a given threshold on some interestingness measure (such as association rule mining or its variation) is not profit mining because of the lack of a specific objective function to be maximized. Classification is a special case of profit mining where the objective function is the accuracy and the targeted population consists of future cases. This paper examines a specific problem of profit mining, i.e., building a model for recommending target products and prices with the objective of maximizing net profit.

Transaction: A transaction is some set of items chosen from a fixed alphabet.

Program Comprehension through Data Mining

Ioannis N. Kouris
University of Patras, Dept. of Computer Engineering and Informatics Greece

INTRODUCTION

Software development has various stages, that can be conceptually grouped into two phases namely development and production (Figure 1). The development phase includes requirements engineering, architecting, design, implementation and testing. The production phase on the other hand includes the actual deployment of the end product and its maintenance. Software maintenance is the last and most difficult stage in the software lifecycle (Sommerville, 2001), as well as the most costly one. According to Zelkowitz, Shaw and Gannon (1979) the production phase accounts for 67% of the costs of the whole process, whereas according to Van Vliet (2000) the actual cost of software maintenance has been estimated at more than half of the total software development cost.

The development phase is critical in order to facilitate efficient and simple software maintenance. The earlier stages should be done by taking into consideration apart from any functional requirements also the later maintenance task. For example the design stage should plan the structure in a way that can be easily altered. Similarly, the implementation stage should create code that can be easily read, understood, and changed, and should also keep the code length to a minimum. According to Van Vliet (2000) the final source code length generated is the determinant factor for the total cost during maintenance, since obviously the less code is written the easier the maintenance becomes.

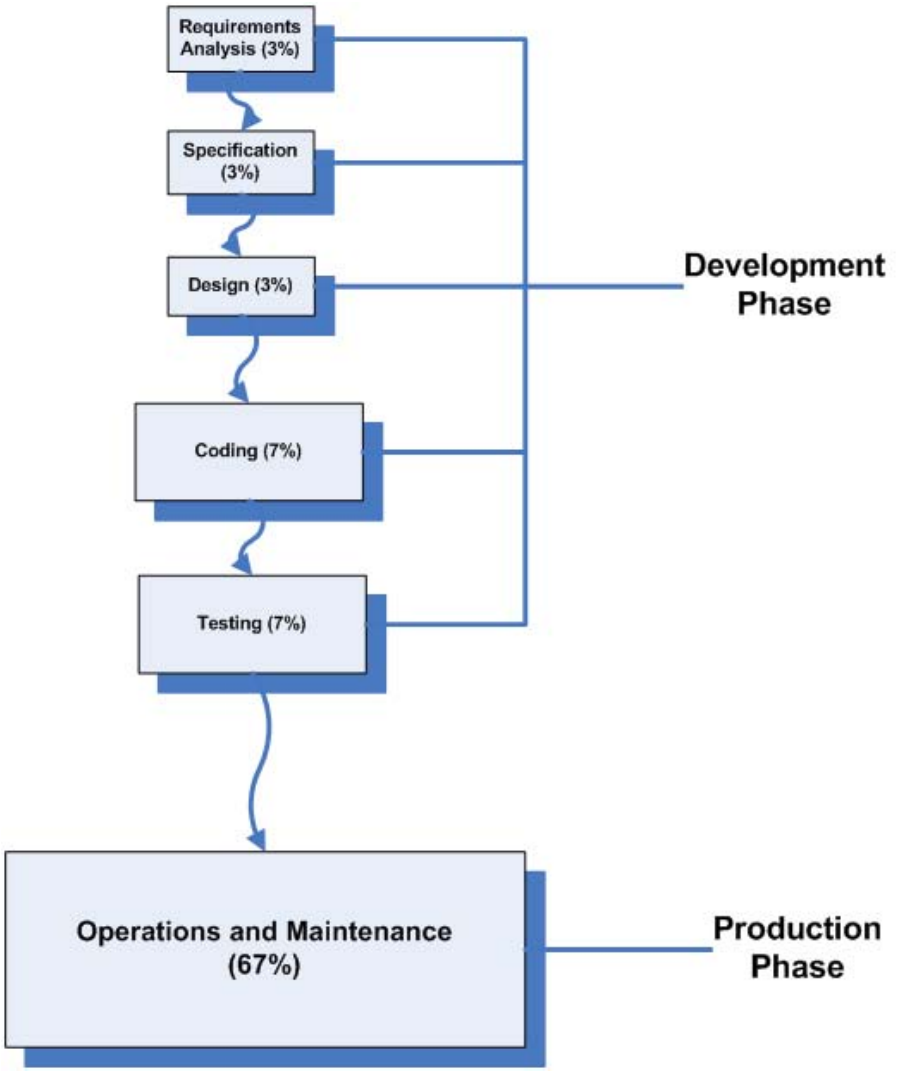
According to Erdil et al. (2003) there are four major problems that can slow down the whole maintenance process: unstructured code, maintenance programmers having insufficient knowledge of the system, documentation being absent, out of date, or at best insufficient, and software maintenance having a bad image. Thus the success of the maintenance phase relies on these problems being fixed earlier in the life cycle. In real life however when programmers decide to perform some maintenance task on a program such as to fix bugs, to make modifications, to create software updates etc. these are usually done in a state of time and commercial pressures and with the logic of cost reduction, thus finally resulting in a problematic system with ever increased complexity. As a consequence the maintainers spend from 50% up to almost 90% of their time trying to comprehend the program (Erdös and Sneed; 1998, Von Mayrhauser and Vans; 1994, Pigoski, 1996). Providing maintainers with tools and techniques to comprehend the programs has become and is receiving a lot of financial and research interest given the widespread of computers and software in all aspects of life. In this work we briefly present some of the most important techniques proposed in the field thus far and focus primarily on the use of data mining techniques in general and especially on association rules. Accordingly we give some possible solutions to problems faced by these methods.

BACKGROUND

Data mining can be defined as the process concerned with applying computational techniques (i.e. algorithms implemented as computer programs) to find patterns in the data. Among others, data mining technologies include association rule discovery, classification, clustering, summarization, regression and sequential pattern discovery (Chen, Han & Yu, 1996).

The use of data mining techniques in program comprehension has been very wide, with clustering being the most popular method. Tjortjis and Layzel (2001) have proposed a tool called DMCC (Data Mining Code Clustering) in order to help maintainers who are not familiar with some software to get a quick overview and speed up the process of getting familiar with it. The specific tool used clustering techniques for grouping together entities that share common characteristics. Mancoridis et al. (1998) have proposed a tool called Bunch that creates a high level decomposition of the structure of a system into meaningful subsystems by using clustering techniques over a Module Dependency Graph. Subsystems provide developers with high-level structural information that helps them navigate through

Figure 1. Software development stages and their relative costs (Zelkowitz, Shaw and Gannon, 1979)



the numerous software components, their interfaces, and their interconnections. Kanellopoulos and Tjortjis (2004) have also used clustering techniques on source code in order to facilitate program comprehension. Their work extracted data from C++ source code, and tried to cluster it in blocks in order to identify logical, behavioral and structural correlations amongst program components.

Other similar works can be found at Anquetil and Lethbridge (1999), Lakhotia (1997) and Tzerpos and Holt (1998). Also an early but thorough overview on software clustering techniques can be found by Wiggerts (1997).

In a significantly smaller degree there has been used also association rules on program comprehension. Tjortjis, Sinos and Layzell (2003) have proposed a technique that inputs data extracted from source code and derives association rules. These rules help the formation of groups of source code containing interrelated entities. Similar work to Mancoridis et al. (1998) but with the use of association rules instead of clustering techniques has been made by De Oca and Carver (1998). In this work by using the ISA (Identification of Subsystems based on Associations) methodology a software system was decomposed into data cohesive subsystems by mining association rules. Use of association rules into program comprehension has been made also by Sartipi, Kontogiannis and Mavaddat (2000) for architectural design recovery.

PROBLEMS FACED

Bellow we give possible solutions to problems suffered by some current methods by borrowing and using techniques from other fields and mainly association rules.

Surpassing the Low Frequency Problem

As noted by Tjortzis, Sinos and Layzel (2003), input tables produced for source code analysis tend to be sparse. Practically these tables tend to be as sparse as those created by using web pages as input, but they are comparably many orders of magnitude smaller than those from the web. According to Tjortzis, Sinos and Layzel (2003) if one wants to retrieve and incorporate more information about block groups of code he would have to use a small support value. But this would create the so called rare itemset dilemma introduced by Mannila (1998). According to this problem trying to overcome the difficulty of having widely varied itemset frequencies or trying to include rare but very important itemsets (whatever this importance might represent) by lowering the single support measure would result in an overall problematic and highly questionable process. This can be seen better through an example: Suppose we have the case where some itemsets hardly appear in our database, but cannot nevertheless be considered useless (e.g. a variable used to point to an important log file or to alert the user about a serious security exception etc.). On the other hand let there be itemsets that appear very frequently in the data, at a very high percentage. How can one include those infrequent itemsets with the frequent ones, especially if overall the frequencies vary a lot? One is then confronted with the following dilemma: If the overall minsup is set too high, then we eliminate all those itemsets that are infrequent. On the other hand if we set the overall minsup too low, in order to find also those itemsets that are infrequent, we will most certainly generate a huge number of frequent itemsets and will produce far too many rules, rules that will be meaningless. Actually we might end up having generated so many rules that we might have to apply data mining techniques upon the rules themselves. Also apart from generating too many useless rules there exists also the possibility that the whole process will require too much time or will not even finish. As an example the Cover Type dataset[1] from UCI repository with only 120 1-itemsets, but with most of them appearing almost all the time, results in about 15 million large itemsets. Using an associations rules algorithm like Apriori (Agrawal and Srikant, 1994) just to find all these large itemsets required more than 96 CPU hours (Webb, 2000).

In order to overcome this problem and to actually incorporate only the information needed a practicable solution would be to use algorithm MSApriori (Liu, Hsu & Ma, 1999) that uses multiple minimum support values for the items in the database. According to the specific algorithm an important item will receive a low support value whereas an unimportant a higher one. So every itemset including an important one will also receive a low support value, thus finally being discovered and presented to the user as a frequent itemset. That way we can finally include only the itemsets that are actually important to us and not every itemset. The only problem that still remains with that technique is the actual determination of the final support value assigned to every itemset. In contrast to the assumption upon which all association rules approaches work including algorithm MSApriori, that is that the correct support value is already known, in practice the correct minimum support value is not known and can only be estimated based on domain knowledge or on previous experience. Also when talking about the "correct" value, this is judged after the completion of the mining process based on the number of discovered frequent itemsets (i.e. too few or too many itemsets as compared to what has been anticipated), or in other words through completely subjective and rather trivial criteria. In practice algorithm MSApriori can be used only with very few items and only with expert knowledge of the field and the data studied.

The specific problem was addressed in (Kouris, Makris & Tsakalidis, 2004), by using an efficient weighting scheme for assigning the correct minimum support values to all the items. The intuition was simple. Every item can have support at maximum:

$$\max \sup(i) = \frac{T_i}{T_{total}}.$$

The closest the support of an item is set to its maximum support, the more appearances there are needed in order for it to quantify as a frequent and the less important it is considered. So we make a pass over the data without having assigned any support values, and at the end of this pass we know the maximum support of every item. So the final support of an item is determined by

multiplying the maximum support an item can have, with a weight that reflects its importance according to the following formula: sup(i) = wf *max sup(i). The determination of this weight - wf is done by the final user and depends on the application and the data. It remains only for a domain expert to adjust this formula for the case of source code.

Incorporating Additional Information into Data Mining

A big problem suffered by traditional association rules methods was that they treated itemsets and extracted patterns as mere statistical probabilities and as Boolean variables. They did not take into account the exact number of appearances of the items in every transaction and also considered all items of the same importance, thus resulting in their homogenization. This problem is common also in program comprehension. According to Tjortzis, Sinos and Layzel (2003), it would desirable to have a quantitative model instead of a pure qualitative one. In other words we would like to know apart from the existence or absence of a code item in a block of code, also the number of occurrences inside blocks. For example a rule of the form:

$$I_A[3] \rightarrow I_B[2 - 5]$$

would mean "if item A occurs 3 times then item B occurs 2 up to 5 times". We extend this idea and suggest a more complete model that would also consider the actual significance a code item carries. So apart from the exact number of appearances of a code item, we should take into consideration the fact that not all items carry the same significance. An item describing a critical procedure or one linking to many other items is much more significant than one that simply prints out a welcome message. So a different degree of importance should be assigned to every item.

Kouris, Makris and Tsakalidis (2005) have taken these considerations into account for the case of retail data and proposed a complete system. The specific system can be used with minimum modifications for the purpose of program comprehension. The heart of this system is an index created using all past transactions, a mechanism widely used in Information Retrieval for organizing and processing effectively large collections of data and mostly text or web documents (Witten, Moffat & Bell, 1999).

The generated index has various functionalities. In our case a very useful function would be its use as a search engine, by giving answers to queries involving any Boolean operator as well as their combinations. For example how many times does a variable appear with another one, or in which procedures or functions some variables co-appear, or in which blocks specific items appear but never some other ones etc. All these queries would be processed with minimum resources. Also apart from the rule proposed above, another form of a rule of the new system could present would be:

$$I_A \rightarrow I_B, I_E, I_N.$$

where we point to the user with which items item A appears together based though not only on their co-appearance but also on their overall presence. In other words if item A appears 10 times together with item E and 9 times with item B but item E appears totally 100 times whereas item B only 15 then we can easily understand that A is much more correlated with B than with E.

Significant would be also the utilization of the system by making use of ranked queries. When using an index for making ranked queries a model called vector space model is employed, where blocks of code are represented vectors in a multidimensional Euclidean space. Each axis in this space corresponds to code item. The functioning of a vector space model can be divided in three logical phases. The first logical phase is the generation of an index based on our collection of code items, whatever these items might represent. The second is the assignment of a weight to all code items in the index and the third and final phase consists of using some similarity measure to rank the blocks of code that constitute the answer to a user query. So for every code item that interests us, we make a ranked query to the index that tries to match it against the existing ones and propose the user with the most relevant blocks of code. The ranked queries technique and the indexes have been used with great success both in Information Retrieval as well as for data mining (Kouris, Makris & Tsakalidis, 2004), and are expected to present very good results in program comprehension too.

FUTURE TRENDS

As noted above program maintenance and especially program comprehension is the most difficult and costly task in the software lifecycle. In the US the cost of software maintenance has been estimated at more than 70 billion annually for ten billion lines of existing code (Sutherland, 1995), in the UK head officials of UK's TaskForce 2000 estimated the cost of Y2K[2] reprogramming at roughly 50 billion US dollars and at for the same cause Nokia Inc. allocated about 90 million US dollars (Koskinen, 2003). As programs unavoidably become more and more complicated and bulky the specific problem will rather deteriorate. In our opinion future research efforts will concentrate on adopting and adapting techniques from other fields (such as data mining and information retrieval) in order to solve specific problems in the field.

CONCLUSION

Program comprehension is a critical task in the software life cycle. In this work we addressed an emerging field, namely program comprehension through data mining. The specific task is considered by many researchers to be one of the "hottest" ones nowadays, with large financial and research interest. As we made apparent in this paper, the use of data mining techniques and especially association rules can facilitate better and easier maintenance of software and extend its lifetime.

KEY TERMS

Software Maintenance: Process involved with enhancing and optimizing deployed software (e.g by the addition of new functionalities), updating previous versions, as well as remedying defects and deficiencies found after deployment (such as bugs).

Program Comprehension: The task dealing with the processes (cognitive or others) used by software engineers to understand programs.

Software Life Cycle: The phases a software product goes through from its initial conception until it is finally rendered obsolete. The continuing process, in which a software project specifies, prototypes, designs, implements, tests, and maintains a piece of software.

Data Mining: Analysis of data in a database using tools which look for trends or anomalies without knowledge of the meaning of the data. The nontrivial extraction of implicit, previously unknown, and potentially useful information from data. The science of extracting useful information from large data sets or databases.

Data Clustering: Clustering is the unsupervised classification of patterns (observations, data items, or feature vectors) into groups (clusters).

Association Rules for Program Comprehension: Finding frequent patterns, associations, correlations, or

causal structures among sets of data items extracted directly from source code. These rules aim at capturing program structure and thus achieving better system understanding.

Itetmsets: A collection or a combination of items (such as variables in the source code of a program) in a database.

ENDNOTES

Program Mining Augmented with Empirical Properties

Hee Beng Kuan Tan
Nanyang Technological University, Singapore

INTRODUCTION

Due to the need to reengineer and migrating aging software and legacy systems, reverse engineering has started to receive some attention. It has now been established as an area in software engineering to understand the software structure, to recover or extract design and features from programs mainly from source code. The inference of design and feature from codes has close similarity with data mining that extracts and infers information from data. In view of their similarity, reverse engineering from program codes can be called as program mining. Traditionally, the latter has been mainly based on invariant properties and heuristics rules. Recently, empirical properties have been introduced to augment the existing methods. This article summarizes some of the work in this area.

BACKGROUND

"Software must evolve over time or it becomes useless" (Lehman). A large part of software engineering effort today is involved not in producing code from scratch but rather in maintaining and building upon existing code. For business, much of their applications and data reside in large, legacy systems. Unfortunately, these systems are poorly documented. Typically, they become more complex and difficult to understand over time.

Due to this need to reengineer and migrating aging software and *legacy systems*, reverse engineering has started to receive some attentions. *Reverse engineering* is an approach to understand the software structure, to recover or extract design and features, given the source code. This process identifies software building blocks, extract structural dependencies, produces higher-level abstractions and present pertinent summaries. Reverse engineering helps by providing computer assistance, often using compiler technologies such as lexical, syntactic and semantic analysis. *Static analysis* strengthens the study by inferring relationships that may not be obvious from the syntax of the code, without running the program.

The inference of *design patterns* and features from codes has close similarity with data mining that extracts and infers information from data. In view of their similarity, reverse engineering from program codes can be called as program mining. Program mining is a challenging task because there are intrinsic difficulties in performing the mapping between the language of high level design requirements and the details of love level implementation. Although program mining depends heavily on human effort, a number of approaches have been proposed to automate or partially automate this process.

Traditionally, approaches to program mining are based on invariant properties of programs or heuristic rules to recover design information from source code (De Lucia, Deufemia, Gravino, & Risi, 2007; Poshyvanyk, Gueheneuc, Marcus, Antoniol, & Rajlich, 2007; Robillard & Murphy, 2007; Shepherd, Fry, Hill, Pollock, & Vijay-Shanker, 2007; Shi & Olsson, 2006). Recently, several researchers have developed *experimental program analysis* approaches (Ruthruff, Elbaum, & Rothermel, 2006; Tonella, Torchiano, Du Bois, & Systa, 2007) as a new paradigm for solving software engineering problems where traditional approaches have not succeeded. The use of empirical properties, which have been validated statistically, to solve problems is very common in the area of medicine (Basili, 1996). However, the application of this method is rather unexplored in software engineering. This paper summarizes some of our work in this area which incorporates the use of empirical properties.

MAIN FOCUS

In this section, we first describe our work on empirical-based recovery and maintenance of input error correction *features* in information system (Ngo & Tan, 2006).We then discuss the use of empirical properties to infer the infeasibility of a program path (Ngo & Tan, 2007). This work on infeasible path detection is useful for all software engineering tasks which rely on static analysis especially testing and coverage analysis. Finally, we present an approach to extract all the possible database interactions from source code (Ngo, Tan, & Trinh, 2006).

Empirical Recovery and Maintenance of Input Error Correction Features

Information systems constitute one of the largest and most important software domains in the world. In many information systems, a major and important component is processing inputs submitted from its external environment to update its database. However, many input errors are only detected after the completion of execution. We refer to this type of input errors as after-effect input errors. As after-effect input error is unavoidable, the provision of after-effect input error correction features is extremely important in any information system. Any omission of the provision of these features will lead to serious adverse impact. We observe that input error correction features exhibits some common properties. Through realizing these properties from source code, input error correction features provided by a system to correct these effects can be recovered. All the empirical properties have been validated statistically with samples collected from a wide range of information systems. The validation gives evidence that all the empirical properties hold for more than 99 percent of all the cases at 0.5 level of significance.

Properties of Input Error Correction Features

Input errors can be approximately classified into: error of commission (EC), error of omission (EO) and value error (VE). In a program, there are statements which when being executed will raise some external effects; these statements are called effect statements. If effect statements are influenced by some input errors, they will result in erroneous effects; we refer to these as effect errors. Effect errors can be classified into EO, EC and VE in the combination of attributes for executing the effect statement.

In an information system, a type of effect error (EO, EC or VE) that may occur in executing an effect statement e can be corrected by executing another effect statement f in the system. We call f an error correction statement (Tan & Thein, 2004) for correcting e. The minimum collection of all the paths for correcting an input error ξ is called the basis collection of error correction paths for correcting ξ. We discover some empirical patterns for realizing the basis collection of error correction paths for correcting an input error as follow:

Empirical Property 1. A set of paths $\{q_1,\ldots, q_k\}$ is a basis collection of error correction paths for correcting the input ξ is and only if we can partition the set of effect errors resulting from ξ into several partitions $\{E_1,\ldots., E_k\}$ such that for each j, $1 \leq j \leq k$, by executing q_j, all the effect errors in E_j are corrected.

For many programs, the correctability of all its input errors can be deduced from existence of basis collection of error correction paths for some of these errors. This is presented in the following empirical property:

Empirical Property 2. If for each path through the control flow graph of a program, there is a basis collection of error correction paths for correcting EC in the input accessed in the path, then any after-effect input error of the program is correctable.

If each path through the control flow graph of a program S is in a basis collection of error correction paths for correcting an input error of program T, then S is called an error correction program for T. The following empirical property suggests a mechanism to verify the correctability of a program V.

Empirical Property 3. It is highly probable that any input error of program V is correctable if and only if one of the following conditions holds:

- Based on basis collections of error correction paths, Empirical Property 2 infers that any after-effect error of V is correctable.
- Program V is an error correction program for program T and any after-effect error of T is correctable.

Automated Recovery of the Input Error Correction Features

Based on the empirical properties established input error correction features provided by a program can be automatically recovered through the following three steps:

- **Step 1—Program analysis:** Each program in the system is transformed into a control flow graph. For each program, the set of all the input errors and resulting effect errors are derived.
- **Step 2—Recovery of input correction features:** For each basic type ξ of input errors, Empirical Property 1 is applied to compute a basis collection of error correction paths for correcting the input error.
- **Step 3—Recovery of program input error correctability:** In this step, Empirical Property 2 and 3 are applied to recover a set of programs, whose input errors are correctable.

Maintaining Input Error Correction Features

We apply the decomposition slicing technique introduced by (Gallagher & Lyle, 1991) to decompose a program with respect to the input error correction features. By doing this, we are able to isolate program statements which implement an error correction feature. We also obtain a smaller view of a correction program with the unrelated statements removed and dependent statements restricted from modification. To apply this technique, we introduce the concept of effect-oriented decomposition slice. The idea is that an effect-oriented decomposition slice of a program, taken with respect to the external effects raised during the execution of the program, should contain only statements which affect the attributes of some external effects raised during the execution of the program.

To maintain a correction set for correcting a given input error ξ, first of all, one needs to compute both the decomposition slice of the effect errors caused by ξ and all the decomposition slices of the correction paths for correcting ξ. After having these computed, removing and adding an error correction feature can be done easily by following the four rules presented by (Gallagher & Lyle, 1991).

Infeasible Path Detection

A great majority of program paths are found to be infeasible, which in turn make static analysis overly conservative. As static analysis plays a central part in many software engineering activities, knowledge about infeasible program paths can be used to greatly improve the performance of these activities especially structural testing and coverage analysis. We have proposed an empirical approach to the problem of infeasible path detection (Ngo & Tan, 2007). We discovered that many infeasible paths exhibit some common properties which are caused by four code patterns including identical/complement-decision, mutually-exclusive-decision, check-then-do and looping-by-flag pattern. Through realizing these properties from source code, many infeasible paths can be precisely detected. Binomial tests have been conducted which give strong statistical evidences to support the validity of the empirical properties. Our experimental results show that even with some limitations in the current prototype tool, the proposed approach accurately detects 82.3% of all the infeasible paths.

Next, we shall characterize four code patterns and the type of infeasible paths caused by each one of them. Our empirical study shows that infeasible paths detected in these code patterns constitute a very large proportion of infeasible paths.

Identical/Complement-Decision Pattern

We have discovered that, sometimes, actions to be performed under the same or completely different conditions could be implemented by separate independent selection constructs (if statements) with identical or complement condition. This is referred to as identical/complement-decision pattern.

Let p and q be two if-statements in a program. If p and q follow identical/complement-decision pattern then any path that contains branches of p and q with syntactically different branch predicates is infeasible.

Mutually-Exclusive-Decision Pattern

Empirically, we have discovered that a decision based on the same set of factors for one purpose is often implemented in a program using two approaches. One alternative for implementing this type of decision is

to use nested-if structure: the next condition will only be checked if the previous condition fails. The second alternative avoids the use of nested-if structure. It formulates a set of mutually exclusive conditions based on the set of factors for making the decision so that a separate selection construct for each condition with only one non-null branch is used to jointly implement the decision. This design pattern is referred to as mutually-exclusive-decision pattern.

Though from code optimization and infeasible path avoidance viewpoint, the first alternative is clearly better, from our empirical observation, the mutually-exclusive decision pattern (second alternative) is frequently used. We believe this could be due to the latter alternative provides a neater code structure.

Any path that contains more than one true branch of mutually-exclusive-decision conditions is infeasible. This is because of the uniqueness of decision which means at most one decision is made at one point in time.

Check-Then-Do Pattern

In many situations, a set of actions is only performed upon the successful checking of a set of conditions. The commonly used design method to implement the above-mentioned requirement is to separate the checking of conditions from the actions to be performed. The checking of conditions reports the outcome through setting a 'flag' variable. Actions are performed in a branch of a predicate node which tests the value of the 'flag' variable. This design pattern is referred to as check-then-do pattern. In this code pattern, any path that fails the checking of the condition and still goes trough the statement which executes the action is feasible. Likewise any path that passes the checking of the condition but does not go through the execution of the action is also infeasible.

Looping-by-Flag Pattern

Sometimes, programmers use a 'flag' variable to control the termination of a loop. Normally, the flag variable is initialized to a value which enables the execution of the loop. Inside the body of the loop, the flag variable will be set to another value if some conditions are satisfied. This value of the flag variable will lead to the termination of the loop. This coding pattern is often referred to as looping-by-flag pattern.

Assuming that p is a path that contains statements following looping-by-flag pattern. If p enters the statement which sets the flag variable to a value which lead to the termination of the loop and then re-enters the loop is infeasible.

Automated Extraction of Database Interactions

Database interactions are among the most essential functional features in web applications. Thus, for the maintenance and understanding of web applications, it is vital that the web engineer could identify all code segments which implement the database interactions features. Unfortunately, the highly dynamic nature of web applications makes it challenging to automatically extract all the possible database interactions from source code. Recent work on extracting functionalities from source code (De Lucia et al., 2007; Poshyvanyk et al., 2007; Robillard & Murphy, 2007; Shepherd et al., 2007) do not differentiate between different types of interactions. Moreover, to the best of our knowledge, no approach to extracting functionalities from source code is capable of dealing with the dynamic nature of web applications.

To overcome this problem, we propose an approach using symbolic execution and inference rules to extract all the possible database interactions automatically (Ngo, Tan & Trinh, 2006). These rules are basically empirical properties of the database interactions. The basic idea behind our approach is that we identify all the paths which could lead to a database interaction and symbolically execute the path by applying the proposed symbolic evaluation rules. We also develop Inference rules, which can be used to infer all the possible database interactions from symbolic expressions. Importantly, our contributions have several advantages, namely: it can extract all the possible interactions; it can distinguish between different types of interactions; it also generates the execution trace to a particular database interaction, which is useful for understanding and maintenance of web applications.

We have introduced Interaction Flow Graph (IFG) which facilitates the extraction of database interactions without having to consider other unrelated program statements. Our approach has four main steps. In the first step, all interaction paths are identified. In the second step, a slice of the interaction path is calculated which contains all the statements involving in the interactions.

In the third step, the set of symbolic rules are applied to symbolically execute each slice. In the last step, inference rules are used to infer all the possible interaction types from each symbolic expression derived in the third step.

The approach was examined via extensive experiments on four open-source web applications. We manually measured the precision of the approach and concluded that the approach precisely extracts all the possible database interactions. Our approach shows usefulness in the testing during system development and maintenance of web applications which involve extensive database interactions.

FUTURE TRENDS

The use of empirical results provide a simple yet efficient way to many software engineering tasks which rely on program analysis, especially program-mining. Experimental program analysis might be able to draw inferences about the properties of a software system in which traditional analyses have not succeeded.

Indeed, many characteristics of scientific experimentation have been utilized by program analysis techniques such as formalization, hypothesis testing or the use of sample cost-effectively explore effects to large population in generalizable manners. Take for example the use of empirical techniques in detecting infeasible paths that we have discussed in Section 3.2. We first routinely form hypotheses about patterns of infeasible program path. We then collect random sample from various application domains. From the results of hypothesis testing, we can either accept or reject the null hypotheses. From here, conclusions can be drawn or new hypothesis can be created. This process is repeated until we can conclude that our hypotheses hold for a high percentage (for e.g. 99 percent) of all the cases in the sample. The similar approach could be found in existing program analysis techniques such as features localization or design pattern recovery (De Lucia et al., 2007; Heuzeroth, Mandel, & Lowe, 2003; Poshyvanyk et al., 2007; Robillard & Murphy, 2007; Shepherd et al., 2007; Shi & Olsson, 2006; Zhang, Young, & Lasseter, 2004). These approaches are inherently experimental in nature.

Experimental program analysis is undoubtedly the future trends for many program analysis tasks. Ruthruff et al. (2006) have concluded on this future trend as follow: *"We believe that experimental program analysis provides numerous opportunities for program analysis and software engineering research. We believe that it offers distinct advantages over other forms of analysis at least for particular classes of analysis tasks, including procedures for systematically controlling sources of variation in order to experimentally analyze software systems, and experimental designs and sampling techniques that reduce the cost of generalizing targeted aspects of a program. We believe that such advantages will lead to significant advances in program analysis research and in the associated software engineering technologies that this research intends to improve."*

CONCLUSION

In this article, we have discussed the use of empirical property to facilitate program mining. We have summarized our major work in this area including an approach to recover and maintain the input error correction features provided by an information system; an approach to detect infeasible path through recognizing their most common patterns; and an approach to extract all the database interactions in a web applications through using empirical symbolic and inference rules.

All the approaches are based on empirical properties and program analysis techniques. However, there is a major theoretical difference between the proposed approach and other approaches that uses program analysis for program mining. The proposed approach is developed through the integration of invariant and empirical properties. All the empirical properties have been validated statistically with samples collected from a wide range of application domains.

Based on the empirical properties, our approach automatically recovers various types of information from source code. The novelty of our approach lies in the use of empirical properties, which provides a simple yet efficient approach to program mining. We believe that this is a promising future direction, which opens a new avenue for the automated reverse engineering.

KEY TERMS

After-Effect Input Error: An after-effect input error is a user input error which is only discovered after the execution of the program.

Control Flow Graph: A control flow graph contains a set of nodes and a set of edges in which, a node represents a program statement and an edge represents the transfer of control between statements.

Database Interaction: A node in the control flow graph of a program which executes, in an arbitrary run of the program, one of the SQL data manipulation language operations select, insert, update or delete is defined as an interaction node. A database interaction in a program *P* corresponds to an execution of an interaction node in the control flow graph of *P*.

Decomposition Slicing: A decomposition slice with respect to a variable *v* captures all the computation of *v* and is independent of program location.

Infeasible Path: An infeasible path is a program path for which there is not input such that the path can be executed.

Program-Mining: In software engineering, program-mining refers to reverse engineering which is a process of identifying software components, their inter-relationships and representing these entities at a higher level of abstraction.

Program Slicing: A slice S(v, n) (of program P) on variable v, or a set of variables, at statement n yields the portions of the program that contributed to the value v of just before statement n is executed.

Projected Clustering for Biological Data Analysis

INTRODUCTION

Clustering can be considered as the most important unsupervised learning problem. It has been discussed thoroughly by both statistics and database communities due to its numerous applications in problems such as classification, machine learning, and data mining. A summary of clustering techniques can be found in (Berkhin, 2002).

Most known clustering algorithms such as DBSCAN (Easter, Kriegel, Sander, & Xu, 1996) and CURE (Guha, Rastogi, & Shim, 1998) cluster data points based on full dimensions. When the dimensional space grows higher, the above algorithms lose their efficiency and accuracy because of the so-called "curse of dimensionality". It is shown in (Beyer, Goldstein, Ramakrishnan, & Shaft, 1999) that computing the distance based on full dimensions is not meaningful in high dimensional space since the distance of a point to its nearest neighbor approaches the distance to its farthest neighbor as dimensionality increases. Actually, natural clusters might exist in subspaces. Data points in different clusters may be correlated with respect to different subsets of dimensions. In order to solve this problem, feature selection (Kohavi & Sommerfield, 1995) and dimension reduction (Raymer, Punch, Goodman, Kuhn, & Jain, 2000) have been proposed to find the closely correlated dimensions for all the data and the clusters in such dimensions. Although both methods reduce the dimensionality of the space before clustering, the case where clusters may exist in different subspaces of full dimensions is not handled well.

Projected clustering has been proposed recently to effectively deal with high dimensionalities. Finding clusters and their relevant dimensions are the objectives of projected clustering algorithms. Instead of projecting the entire dataset on the same subspace, projected clustering focuses on finding specific projection for each cluster such that the similarity is reserved as much as possible.

BACKGROUND

Projected clustering algorithms generally fall into two categories: density-based algorithms (Agrawal, Gehrke, Gunopulos, & Raghavan, 1998; Procopiuc, Jones, Agarwal, & Murali, 2002; Liu & Mamoulis, 2005; Ng, Fu, & Wong, 2005; Moise, Sander, & Ester, 2006) and distance-based algorithms (Aggarwal, Procopiuc, Wolf, Yu, & Park, 1999; Aggarwal & Yu, 2000; Deng, Wu, Huang, & Zhang, 2006; Yip, Cheung, & Ng, 2003; Tang, Xiong, Zhong, & Wu, 2007). Density-based algorithms define a cluster as a region that has a higher density of data points than its surrounding regions. Dense regions only in their corresponding subspaces need to be considered in terms of projected clustering. Distance-based algorithms define a cluster as a partition such that the distance between objects within the same cluster is minimized and the distance between objects from different clusters is maximized. A distance measure is defined between data points. Compared to density-based methods in which each data point is assigned to all clusters with a different probability, distance-based methods assign data to a cluster with probability 0 or 1. Three criteria (Yip, Cheung, & Ng, 2003) have been proposed to evaluate clusters: the number of data points in a cluster, the number of selected dimensions in a cluster, and the distance between points at selected dimensions.

PROCLUS (Aggarwal, Procopiuc, Wolf, Yu, & Park, 1999) is a typical distance-based projected clustering algorithm which returns a partition of the data points, together with sets of dimensions on which data points in each cluster are correlated by using Manhattan segmental distance. However, this algorithm loses its effectiveness when points in different dimensions have different variance. We propose our algorithm, IPROCLUS (Improved PROCLUS) based on the following enhancements. We propose the modified Manhattan segmental distance which is more accurate and meaningful in projected clustering in that the closeness of points in different dimensions not only depends on the distance between them, but also relates to the distributions of points along those dimensions. Since PROCLUS strongly depends on two user parameters, we propose a dimension tuning process to reduce the dependence on one of the user parameters. We also propose a simplified replacing logic compared to PROCLUS.

MAIN FOCUS

Our algorithm, IPROCLUS, which allows the selection of different subsets of dimensions for different clusters, is based on PROCLUS. Our algorithm takes the number of clusters k and the average number of dimensions l in a cluster as inputs. It has three phases: an initialization phase, an iterative phase, and a cluster refinement phase. The medoid for a cluster is the nearest data point to the center of the cluster. The detail of our algorithm can be found in (Deng, Wu, Huang, & Zhang, 2006).

Modified Manhattan Segmental Distance

Manhattan segmental distance is defined as $(\sum_{i\in D}|p_{1,i}-p_{2,i}|)/|D|$ in PROCLUS. In our algorithm, we propose the modified Manhattan segmental distance as the distance measure to improve accuracy. We find that the closeness of points in different dimensions not only depends on the distance between them, but also depends on the distributions of points along different dimensions. Therefore we define a normalization factor n_i for each dimension, which is the standard deviation of all points in a dataset along dimension i. The modified Manhattan segmental distance between x_1 and x_2 relative to dimension set D can be defined as: $(\sum_{i\in D}|p_{1,i}-p_{2,i}|/n_i)/|D|$.

Initialization Phase

In the initialization phase, all data points are first chosen by random to form a random data sample set S with size A×k, where A is a constant. Then S is chosen by a greedy algorithm to obtain an even smaller set of points M with size B×k, where B is a small constant. The greedy algorithm (Gonzalez, 1985) is based on avoiding choosing the medoids from the same cluster. Therefore, the set of points which are most far apart are chosen.

Iterative Phase

We begin by choosing a random set of k points from M. Then the bad medoids (Aggarwal, Procopiuc, Wolf, Yu, & Park, 1999) in the current best medoids set are iteratively replaced with random points from M until the current best medoids set does not change after a certain number of replacements have been tried.

In each iteration, we first find dimensions for each medoid in the set, and form the cluster corresponding to each medoid. Then the clustering is evaluated and the bad medoids in the current best medoids set are replaced if the new clustering is better.

In order to find dimensions, several terms need to be defined first. For each medoid m_i, δ_i is the minimum distance from any other medoids to m_i based on full dimensions. The locality L_i is the set of points within the distance of δ_i from m_i. $X_{i,j}$ is the average distance to m_i along dimension j, which is calculated by dividing the average distance from the points in L_i to m_i along dimension j by the normalization factor n_j. There are two constraints when associating dimensions to medoids. The total number of dimensions associated to medoids must be equal to $k\times l$. The number of dimensions associated with each medoid must be at least 2. For each medoid i, we compute the mean $Y_i=\left(\sum_{j=1}^{d}X_{i,j}\right)/d$, and the standard deviation $\sigma_i=\sqrt{\sum_j\left(X_{i,j}-Y_i\right)^2/(d-1)}$ of the values $X_{i,j}$. Y_i represents the average modified Manhattan segmental distance of the points in L_i relative to the entire space. Thus $Z_{i,j}=\left(X_{i,j}-Y_i\right)/\sigma_i$ indicates how the average distance along dimension j associated with the medoid m_i is related to the average

modified Manhattan segmental distance associated with the same medoid. Dimensions for all clusters are decided by picking the smallest $Z_{i,j}$ values by a greedy algorithm (Ibaraki & Katoh, 1988) such that the above two constraints are met.

A single pass is done over the database to assign the points to the medoids. For each *i*, we compute the modified Manhattan segmental distance relative to D_i between a point and the medoid m_i, and assign the point to the closest medoid. The quality of a set of medoids is evaluated by the average modified Manhattan segmental distance from the points to the centroids of the clusters to which they belong.

We propose a simplified replacing logic compared to PROCLUS to decide whether to replace the bad medoids in the current best medoids set with new medoids. When replacing the bad medoids, δ_i for each medoid m_i is calculated first. We only recalculate the $X_{i,j}$ values for those medoids whose δ_i values change (store the $X_{i,j}$ value for current best objective case so that for those medoids whose δ_i values don't change, their $X_{i,j}$ values can be recovered from the stored values). Then we calculate Y_i, σ_i and $Z_{i,j}$. Dimensions are picked for all clusters by the $Z_{i,j}$ values. When we assign points to clusters, there are two cases. For the points previously in the dimensions whose δ values don't change, we only compare their modified Manhattan segmental distance from the current medoids with their modified Manhattan segmental distance from the medoids whose δ values change. For the points previously in the dimensions whose δ values change or in the bad medoid's cluster, we compare its distance to all the current medoids to decide which cluster it belongs to. Then the new clusters are evaluated to decide whether the objective value is better. The simplified logic for assigning points in the iterative phase is achieved by the IterativeAssignPoints function (Deng, Wu, Huang, & Zhang, 2006).

Refinement Phase

In the refinement phase, we redo the process in the iterative phase once by using the data points distributed by the result clusters at the end of the iterative phase, as opposed to the localities of the medoids. Once the new dimensions have been computed, the points are reassigned to the medoids relative to these new sets of dimensions. Outliers are also handled during the last pass over the data as in PROCLUS.

Users need to specify the average number of dimensions denoted as *l* in PROCLUS. Although it has achieved that different clusters have different subsets of dimensions, the number of dimensions for each cluster is still under the control of *l*. According to one of the three criteria discussed in the background section, we want the number of dimensions in a cluster to be as large as possible. Therefore, we propose one more step at the end of the refinement phase to reduce the dependence on *l*. In this step, for each cluster *i*, we choose the dimension with the smallest $Z_{i,j}$ value from the dimensions that are not chosen in previous steps and add it to the dimensional space. If the new cluster is better, we keep the newly added dimension and repeat this process to try to add more dimensions; otherwise, it will be discarded and we stop trying for this cluster. This process is achieved by the DimensionTuning algorithm (Deng, Wu, Huang, & Zhang, 2006). The quality of a cluster is evaluated by the remaining two criteria. A user-defined threshold is set for the number of points. Clusters that pass the threshold will be evaluated by the distance between points. All criteria have been considered in our algorithm, which gives a more balanced result.

Empirical Results and Analysis

The experimental evaluation was performed on a Dell Dimension 4600 Intel Pentium IV processor 2.4GHz with 1.00GB of memory, running Windows XP professional with service pack 2. The data was stored on a 7200RPM, 8MB cache, 80G hard drive. The flow chart of the experimental evaluation for a dataset is illustrated in Figure 1.

We test the performance of IPROCLUS and PROCLUS for synthetic data and real biological data. Synthetic data generation and the results of running PROCLUS and IPROCLUS on synthetic datasets can be found in (Deng, Wu, Huang, & Zhang, 2006). In a summary, our algorithm shows much higher accuracy and lower dependence on one user input than PROCLUS. In addition, two algorithms show comparable running time since the simplified replacing logic offsets the running time increase from the dimension tuning.

One challenge of applying clustering algorithms on gene expression data is the huge number of genes (dimensions) involved. Projected clustering algorithms are designed to deal with high dimensionalities. This leads us to test the projected clustering algorithms on

Figure 1. Flow chart of the experiment

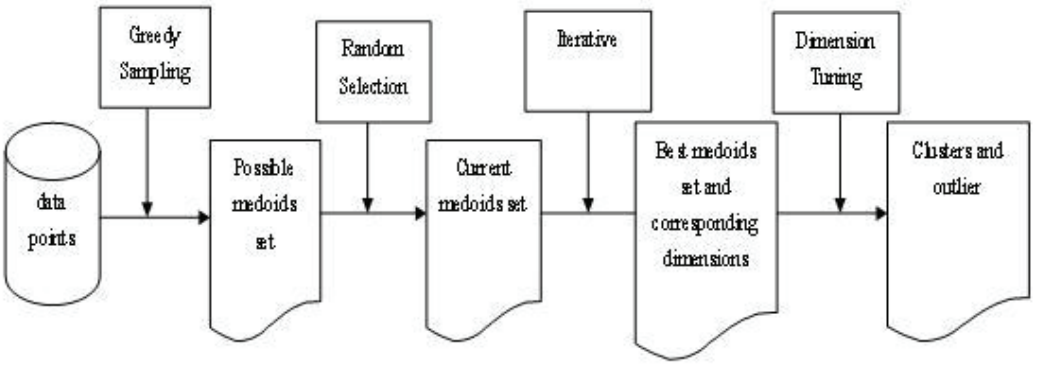

Figure 2. Confusion matrices on the colon tumor dataset

Input / Output	Normal	Tumor

(b) PROCLUS

biological datasets. We compared the performance of IPROCLUS and PROCLUS on the Colon Tumor dataset (Alon et al., 1999) and the Leukemia dataset (Golub et al., 1999). These two biological datasets are well documented and have been widely used in the bioinformatics research.

The Colon Tumor dataset consists of the expression values on 2000 genes of 40 tumor and 22 normal colon tissue samples. Since each cell is either a tumor or a normal cell, we removed the outlier logic in both PROCLUS and IPROCLUS algorithms. Figure 2 gives a typical result for the two algorithms. Confusion matrix is defined in the same way as in the PROCLUS paper. Entry (i, j) is equal to the number of data points assigned to output cluster i, which were generated as part of input cluster j. The result is obtained when k is set to 2 since there are only two clusters and l is set to 124, which is based on our experimental analysis. For the Colon Tumor dataset, IPROCLUS can correctly classify 52 out of the 62 tissues, achieving the accuracy of 83.9%, while PROCLUS can only achieve the accuracy of 53.2% (33 correctly classified). We can see that IPROCLUS can achieve much better accuracy on the Colon Tumor dataset than PROCLUS.

The same algorithms are applied to the Leukemia dataset. The Leukemia dataset consists of the expression values for 7129 genes of 47 acute lymphoblastic leukemia (ALL) samples and 25 acute myeloid leukemia (AML) samples. Figure 3 gives a typical result for the two algorithms. IPROCLUS achieves an excellent accuracy rate of 97.2% (70 out of 72 correctly classified). PROCLUS also achieves a higher accuracy rate compared with the Colon Tumor dataset case. However, its accuracy rate, 72.2% (52 out of 72), is still much lower than that of IPROCLUS.

FUTURE TRENDS

Projected clustering in high dimensional space is an interesting research topic and a number of algorithms have been proposed. Biological datasets are always in high dimensional space, which gives projected clustering algorithms a natural advantage in dealing with biological datasets. Several algorithms have been proposed to cluster gene expression data (Yu, Chung, Chan & Yuen, 2004; Bouguessa & Wang, 2007). We expect to see more work on applying projected clustering algorithms on biological datasets. In order to

(b) PROCLUS

make projected clustering algorithms practical, future research needs to remove the dependence on user-chosen parameters and capture biological significant information so that the resulting clusters are more meaningful for biologists. Another direction is called semi-supervised projected clustering (Yip, Cheung, & Ng, 2005; Tang, Xiong, Zhong, & Wu, 2007) which uses limited domain knowledge to aid unsupervised projected clustering process.

CONCLUSION

We have proposed an effective and efficient projected clustering algorithm, IPROCLUS, which is based on PROCLUS. We have significantly improved the accuracy by proposing the modified Manhattan segmental distance. We have reduced the dependence on user input *l* by adding the dimension tuning process at the end of the refinement phase and we have proposed a simplified replacing logic in the iterative phase to offset the running time increase caused by the dimension tuning process.

Empirical results have shown that IPROCLUS is able to accurately discover clusters embedded in lower dimensional subspaces. For the synthetic datasets, it can achieve much higher accuracy and lower dependence on *l* than PROCLUS. We have also applied our algorithm on two biological datasets: the Colon Tumor dataset and the Leukemia dataset. IPROCLUS still achieves much higher accuracy than PROCLUS.

KEY TERMS

Clustering: Given a set of data points, find groups of data points so that the points within each group are similar to one another and are dissimilar to the data points belonging to other groups..

Density-Based Clustering: The clustering that defines a cluster as a region that has a higher density of data points than its surrounding regions.

Dimension Reduction: A method concerned with removing the dimensions in the entire data set so that the least amount of information is lost.

Distance-Based Clustering: The clustering that defines a cluster as a partition such that the distance between objects within the same cluster is minimized and the distance between objects from different clusters is maximized.

Feature Selection: A technique to find the closely correlated dimensions for all the data and the clusters in such dimensions.

Medoid: The data point which is the nearest to the center of a cluster.

Projected Clustering: Given a set of data points, find clusters and their relevant dimensions from a dataset such that the similarity is reserved as much as possible.

INTRODUCTION

Clustering is considered the most important aspect of unsupervised learning in data mining. It deals with finding *structure* in a collection of unlabeled data. One simple way of defining clustering is as follows: the process of organizing data elements into groups, called clusters, whose members are similar to each other in some way. Several algorithms for clustering exist (Gan, Ma, & Wu, 2007); proximity-graph-based ones, which are untraditional from the point of view of statisticians, emanate from the field of computational geometry and are powerful and often elegant (Bhattacharya, Mukherjee, & Toussaint, 2005). A proximity graph is a graph formed from a collection of elements, or points, by connecting with an edge those pairs of points that satisfy a particular neighbor relationship with each other. One key aspect of proximity-graph-based clustering techniques is that they may allow for an easy and clear visualization of data clusters, given their geometric nature. Proximity graphs have been shown to improve typical instance-based learning algorithms such as the *k*-nearest neighbor classifiers in the typical nonparametric approach to classification (Bhattacharya, Mukherjee, & Toussaint, 2005). Furthermore, the most powerful and robust methods for clustering turn out to be those based on proximity graphs (Koren, North, & Volinsky, 2006). Many examples have been shown where proximity-graph-based methods perform very well when traditional methods fail miserably (Zahn, 1971; Choo, Jiamthapthaksin, Chen, Celepcikay, Giusti, & Eick, 2007)

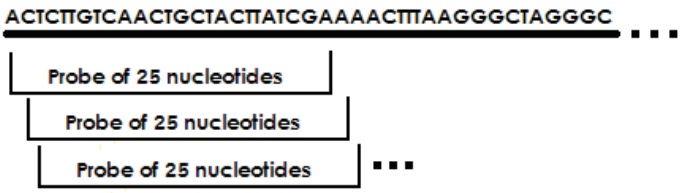
The most well-known proximity graphs are the nearest neighbor graph (*NNG*), the minimum spanning tree (*MST*), the relative neighborhood graph (*RNG*), the Urquhart graph (*UG*), the Gabriel graph (*GG*), and the Delaunay triangulation (*DT*) (Jaromczyk, & Toussaint, 1992). The specific order in which they are introduced is an inclusion order, i.e., the first graph is a subgraph of the second one, the second graph is a subgraph of the third and so on. The *NNG* is formed by joining each point by an edge to its nearest neighbor. The *MST* is formed by finding the minimum-length tree that connects all the points. The *RNG* was initially proposed as a tool for extracting the shape of a planar pattern (Jaromczyk, & Toussaint, 1992), and is formed by connecting an edge between all pairs of distinct points if and only if they are relative neighbors. Two points A and B are relative neighbors if for any other point C, the maximum of d(A, C), d(B, C) is greater than d(A, B), where d denotes the distance measure. A triangulation of a set of points is a planar graph

connecting all the points such that all of its faces, except for the outside face, are triangles. The *DT* is a special kind of triangulation where the triangles are as "fat" as possible, i.e., the circumcircle of any triangle does not contain any other point in its interior. The *UG* is obtained by removing the longest edge from each triangle in the *DT*. Finally, the *GG* is formed by connecting an edge between all pairs of distinct points if and only if they are Gabriel neighbors. Two points are Gabriel neighbors if the hyper-sphere that has them as a diameter is empty, i.e., if it does not contain any other point in its interior. Clustering using proximity graphs consists of first building a proximity graph from the data points. Then, edges that are deemed long are removed, according to a certain edge-cutting criterion. Clusters then correspond to the connected components of the resulting graph. One edge-cutting criterion that preserves Gestalt principles of perception was proposed in the context of *MST*s by C. T. Zahn (Zahn, 1971), and consists in breaking those edges *e* that are at least say, twice as long as the average length of the edges incident to the endpoints of *e*. It has been shown that using the *GG* for clustering, or as part of a clustering algorithm, yields the best performance, and is adaptive to the points, in the sense that no manual tweaking of any particular parameters is required when clustering point sets of different spatial distribution and size (Bhattacharya, Mukherjee, & Toussaint, 2005).

The applications of proximity-graph-based clustering, and of clustering in general, are numerous and varied. Possibilities include applications in the fields of marketing, for identifying groups of customers with similar behaviours; image processing, for identifying groups of pixels with similar colors or that form certain patterns; biology, for the classification of plants or animals given their features; and the World Wide Web, for classifying Web pages and finding groups of similar user access patterns (Dong, & Zhuang, 2004). In bioinformatics, scientists are interested in the problem of DNA microarray analysis (Schena, 2003), where clustering is useful as well. Microarrays are ordered sets of DNA fragments fixed to solid surfaces. Their analysis, using other complementary fragments called probes, allows the study of gene expression. Probes that bind to DNA fragments emit fluorescent light, with an intensity that is positively correlated, in some way, to the concentration of the probes. In this type of analysis, the calibration problem is of crucial importance. Using an experimental data set, in which both concentration and intensity are known for a number of different probes, one seeks to learn, in a supervised way, a simple relationship between intensity and concentration so that in future experiments, in which concentration is unknown, one can infer it from intensity. In an appropriate scale, it is reasonable to assume a linear relationship between intensity and concentration. However, some features of the probes can also be expected to have an effect on the calibration equation; this effect may well be non-linear. Arguably, one may reason that if there is a natural clustering of the probes, it would be desirable to fit a distinct calibration equation for each cluster, in the hope that this would be sufficient to take into account the impact of the probes on calibration. This hope justifies a systematic application of unsupervised learning techniques to features of the probes in order to discover, such a clustering, if it exists.

The main concern remains whether one is able to discover the absence or presence of any real clustering of the probes. Traditionally, clustering of microarray probes has been based on standard statistical approaches, which were used to validate an empirically found clustering structure; however, they were usually complex and depended on specific assumptions (Johnson, & Wichern, 2007). An alternative approach

Figure 1.Probes of 25 nucleotides to be clustered. Shown is a gene sequence and a probe window sliding by one nucleotide.



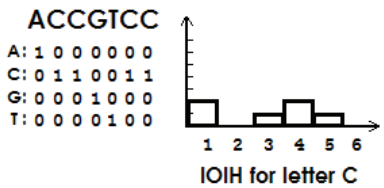
based on proximity graphs could be used, which has the advantage of being relatively simple and of providing a clear visualization of the data, from which one can directly determine whether or not the data support the existence of clusters.

BACKGROUND

A probe is a sequence of a fixed number of nucleotides, say 25 (Fig. 1), and it could simply be regarded as a string of 25 symbols from the alphabet {A, C, G, T}.

Probes are generated by sliding over, by one, a window of size 25 on the same nucleotide sequence. This procedure is not typical but particular to the Mei et. al dataset (Mei, Hubbell, Bekiranov, Mittmann, Christians, Shen, Lu, Fang, Liu, Ryder, Kaplan, Kulp, & Webster, 2003). In order to cluster the probes, one can either resort to classical clustering techniques, or to proximity-graph-based ones, or both. Moreover, for each of these sets of techniques, two approaches can be considered: the feature-based approach and the sequence-based approach. The first one builds the dataset from characteristics extracted from the probes, while the second one deals with the probe sequence directly. In the feature-based approach, classical probe features can be computed such as the frequency of different nucleotide types in the whole probe, and in either of its halves (Johnson, & Wichern, 2007). But current interdisciplinary work on the research theme reveals novel and creative probe-feature-extraction methods. One may, for instance, combine tools from computational music theory and bioinformatics, by considering features inspired from the rhythmic analysis proposed by Gouyon et. al. (Gouyon, Dixon, Pampalk, & Widmer, 2004) and extracting them from microarray probes. In this approach, for each probe, an inter-onset interval histogram (*IOIH*) (Toussaint, 2004; Toussaint, 2005) is built for each letter of the alphabet, and 8 features are computed for each histogram, namely the mean, the geometric mean, the total energy, the centroid, the flatness, the kurtosis, the high-frequency content, and the skewness (Gouyon, Dixon, Pampalk, & Widmer, 2004). The *IOIH* is a histogram that summarizes how many intervals there exist in a binary string of a fixed length, where 'interval' denotes the distance between two not necessarily successive set bits (or '1's). In the left-hand side of Fig. 2, four binary strings are first generated from the DNA sequence, one for each letter, by writing a '1' where that letter occurs and a '0' where it does not. Only the *IOIH* for letter C is shown, in the right-hand side of Fig. 2.

Figure 2. Example of inter-onset interval histogram. We see that there are two inter-onset intervals of length 1, one inter-onset interval of length 3, two inter-onset intervals of length 4, one inter-onset interval of length 5 and no inter-onset intervals of lengths 2, 6.



Then, 6 inter-histogram distances are computed using the Kolmogorov distance. Hence, in total, 32+6 = 38 features are extracted for each probe. Six classical distances are used for defining the dissimilarity of the points in the feature space. They are the standardized and unstandardized Manhattan distance, the standardized and unstandardized Euclidean distance, the Mahalanobis distance and the Mahalanobis-Manhattan distance (Johnson, & Wichern, 2007). The Manhattan distance is the distance between two points measured along axes at right angles. The Mahalanobis distance is effectively a weighted Euclidean distance where the weighting is determined by the sample correlation matrix of the point set.

The second approach is based entirely on the sequence of the symbols in the probe, and aims at producing a distance matrix that summarizes the distances between all pairs of probes, and which serves as input for a clustering algorithm. Sequence-based distances with normalization variations can be derived. These include the nearest neighbour distance, the edit distance (Levenshtein, 1966) and the directed swap distance (Colannino, & Toussaint, 2005). The nearest neighbor distance measures the dissimilarity of two binary strings via the concept of nearest set bit neighbor mapping. A first pass is done over the first string, say from left to right, and set bits are mapped to their closest set-bit neighbors in the second string, in terms of character count. The same kind of mapping is done in a second pass over the second string. The nearest neighbor distance is the accumulated distances

of each mapping link without counting double links twice. The edit distance is a metric that measures the dissimilarity of two strings by counting the minimum number of editing operations needed to transform one string into another. The editing operations typically considered are 'replace', 'insert' and 'delete'. A cost can be associated with each operation, hence penalizing the use of one operation over another. Finally, the directed swap distance measures the dissimilarity of two binary strings via the concept of an assignment. It is equal to the cost of the minimum-cost assignment between the set bits of the first string and the set bits of the second string, where cost is taken to be the minimum number of swaps between adjacent bits needed to displace a set bit in the first string to the position of a set bit in the second string, thereby making one assignment.

Classical clustering techniques include the k-medoids clustering using partitioning around medoids (*PAM*) (Handl, & Knowles, 2005), the hierarchical clustering using single linkage, and classical multidimensional scaling (*CMDS*). *PAM* is an algorithm that clusters around medoids. A medoid is the data point which is the most centrally located in a point set. The sum of the distances of this point to all other points in a point set is less than or equal to the sum of the distances of any other point to all other points in the point set. *PAM* finds the optimal solution. It tends to find 'round' or 'spherical' clusters, and hence is not very efficient when the clusters are in reality elongated, or in line patterns. Hierarchical clustering is a traditional clustering technique that clusters in an agglomerative approach. First, each point is assigned to its own cluster and then, iteratively, the two most similar clusters are joined, until there is only one cluster left. If the 'single linkage' version is used, it becomes equivalent to clustering with minimum spanning trees. Other options include 'complete linkage' and 'average linkage'. Finally, *CMDS* is an algorithm that takes as input a distance matrix and returns a set of points such that the Euclidean distances between them approximate the corresponding values in the distance matrix. This method, in the context of clustering, allows one to try different dimensions in which clustering can be performed. On the other hand, it is a technique to reduce the dimensionality of the data to one that can be easily visualized.

As to proximity-graph-based clustering techniques, they are: *ISOMAP* (Tenenbaum, de Silva, Langford, 2000), and clustering using Gabriel graphs with the Zahn edge-cutting criterion. *ISOMAP* is a proximity-graph based algorithm similar in its goal to *CMDS*, but with the flexibility of being able to learn a broad class of nonlinear manifolds. A manifold is an abstract space in which every point has a neighborhood which resembles the Euclidean space, but in which the global structure may be more complicated. The idea of dimension is important in manifolds. For instance, lines are one-dimensional, and planes two-dimensional. *ISOMAP* is computationally efficient and ensures global optimality and asymptotic convergence. It tries to conserve the geodesic distances between the points, and for that it constructs the *k*-nearest neighbor graph. This set of techniques can help to find and visualize the presence or absence of any real clustering in the data.

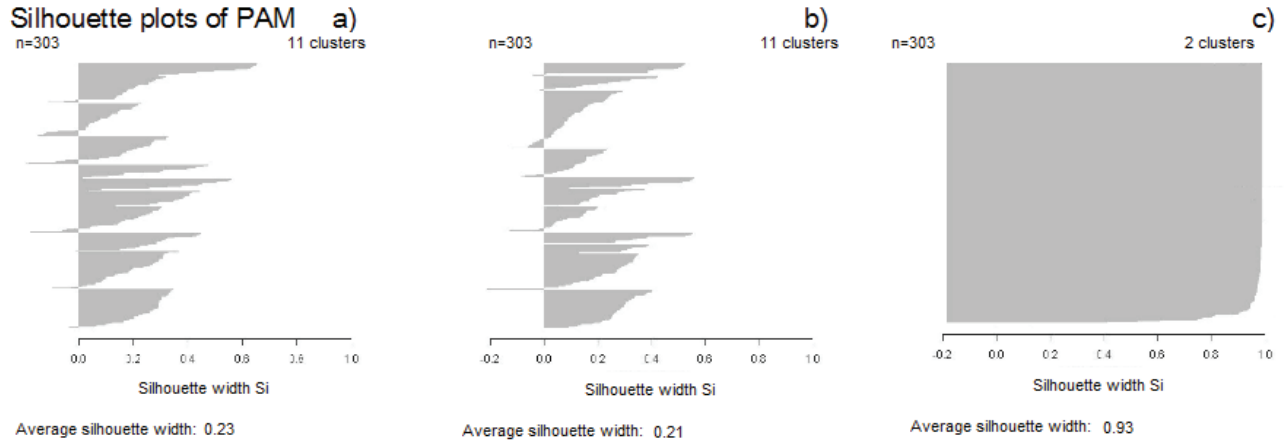
MAIN FOCUS

The rhythmic-analysis-based feature extraction applied to microarray probes, and the nearest neighbor distance for measuring probe dissimilarity are, in themselves, a novelty in the current research on microarray data mining. What is further emphasized here is the comparison between traditional clustering techniques and novel proximity-graph-based clustering techniques, the latter which give a simple and clear way of visualizing the clustering and, for our DNA microarray clustering example, it shows that the data lacks any real clustering.

Dataset

The dataset consists of a collection of genes, with sliding probes (Fig. 1) for each gene. The HTC (Human Test Chip) data set is used. This is a proprietary data set that Affymetrix used in its probe selection algorithm study (Mei, Hubbell, Bekiranov, Mittmann, Christians, Shen, Lu, Fang, Liu, Ryder, Kaplan, Kulp, & Webster, 2003) and was accessed through Simon Cawley and Teresa Webster (Affymetrix). A set of 84 transcripts (77 human and 7 bacterial) were used for probe selection analysis. Each human gene has approximately 500 probes made of 25 nucleotides each. Let us consider one representative gene from which 303 probes have been generated. The dataset is therefore the collection of the 303 probes.

Figure 3. PAM silhouettes using: a) Standardized Manhattan distance, b) Standardized Eucidean distance, c) Mahalanobis distance. A silhouette plot is a plot that displays a measure of how close each point in one cluster is to points in the neighboring clusters. No good clustering of the probes is found, as the average silhouette widths are either small (a and b), or they are high but with only 2 disproportionate clusters found (c).



Methods

PAM and hierarchical clustering using single linkage are used as a baseline to which proximity-graph-based clustering methods are compared.

Clustering of Microarray Probes using Classical Techniques

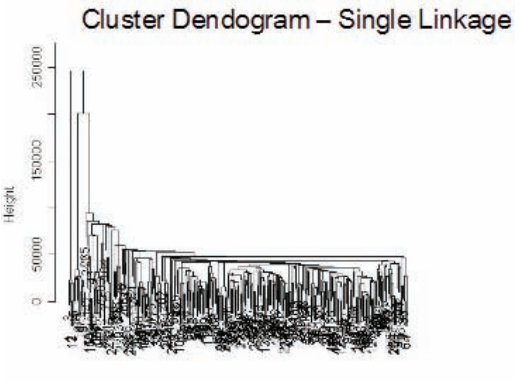
First, *PAM* is applied using the feature-based approach. No good clustering is obtained. Fig. 3 shows a silhouette plot for each of the three distance measures used. A silhouette plot is a plot that displays a measure of how close each point in one cluster is to points in the neighboring clusters. It takes into account both cohesion and separation. A detailed definition is given by (Choo, Jiamthapthaksin, Chen, Celepcikay, Giusti, & Eick, 2007). It is therefore an indicator of the 'goodness' of the clustering. The plots show that clusters do not look well defined; they hence give a first indication that there is no cluster structure in the data.

Next, hierarchical clustering with single linkage, using the feature-based approach, is applied. Fig. 4 shows one representative dendrogram. A dendrogram is a tree diagram used to illustrate the arrangement of the clusters produced by the hierarchical clustering algorithm. The leafs represent the data points, children of the same parent are points in the same cluster, and the edge lengths correspond to the distances between clusters. The dendrogram in Fig. 4 shows, again, that no clustering structure seems to be present in the data, this time with long clusters, just as with spherical ones.

Now, let us apply *PAM* again, but with the sequence-based approach. The total average silhouette width was chosen as an indicator of the 'goodness' of the clustering using *PAM*. With the non-normalized edit distance, a clustering with 61 clusters yielded the best average width. With the nearest neighbor distance, a clustering with 5 clusters yielded the best average width. In both cases, however, the corresponding silhouette plots showed no real clustering. The dendrograms output by the hierarchical clustering with single linkage algorithm also showed no clustering for both the edit distance and the nearest neighbor distance.

The last method we can apply in classical clustering is *CMDS*. As previously defined, *CMDS* can reduce the dimensionality of the data to one that can be visualized. However, clustering would have to be visually performed, which is often difficult and inaccurate. Fig. 5 shows the probe set in a three dimensional space after *CMDS* is applied.

Figure 4. Representative dendrogram for single-linkage clustering, using the unstandardized Manhattan distance. No underlying good clustering is apparent.



Clustering of Microarray Probes using Proximity Graphs

Now, proximity-graph-based clustering techniques are applied on the same dataset and using the same two approaches. In the feature-based approach, clustering using the Gabriel graph – Zahn's criterion gives rise to the plots in Fig. 6. The result, for each distance measure, consists of one very large cluster, containing most of the probes and one or more smaller clusters containing too few probes to be considered. Therefore, we can consider this as more evidence to the theory that no natural clustering structure is present in the data. This time, edges allow an easy visualization of the clustering.

For the sequence-based approach, the *ISOMAP* algorithm is first used to embed the distance matrix in the best Euclidean space, taking into account the possibility that the data set is in reality manifold-shaped. *ISOMAP* found the 3D space to be the best space in which to embed our probes. This makes it possible to plot the points in 3D and to apply clustering using the Gabriel graph – Zahn's criterion algorithm as shown next in Fig. 7. If a higher dimensional space was found by *ISOMAP*, clustering using Gabriel graphs would still be possible, and visualizing it would require additional projection methods. Again, no good clustering is found, as one cluster turns to have most of the points, and the others only few. This time, the absence of real clustering in the data is confirmed.

FUTURE TRENDS

Proximity graphs will continue to play a crucial role in applications such as the calibration problem in microarray analysis, as well as in other clustering applications, especially in those applications where clustering is a preprocessing step for a problem where the need to discover the presence or absence of any real clustering in the data, and where the visualization of the data points and clusters plays a determining role to this end. The current most efficient manifold-learning algorithms are based on nearest neighbor types of graphs. Further research on incorporating Gabriel graphs in manifold learning algorithms, such as *ISOMAP*, should be considered, since Gabriel graphs have consistently been proven to be powerful and helpful tools in designing unsupervised learning and supervised instance-based learning algorithms. Moreover, answers to open questions that arise when

Figure 5. Classical mutidimensional scaling with: a) Edit distance (non-normalized), b) Nearest neighbor distance. No clustering is noticeable.

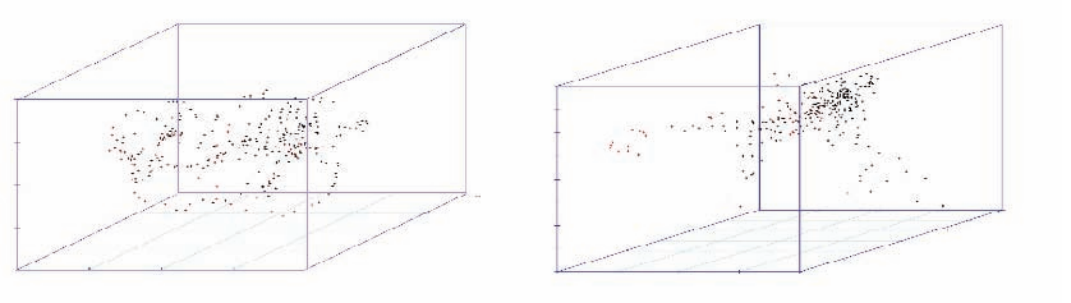


Figure 6.Gabriel graph with Zahn's edge cutting criterion: a) Standardized Manhattan distance, b) Standardized Euclidean distance, c) Mahalanobis distance. No real clustering of the probes is noticeable.

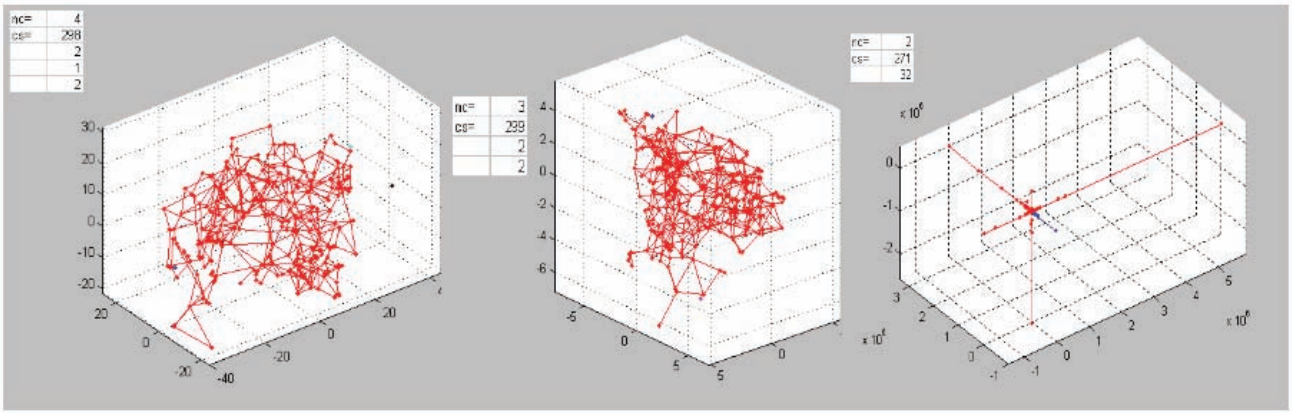

Figure 7. Gabriel Graph with Zahn edge cutting criterion: a) Edit distance, b) Nearest neighbor distance. No real clustering of the probes is noticeable.

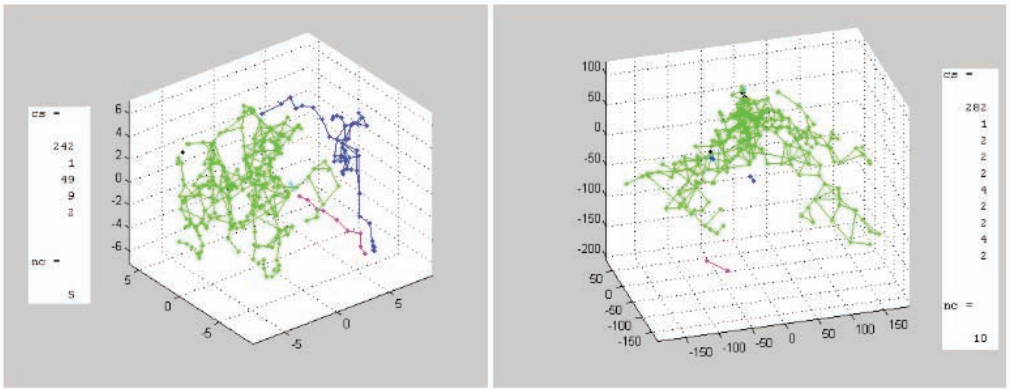

applying Gabriel-graph-based clustering on a fixed-size set of points as the dimension gets higher, will have to be investigated. In fact, in a situation like this, Gabriel graphs can have edges between all pairs of points (Chazelle, Edelsbrunner, Guibas, Hershberger, Seidel, & Sharir, 1990; Jaromczyk, & Toussaint, 1992); a situation that may also be viewed from the standpoint of supervised learning, when features of a dataset, which correspond to dimensions, are so numerous, that a comparatively smaller number of data points is not enough to learn them, essentially leading to what is termed the curse of dimensionality. Which subgraph of the Gabriel graph would give the best result in this case, or how sparse the graph should be, will then be interesting future research problems to be solved in this field.

CONCLUSION

Proximity-graph-based clustering can be a very helpful preprocessing tool for the calibration problem in microarray analysis. Both classical and proximity-graph-based clustering methods can be used to cluster microarray probes. However, classical methods do not provide a simple, elegant, and clear way of visualizing the clustering, if it exists. Furthermore, unlike some proximity-graph-based algorithms, they almost always

fail to detect any clusters of structurally complex higher level shapes, such as a manifold. Proximity-graph-based clustering methods can hence be efficient and powerful alternate or complementary tools for traditional unsupervised learning. These methods can also play a useful role in visualizing the absence (or presence) of any real clustering in the data that may have been found using classical clustering methods. Moreover, in this context, novel interdisciplinary probe-feature-extraction methods are being considered, and a sequence-based approach that defines novel distance measures between probes is currently under investigation.

KEY TERMS

Clustering: Data mining technique falling under the unsupervised learning category. It is the process of organizing data elements into groups, called clusters, whose members are similar in some way

Gabriel Graph (GG): A proximity graph formed by joining by an edge all Gabriel neighbors.

Gabriel Neighbors: Two points are Gabriel neighbors if the hyper-sphere that has them as diameter is empty, i.e., if it does not contain any other point.

Inter-Onset Interval Histogram (IOIH): A histogram that summarizes how many intervals there exist in a binary string of a fixed length, where 'interval' denotes the distance between two (not necessarily successive) set bits.

Microarray: An array of ordered sets of DNA fragments fixed to solid surfaces. Their analysis, using other complementary fragments called probes, allows the study of gene expression.

Nearest Neighbor: The point, in a point set, that has the minimum distance to a given point, with respect to a certain distance measure.

Nearest Neighbor Distance: A distance measure that measures the dissimilarity of two binary strings via the concept of nearest set bit neighbor mapping. A first pass is done over the first string, say from left to right, and set bits are mapped to their closest set-bit neighbors in the second string, in terms of character count. The same kind of mapping is done in a second pass over the second string. The nearest neighbor distance is the accumulated distances of each mapping link without counting twice double links.

Nucleotide: A subunit of DNA or RNA. Thousands of nucleotides are joined in a long chain to form a DNA or an RNA molecule,. One of the molecules that make up a nucleotide is a nitrogenous base (A, G, C, or T in DNA; A, G, C, or U in RNA); hence a nucleotide sequence is written as a string of characters from these alphabets.

Probe: A sequence of a fixed number of nucleotides used for the analysis of microarrays. It is designed to bind to specific DNA fragments in a microarray, and emit fluorescent light as an indicator of the binding strength.

Proximity Graph: A graph constructed from a set of geometric points by joining by an edge those points that satisfy a particular neighbor relationship with each other. The most well-known proximity graphs are the nearest neighbor graph (*NNG*), the minimum spanning tree (*MST*), the relative neighborhood graph (*RNG*), the Urquhart graph (*UG*), the Gabriel graph (*GG*), and the Delaunay triangulation (*DT*).

Pseudo-Independent Models and Decision Theoretic Knowledge Discovery

Yang Xiang
University of Guelph, Canada

INTRODUCTION

Graphical models such as Bayesian networks (BNs) (Pearl, 1988; Jensen & Nielsen, 2007) and decomposable Markov networks (DMNs) (Xiang, Wong., & Cercone, 1997) have been widely applied to probabilistic reasoning in intelligent systems. Knowledge representation using such models for a simple problem domain is illustrated in Figure 1: Virus can damage computer files and so can a power glitch. Power glitch also causes a VCR to reset. Links and lack of them convey dependency and independency relations among these variables and the strength of each link is quantified by a probability distribution. The networks are useful for inferring whether the computer has virus after checking files and VCR. This chapter considers how to discover them from data.

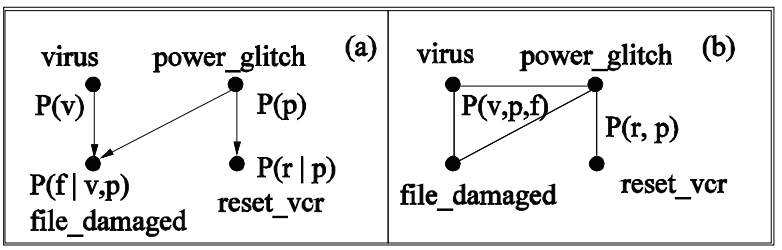
Discovery of graphical models (Neapolitan, 2004) by testing all alternatives is intractable. Hence, heuristic search are commonly applied (Cooper & Herskovits, 1992; Spirtes, Glymour, & Scheines, 1993; Lam & Bacchus, 1994; Heckerman, Geiger, & Chickering, 1995; Friedman, Geiger, & Goldszmidt, 1997; Xiang, Wong, & Cercone, 1997). All heuristics make simplifying assumptions about the unknown data-generating models. These assumptions preclude certain models to gain efficiency. Often assumptions and models they exclude are not explicitly stated. Users of such heuristics may suffer from such exclusion without even knowing. This chapter examines assumptions underlying common heuristics and their consequences to graphical model discovery. A decision theoretic strategy for choosing heuristics is introduced that can take into account a full range of consequences (including efficiency in discovery, efficiency in inference using the discovered model, and cost of inference with an incorrectly discovered model) and resolve the above issue.

BACKGROUND

A graphical model encodes probabilistic knowledge about a problem domain concisely (Pearl, 1988; Jensen & Nielsen, 2007). Figure 1 illustrates a BN in (a) and a DMN in (b). Each node corresponds to a binary variable. The graph encodes dependence assumptions among these variables, e.g., that *f* is directly dependent on *v* and *p*, but is independent of *r* once the value of *p* is observed. Each node in the BN is assigned a conditional probability distribution (CPD) conditioned on its parent nodes, e.g., $P(f \mid v, p)$ to quantify the uncertain dependency. The joint probability distribution (JPD) for the BN is uniquely defined by the product $P(v, p, f, r) = P(f \mid v, p)\, P(r \mid p)\, P(v)\, P(p)$. The DMN has two groups of nodes that are maximally pairwise connected, called *cliques*. Each is assigned a probability distribution, e.g., $\{v, p, f\}$ is assigned $P(v, p, f)$. The JPD for the DMN is $P(v, p, f)\, P(r, p) / P(p)$.

When discovering such models from data, it is important that the dependence and independence relations

Figure 1. (a) An example BN (b) A corresponding DMN



expressed by the graph approximate true relations of the unknown data-generating model. How accurately can a heuristics do so depends on its underlying assumptions.

To analyze assumptions underlying common heuristics, we introduce key concepts for describing dependence relations among domain variables in this section. Let V be a set of discrete variables $\{x_1, \dots, x_n\}$. Each x_i has a finite space $S_{xi} = \{x_{i,j} | 1 \le j \le D_i\}$. When there is no confusion, we write $x_{i,j}$ as x_{ij} . The space of a set $X \subseteq V$ of variables is the Cartesian product $S_X = \prod_{x_i \in X} S_i$. Each element in S_X is a configuration of X, denoted by $x = (x_1, \dots, x_n)$. A probability distribution $P(X)$ specifies the probability $P(x) = P(x_1, \dots, x_n)$ for each x . $P(V)$ is the *JPD* and $P(X)$ ($X \subset V$) is a *marginal distribution.* A probabilistic domain model (PDM) over V defines $P(X)$ for every $X \subseteq V$.

For disjoint subsets W, U and Z of V, W and U are *conditionally independent* given Z, if $P(w \mid u, z) = P(w \mid z)$ for all configurations such that $P(u, z) > 0$. The condition is also denoted $P(W \mid U, Z) = P(W \mid Z)$. It allows modeling of dependency within $W \bigcup U \bigcup Z$ through *overlapping* subsets $W \bigcup Z$ and $U \bigcup Z$.

W and U are *marginally independent* if $P(W \mid U) = P(W)$ holds whenever $P(U) > 0$. The condition allows dependency within $W \bigcup U$ to be modeled over *disjoint* subsets. If each variable x_i in a subset X is marginally independent of $X \setminus \{x_i\}$, then variables in X are *marginally independent*.

Variables in a subset X are *generally dependent* if $P(Y \mid X \setminus Y) \neq P(Y)$ for every $Y \subset X$. For instance, $X = \{x_1, x_2, x_3\}$ is *not* generally dependent if $P(x_1, x_2 | x_3) = P(x_1, x_2)$. It is generally dependent if $P(x_1, x_2 | x_3) \neq P(x_1, x_2)$, $P(x_2, x_3 | x_1) \neq P(x_2, x_3)$ and $P(x_3, x_1 | x_2) \neq P(x_3, x_1)$. Dependency within X cannot be modeled over disjoint subsets but may through overlapping subsets, due to conditional independence in X.

Variables in X are *collectively dependent* if, for each proper subset $Y \subset X$, there exists no proper subset $Z \subset X \setminus Y$ that satisfies $P(Y \mid X \setminus Y) = P(Y \mid Z)$. Collective dependence prevents modeling through overlapping subsets and is illustrated in the next section.

MAIN THRUST OF THE CHAPTER

Pseudo-Independent (PI) Models

A *pseudo-independent* (PI) model is a PDM where proper subsets of a set of collectively dependent variables display marginal independence (Xiang, Wong., & Cercone, 1997). Common heuristics often fail in learning a PI model (Xiang, Wong., & Cercone, 1996). Before analyzing how assumptions underlying common heuristics cause such failure, we introduce PI models below. PI models can be classified into three types: *full, partial, and embedded*. The basic PI model is a full PI model.

Definition 1. A PDM over a set V ($|V| \ge 3$) of variables is a *full PI model* if the following hold:

(S_I) Variables in each proper subset of V are marginally independent.

(S_{II}) Variables in V are collectively dependent.

Example 1 Patient of a chronicle disease changes the health state (denoted by variable s) daily between stable ($s = t$) and unstable ($s = u$). Patient suffers badly in an unstable day unless treated in the morning, at which time no indicator of the state is detectable. However, if treated at the onset of a stable day, the day is spoiled due to side effect. From historical data, patient's states in four consecutive days observe the estimated distribution in Table 1.

The state in each day is uniformly distributed, i.e., $P(s_i = t) = 0.5$ where $1 \le i \le 4$. The state of each day is marginally independent of that of the previous day, i.e., $P(s_i = t | s_{i-1}) = 0.5$ where $2 \le i \le 4$. It is marginally independent of that of the previous two days, i.e., $P(s_i = t | s_{i-1}, s_{i-2}) = 0.5$ where $3 \le i \le 4$. However, states of four days are collectively dependent, e.g., $P(s_4 = u | s_3 = u, s_2 = t, s_1 = t) = 1$, which allows the state of the last day to be predicted from states of previous three days. Hence, the patient's states form a full PI model.

By relaxing condition (S_I), full PI models are generalized into partial PI models defined through *marginally independent partition* (Xiang, Hu, Cercone, & Hamilton, 2000):

Table 1. Estimated distribution of patient health state

(s_1,s_2,s_3,s_4)	P(.)	(s_1,s_2,s_3,s_4)	P(.)
(t, t, t, t)	1/8	(u, t, t, t)	0
(t, t, t, u)	0	(u, t, t, u)	1/8
(t, t, u, t)	0	(u, t, u, t)	1/8
(t, t, u, u)	1/8	(u, t, u, u)	0
(t, u, t, t)	0	(u, u, t, t)	1/8
(t, u, t, u)	1/8	(u, u, t, u)	0
(t, u, u, t)	1/8	(u, u, u, t)	0
(t, u, u, u)	0	(u, u, u, u)	1/8

Definition 2. Let V ($|V| \geq 3$) be a set of variables, and $B = \{ B^1, \ldots, B^m \}$ ($m \geq 2$) be a partition of V. B is a *marginally independent partition* if, for every subset $X = \{x_i^k \mid x_i^k \in B^k, k = 1,\ldots,m\}$, variables in X are marginally independent. Each B^i is a *marginally independent block*.

A marginally independent partition groups variables into m blocks. If a subset X is formed by taking one element from each block, then variables in X are marginally independent. Partial PI models are defined by replacing marginally independent subsets with the marginally independent partition.

Definition 3. A PDM over a set V ($|V| \geq 3$) of variables is a *partial PI model* if the following hold:

(S_I') V can be partitioned into marginally independent blocks.

(S_{II}) Variables in V are collectively dependent.

Table 2 shows the JPD of a partial PI model over $V = \{x_1, x_2, x_3\}$ where x_1 and x_2 are ternary. The marginal probabilities are

$P(x_{1.0}) = 0.3$, $P(x_{1.1}) = 0.2$, $P(x_{1.2}) = 0.5$,
$P(x_{2.0}) = 0.3$, $P(x_{2.1}) = 0.4$, $P(x_{2.2}) = 0.3$,
$P(x_{3.0}) = 0.4$, $P(x_{3.1}) = 0.6$.

The marginally independent partition is $\{\{x_1\}, \{x_2, x_3\}\}$. Variable x_1 is marginally independent of each variable in the other block, e.g., $P(x_1, x_{2.0}) = P(x_{1.1})\,P(x_{2.0}) = 0.06$. However, variables in block $\{x_2, x_3\}$ are dependent, e.g., $P(x_{2.0}, x_{3.1}) = 0.1 \neq P(x_{2.0})\,P(x_{3.1}) = 0.18$. The three variables are collectively dependent, e.g., $P(x_{1.1} \mid x_{2.0}, x_{3.1}) = 0.1$ and $P(x_{1.1} \mid x_{2.0}) = P(x_{1.1} \mid x_{3.1}) = 0.2$.

A partial PI model may involve only a proper subset of V and remaining variables show normal dependency. The subset is an *embedded* PI submodel. A PDM can embed multiple submodels.

Definition 4. Let a PDM be over a set V of generally dependent variables. A proper subset $V' \subset V$ ($|V'| \geq 3$) of variables forms an *embedded* PI submodel if the following hold:

(S_{III}) V' forms a partial PI model.

(S_{IV}) The marginal independent partition $B = \{ B^1, \ldots, B^m \}$ of V' extends into V. That is, V partitions into $\{X^1,\ldots,X^m\}$ such that $B^i \subseteq X^i, (i = 1,\ldots,m)$ and, for each $x \in X_i$ and $y \in X_j$ $(i \neq j)$, x and y are marginally independent.

Table 3 shows the JPD of a PDM with an embedded PI submodel over x_1, x_2 and x_3. The marginal probabilities are $P(x_{1.0}) = 0.3$, $P(x_{2.0}) = 0.6$, $P(x_{3.0}) = 0.3$, $P(x_{4.0}) = 0.34$, $P(x_{5.0}) = 0.59$.

The marginally independent partition of the submodel is $\{B^1 = \{x_1\}, B^2 = \{x_2, x_3\}\}$.

Table 2. A partial PI model where v = (x_1, x_2, x_3)

v	P(.)	v	P(.)	v	P(.)	v	P(.)	v	P(.)	v	P(.)
(0,0,0)	0.05	(0,1,1)	0.11	(1,0,0)	0.05	(1,1,1)	0.08	(2,0,0)	0.10	(2,1,1)	0.11
(0,0,1)	0.04	(0,2,0)	0.06	(1,0,1)	0.01	(1,2,0)	0.03	(2,0,1)	0.05	(2,2,0)	0.01
(0,1,0)	0.01	(0,2,1)	0.03	(1,1,0)	0	(1,2,1)	0.03	(2,1,0)	0.09	(2,2,1)	0.14

Table 3. A PDM with an embedded PI submodel where v =$\{x_1, x_2, x_3, x_4, x_5\}$

v	P(.)	v	P(.)	v	P(.)	v	P(.)
(0,0,0,0,0)	0	(0,1,0,0,0)	.0018	(1,0,0,0,0)	.0080	(1,1,0,0,0)	.0004
(0,0,0,0,1)	0	(0,1,0,0,1)	.0162	(1,0,0,0,1)	.0720	(1,1,0,0,1)	.0036
(0,0,0,1,0)	0	(0,1,0,1,0)	.0072	(1,0,0,1,0)	.0120	(1,1,0,1,0)	.0006
(0,0,0,1,1)	0	(0,1,0,1,1)	.0648	(1,0,0,1,1)	.1080	(1,1,0,1,1)	.0054
(0,0,1,0,0)	.0288	(0,1,1,0,0)	.0048	(1,0,1,0,0)	.0704	(1,1,1,0,0)	.0864
(0,0,1,0,1)	.0072	(0,1,1,0,1)	.0012	(1,0,1,0,1)	.0176	(1,1,1,0,1)	.0216
(0,0,1,1,0)	.1152	(0,1,1,1,0)	.0192	(1,0,1,1,0)	.1056	(1,1,1,1,0)	.1296
(0,0,1,1,0)	.0288	(0,1,1,1,1)	.0048	(1,0,1,1,1)	.0264	(1,1,1,1,1)	.0324

Outside the submodel, B^1 extends to include x_4 and B^2 extends to include x_5. Each variable in one block is marginally independent of each variable in the other block, e.g.,

$P(x_{1,1}, x_{5,0}) = P(x_{1,1})\, P(x_{5,0}) = 0.413.$

Variables in the same block are pairwise dependent, e.g.,

$P(x_{2,1}, x_{3,0}) = 0.1 \neq P(x_{2,1})\, P(x_{3,0}) = 0.12.$

Variables in the submodel are collectively dependent, e.g.,

$P(x_{1,1} \mid x_{2,0}, x_{3,1}) = 0.55,\ P(x_{1,1} \mid x_{2,0}) = P(x_{1,1} \mid x_{3,1}) = 0.7.$

However, x_5 is independent of other variables given x_3, displaying conditional independence, e.g.,

$P(x_{5,1} \mid x_{2,0}, x_{3,0}, x_{4,0}) = P(x_{5,1} \mid x_{3,0}) = 0.9.$

PDMs with embedded PI submodels are the most general PI models.

Heuristics for Model Discovery

Given a data set over *n* variables, the number of possible network structures is super-exponential (Cooper & Herskovits, 1992). To make discovery tractable, a number of heuristics are commonly applied. The most common is the *Naive Bayes* heuristic (Zhang, 2004). It restricts potential models to Naive Bayes models whose graph consists of a single root (the *hypothesis*) and its observable child nodes (the *attributes*). Since the hypothesis is given, discovery focuses on finding the CPD at each node and is very efficient.

Another heuristic is the *TAN* heuristic, that restricts potential models to *tree augmented Naive Bayes* models (Friedman, Geiger, & Goldszmidt, 1997). Its graph also has a single root (the hypothesis). However, attributes themselves form a tree (see Figure 2). Each attribute has the hypothesis and at most one other attribute as its parent nodes.

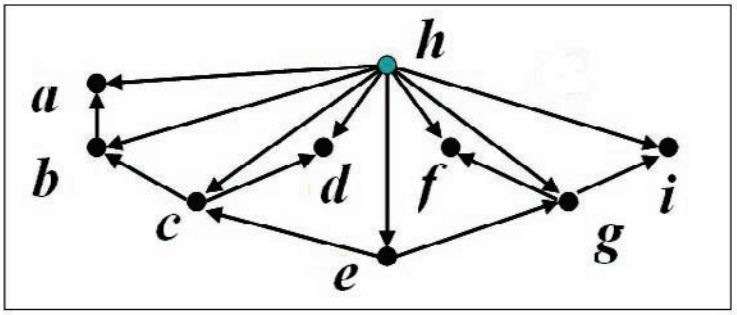
The above heuristics limit the model space. Heuristics below limit the search procedure. One common heuristic is the *single-link lookahead* (Cooper & Herskovits, 1992; Heckerman, Geiger & Chickering, 1995; Lam & Bacchus, 1994). Learning starts with an initial graph. Successive graphical structures, representing different sets of independence assumptions, are adopted. Each adopted structure differs from its predecessor by a single link and improves a score metric optimally.

An alternative is the *bounded multi-link lookahead* (Hu & Xiang, 1997) where an adopted structure differs from its predecessor by up to $k > 1$ links. The algorithm applies single-link lookahead and low-order (small *k*) multi-link lookahead as much as possible, and uses high-order (large *k*) multi-link lookahead only when necessary.

Underlying Assumptions and their Implications

Knowledge discovery starts with a dataset generated by an unknown PDM *M*. The goal is to uncover a graphical model that approximates *M*. The best outcome is often known as the *minimal I-map* (Pearl, 1988). It is a graph *G* whose nodes correspond to variables in

Figure 2. Graph structure of a TAN model where h is the hypothesis



M and whose links are as fewer as possible such that graphical separation among nodes in *G* implies conditional independence in *M*. The assumption underlying a heuristic determines its ability to discover minimal I-maps for various PDMs. The following are assumptions underlying Naïve Bayes and TAN.

Proposition 1. In a Naïve Bayes model, every two attributes are conditionally independent given the hypothesis.

Proposition 2. In a TAN model, every two non-adjacent attributes are conditionally independent given the parent of one of them and the hypothesis.

The general assumption underlying the single-link lookahead is unclear. Known results are based on particular algorithms using the heuristic and are centered around *faithfulness*. A PDM *M* is *faithful* if there exists some graph *G* such that conditional independence among variables in *M* implies graphical separation among corresponding nodes in *G*, and vice versa. Spirtes, Glymour and Scheines (1993) present a sufficient condition: If *M* is faithful, the algorithm in question can discover a minimal I-map of *M*. Xiang, Wong and Cercone (1996) present a necessary condition: If *M* is unfaithful, the output of the algorithm in question will not be an I-map. Hence, faithfulness will be regarded as the primary assumption underlying the single-link lookahead heuristic.

The bounded multi-link lookahead heuristic does not make any of the above assumptions and is the most general among heuristics mentioned above. Implications of these assumptions to discovery of PI models are summarized below (Xiang, 2007).

Theorem 1. Let Λ be the set of all Naive Bayes models and Λ' be the set of all PI models over *V*. Then $\Lambda \cap \Lambda' = \varnothing$.

Theorem 2. Let Λ be the set of all TAN models over *V*. Let Λ' be the set of all PI models over *V* such that each PI model in Λ' contains at least one embedded PI submodel over 4 or more variables. Then $\Lambda \cap \Lambda' = \varnothing$.

Theorem 3. A PI model is unfaithful.

Theorems 1 and 3 say that Naive Bayes and single-link lookahead heuristics cannot discover a minimal I-map if the unknown PDM is PI. Theorem 2 says that if the unknown PDM is beyond the simplest PI model (with exactly 3 variables), then the TAN heuristic cannot discover a minimal I-map.

Suppose that these three heuristics (coupled with known algorithms) are applied to the data in Example 1 in order to find the best strategy for patient treatment. They will be mislead by the marginal independence and return an empty graph (four nodes without links). This is equivalent to say that there is no way that the patient can be helped (either untreated and possibly suffering from the disease, or treated and possibly suffering from the side effect).

On the other hand, if a bounded 6-link lookahead heuristic is applied, the correct minimal I-map will be returned. This is due to the ability of multi-link lookahead to identify collective dependence. Although in this small example, the minimal I-map is a complete graph, the bounded 6-link lookahead can still discover a minimal I-map when the PI model is embedded in a much large PDM. From this discovered model, a targeted treatment strategy can be developed by predict-

ing the patient's state from states of the last three days. Discovery of a PI model from social survey data and experimental result on its performance can be found in (Xiang, Hu, Cercone, & Hamilton, 2000).

FUTURE TRENDS

Decision Theoretic Strategy

Heuristics such as Naïve Bayes, TAN and single-link lookahead are attractive to data mining practitioners due to mostly two reasons: First, they are more efficient. Second, PDMs that violate their underlying assumptions are less likely. For instance, unfaithful PDMs are considered much less likely than faithful ones (Spirtes, Glymour and Scheines, 1993). Although efficiency in discovery and prior probability of potential model are important factors, an additional factor, the cost of suboptimal decision (such as that according to the discovered empty graph for Example 1) has not been paid sufficient attention. A decision theoretic strategy (Xiang, 2007) that integrates all these factors is outlined below, where faithfulness is used as an example assumption.

Let A and A' be alternative discovery algorithms, where A assumes faithfulness and A' does not. Costs of discovery computation are $C_{disc}(A) = d$ and $C_{disc}(A') = d'$, where $d < d'$. The unknown PDM M has a small probability ε to be unfaithful. Choosing A, if M is faithful, the discovered model supports optimal actions. If M is unfaithful, the discovered model causes suboptimal actions. Choosing A', no matter M is faithful or not, the discovered model supports optimal actions. Let the action cost of a correct model (a minimal I-map) be $C_{opt} = 0$ and that of an incorrect model be $C_{sub} = \omega > 0$. The expected cost of choosing A is

$$C_{disc}(A) + (1-\varepsilon) C_{opt} + \varepsilon C_{sub} = d + \varepsilon \omega$$

and that of choosing A' is $C_{disc}(A') + C_{opt} = d'$. According to decision theory, A' is a better choice if and only if

$$\omega > (d' - d)/\varepsilon .$$

In other words, for mission critical applications, where the above inequation often holds, the less efficient but more open-minded algorithm A' should be preferred.

CONCLUSION

Heuristics must be used to render discovery of graphical models computationally tractable. They gain efficiency through underlying assumptions. Naive Bayes makes the strongest assumption, followed by TAN, followed by single-link lookahead, followed by bounded multi-link lookahead, while their complexities are reversely ordered. These assumptions are not subject to verification in the discovery process. The stronger the assumption made, the more likely that the discovered model is not the minimal I-map and, as a result, the model does not support the optimal decision. A decision-theoretic strategy chooses heuristic based on discovery efficiency, likelihood of discovering an incorrect model, as well as consequence in applying an incorrectly discovered model in decision making. For mission critical applications, a more open-minded heuristic should be preferred even though the computational cost of discovery may be higher.

KEY TERMS

Bounded Multi-Link Lookahead Heuristic: It differs from the single-link lookahead in that each adopted graph is selected from candidates that differ from its successor by up to $k>1$ links. It requires higher but bounded computational cost, makes the weakest assumption, and can discover PDMs that are not discoverable by the single-link lookahead such as PI models.

Embedded PI Submodel: An embedded PI submodel is a full or partial PI model over a proper subset of domain variables. The most general PI models are those that embed PI submodels in large problem domains.

Full PI Model: A full PI model is a PDM where every proper subset of variables is marginally independent but the entire set is collectively dependent. They are the most basic PI models.

Naïve Bayes Heuristic: It assumes that the model graph consists of a single root (the *hypothesis*) and its observable child nodes (the *attributes*). It makes the strongest independence assumption and is the most efficient.

Partial PI Model: A partial PI model is otherwise the same as a full PI model except that some subsets of variables may not be marginally independent. A full PI model is also a partial PI model. Hence, partial PI models are more general.

Single-Link Lookahead Heuristic: The discovery process using this heuristic consists of a sequence of adopted graphs such that each is selected from candidates that differ from its successor by exactly one link. Models discoverable with this heuristic are usually faithful PDMs.

TAN Heuristic: It assumes the same as Naïve Bayes plus that each attribute may have at most one other attribute as the additional parent.

Quality of Association Rules by Chi-Squared Test

INTRODUCTION

Mining market basket data (Agrawal et al. 1993, Agrawal et al. 1994) has received a great deal of attention in the recent past, partly due to its utility and partly due to the research challenges it presents. Market basket data typically consists of store items purchased on a per-transaction basis, but it may also consist of items bought by a customer over a period of time. The goal is to discover buying patterns, such as two or more items that are often bought together. Such finding could aid in marketing promotions and customer relationship management. Association rules reflect a fundamental class of patterns that exist in the data. Consequently, mining association rules in market basket data has become one of the most important problems in data mining.

Agrawal et al. (Agrawal, et al. 1993, Agrawal et al. 1994) have provided the initial foundation for this research problem. Since then, there has been considerable amount of work (Bayardo et al. 1999, Bayardo et al. 1999, Brin et al. 1997, Han et al. 2000, Park et al. 1995, Srikant et al. 1995, Srikant et al. 1997, Zaki et al. 1997, etc.) in developing faster algorithms to find association rules. While these algorithms may be different in their efficiency, they all use minsup (minimum support) and minconf (minimum confidence) as the criteria to determine the validity of the rules due to their simplicity and natural appeals. Few researchers (Brin et al. 1997, Aumann et al. 1999, Elder, 1999, Tan et al. 2002) have suspected the sufficiency of these criteria. On the other hand, Chi-squared test has been used widely in statistics related fields for independence test. In this research, we shall examine the rules derived based on the support-confidence framework (Agrawal et al. 1993, Agrawal et al. 1994) statistically by conducting Chi-squared tests. Our experimental results show that a surprising 30% of the rules fulfilling the minsup and minconf criteria are indeed insignificant statistically.

BACKGROUND

The task of mining association rules is first to find all itemsets that are above a given minimum support ratio (minsup). Such itemsets are called large or frequent itemsets. Then, association rules are derived based on these frequent itemsets. For example, both {A, B, C, D} and {A, B} are frequent itemsets. The association rule, AB=>CD, is derived if at least c% of the transactions that contain AB also contain CD, where c% is a pre-specified constant called minimum confidence (minconf).

Support-Confidence Framework

We use the example in (Brin et al. 1997) to illustrate the support-confidence framework (Agrawal, et al. 1993, Agrawal et al. 1994). Suppose there are totally 100 transactions. 25 transactions buy tea and among them, 20 transactions also buy coffee. Based on the support-confidence framework, the rule 'tea=> coffee' has a support of 20% (20 / 100) and a confidence of 80% (20 / 25). Suppose minsup =5% and minconf =60%. Then, the rule is validated by the framework.

Chi-Squared Test for Independence

Chi-squared (χ^2) test is a non-parametric statistical method that can be used to test independence among attributes. Compared to the support-confidence framework, it uses more information, such as the numbers of transactions that buy tea but not coffee, buy coffee but not tea, and buy neither coffee nor tea, to determine the independence of attributes.

Table 1. 2 by 2 contingency table

	coffee	no_coffee	∑ row rorow
tea	20	5	25
no_tea	70	5	75
∑ col	90	10	100

In Table 1, we show a 2 by 2 contingency table (Glass, 1984, Gokhale, 1978), which contains more information for the independence test. The chi-square test result indicates that tea and coffee are independent variables since $\chi^2 = 3.703703$ (with degree of freedom = 1) is non-significant at 95% confidence level. In other words, tea is not a determining factor whether people will buy coffee or not, contradicting the rule derived by the support-confidence framework.

Chi-squared test is reliable under a fairly permissive set of assumptions. As a rule of thumb, Chi-squared test is recommend (Glass, 1984, Mason, et al. 1998) only if (1) all cells in the contingency table have expected value greater than 1, and (2) at least 80% of the cells in the contingency table have expected value greater than 5. For the large tables (more than four cells), the usual alternative is to combine or collapse cells (Glass, 1984, Han, et al. 2000, Mason, et al. 1998) when the cells have low values. The potential advantages of the χ^2 statistics (Brin, et al. 1997) over the commonly used support-confidence framework are:

1. The use of the Chi-squared significance test for independence is more solidly grounded in statistical theory. In particular, there is no need to choose ad-hoc values for support and confidence.
2. The Chi-squared statistic simultaneously and uniformly takes into account all possible combinations of the presence and absence of the various attributes being examined as a group.
3. Chi-squared test at a given significance level is upward closed. In other words, if an i-itemset is correlated, all its supersets are also correlated.

MAIN FOCUS

Experimental Design

Four synthetic data sets are generated using the IBM/ Quest data generator (Bayardo et al. 1999), which has been widely used for evaluating association rule mining algorithms. The data sets generated are then fed into CBA/DBII data mining system (Liu et al. 1999) to generate association rules. Finally, Chi-squares tests are conducted on the association rules generated.

The synthetic transactions are to mimic the transactions generated in the retailing environment. A realistic model will address the observation that people tend to buy a number of items together. Thus, transaction sizes are typically clustered around a mean and a few transactions have many items.

In order to model the phenomenon that frequent itemsets often have common items, some fraction of items in subsequent itemsets are chosen from the previous itemset generated. It uses an exponentially distributed random variable (Bayardo et al. 1999) with the mean equal to a given correlation level to decide this fraction for each itemset. The remaining items are picked at random. In this study, the correlation level was set to 0.25. Bayardo et al. (Bayardo et al. 1999) ran some experiments with correlation levels set to 0.5 and 0.75 but did not find much difference in the results.

Each itemset in the database has a weight associated with it, which corresponds to the probability that this itemset will be picked. This weight is picked from an exponential distribution with unit mean, and is then normalized so that the sum of the weights for all the itemsets is 1.

Four synthetic datasets were generated with slightly different parameters, such as the number of transactions, number of items, and average confidence for rules (see Table 2). The other common factors are 'average transaction length (5),' 'number of patterns (100),' 'average length of pattern (4),' and 'correlation between consecutive patterns (0.25).'

Once the data sets are generated, CBA system (Liu et al. 1999, Liu et al. 1999) is used to generate association rules that satisfy the given minsup and minconf.

Table 2. Four datasets

Data Set	Num of Transactions	Num of Items	Avg. Conf. Level
1	2217	20	0.5
2	5188	20	0.5
3	5029	40	0.5
4	5096	40	0.75

Experimental Results

Effects of Minsup and Minconf

The value of minsup controlls the number of frequent itemsets generated. Table 3 shows the reduction of the numbers of frequent itemsets in relation to the increase in the minsup value. For example, for dataset 1, the number of frequent itemsets drops from 3401 to 408 when minsup increases from 1% to 5%. In addition, the size of the dataset could also affect the selection of minsup significantly. The larger the data size, the larger the variety of items, and thus the smaller the support for each itemset. For example, the datasets with over 5,000 transactions, i.e., datasets 2, 3, and 4, generated much smaller numbers of frequent itemsets than dataset 1 with 2,217 transactions (see Table 3) as there is a larger variety of items in the transactions.

The relationship among minsup, minconf, and the number of association rules generated is shown in Table 4 for each dataset. The confidence level affects the number of association rules generated. The higher the level of minconf, the less the numbers of frequent itemsets and association rules sustain. When the data size is large, the lower minsup was preferred as there are too many different items. If the minsup is set too high, combined with high minconfs, such as 75% or 90%, it can often generate zero association rule in the

Table 3. Numbers of frequent itemsets at various minsup levels

Dataset / Minsup	1%	2%	5%	10%	15%	20%
1	3401	1488	408	131	65	36
2	1836	808	246	84	37	24
3	1513	521	118	40	17	11
4	1600	531	118	40	17	11

Table 4. The relationship among minsup, minconf, and the number of the association rules

Dataset	Minsup	1%			2%			5%			10%		
	minconf	50%	75%	90%	50%	75%	90%	50%	75%	90%	50%	75%	90%
1	#Rules	3169	1261	89	1365	353	2	358	38	0	112	3	0
2	#Rules	1487	217	9	626	43	0	176	5	0	57	0	0
3	#Rules	576	247	30	130	16	1	21	0	0	6	0	0
4	#Rules	677	204	64	150	18	3	24	0	0	8	0	0

experiments. For example, for the dataset with 5,188 transactions, i.e., dataset 2 in Table 4, at minsup=1% and minconf=50%, it generated 1487 rules; but when the minsup becomes 2% and minconf=75%, it generated only 43 rules.

Chi-Square Tests for Independence Results

The results of Chi-squared tests constituted the major findings of this study. Note that all Chi-squared tests conducted in this study adopt the commonly used significance level, $p \leq 0.05$, as a cutoff point. The critical value is 3.841 for 1 degree of freedom.

In the following, we use the dataset with 2,217 transactions as an example. Each transaction had three attributes: Transaction number, Customer ID, and Item. There are 20 different items in the transactions.

The first experiment was conducted at minsup=10% and minconf=50%. CBA produced 112 association rules as shown in Table 4. The 112 rules were then tallied into 2 by 2 contingency tables and tested by the Chi-squared for independence. The results showed that 37 out of 112 rules were not significant. In other words, in 37 rules, there is no relationship between the antecedent and the consequent.

With the same dataset, the minsup was reduced to 5% and the minconf kept at the same level of 50%, that is, the restriction was loosened, CBA program produced 385 association rules as shown in Table 4. Out of these 385 rules, 134 rules were not significant. The previous 37 rules were part of these 134 rules. It again showed that no relationship between antecedent and consequent in one third of the association rules. The results demonstrated a striking discrepancy between the results generated by the support-confidence framework and those by the Chi-squared tests.

Chi-squared Test vs. Support-Confidence

We present more detailed comparisons between the results of the support-confidence framework and Chi-squared tests. In the Tables 5, the cell values are the number of transactions. L and R are the itemsets on the left- and right-hand sides of the rule, respectively; NO-L and NO-R are itemsets that do not have any items in L and R, respectively; T_ROW and T_COL are the total numbers of transactions on each row and column, respectively; SUP_L and SUP_R are the supports for the itemsets on the left- and right-hand sides of the rule; CONF is confidence.

With minsup=50% and minconf=1%, Rules 175 and 169 are validated by the support-confidence framework with the same confidence of 60% and support of 5.01% as shown in Tables 5 and 6. However, the Chi-squared tests give different results for these two rules. That is, there is no relationship between L and R in rule 175, but there exists a relation in rule 169. For rule 175, the χ^2 test result was not significant ($p > 0.05$), indicating that 'buying apple and ketchup' is independent from 'buying pamper". For rule 169, the χ^2 result was significant ($p < 0.05$), which indicated that there is a relationship between 'buying an oven' and 'buying apple and ketchup'.

Example 1: Uni-Directional vs. Bi-Directional

The association rule in minsup/minconf is uni-directional. A rule X -> Y does not necessarily imply the rule Y -> X. In addition, it cannot detect negative implication, such as buying product X and not buying product Y. However, the Chi-squared statistic simultaneously and

Table 5. Non-significant relationship

Rule 169: AP/KP -> OV					
	R	NO_R	T_ROW	SUP_L	CONF
L	111	74	185	8.34%	60.00%
NO_L	1037	995	2032		
T_COL	1148	1069	2217		
SUP_R	51.78%			5.01%	
$p \leq 0.019456897$					

Table 6. Significant relationship

Rule 175: AP/KP ->PA					
	R	NO_R	T_ROW	SUP_L	CONF
L	111	74	185	8.34%	60.00%
NO_L	1134	898	2032		
T_COL	1245	972	2217		
SUP_R	56.16%			5.01%	
$p \leq 0.271182286$					

uniformly takes into account all possible combinations of the presence and absence of the various attributes being examined as a group. We shall illustrate these in the following examples.

Example 2

At minconf =50%, Rule 1 is accepted as an association rule while Rule 2 is pruned off because of its low confidence (24.32%). However, the χ^2 test shows both P values were less than 0.05, which it implies that T and S are correlated and S->T should have also be accepted as a rule.

Chi-square test can be used to detect negative implication, illustrated by the following example.

Example 3

As shown in Table 8, the χ^2 values for both L -> R and L -> (NO_R) are the same. Since $p > 0.05$, it indicated that L and R were two independent attributes. However, at minconf =50%, Rule 3 was accepted as an association rule while Rule 4 was pruned off because of low confidence (47.27%).

FUTURE TRENDS

While the support-confidence framework lays the foundation of modern market basket data mining, it has some obvious weakness. We believe incorporating statistical methods into this framework would make it more robust and reliable.

CONCLUSION

This empirical study aimed at evaluating the validity of association rules derived based on the minsup and minconf criteria. The results of this study strongly suggest that minsup and minconf do not provide adequate discovery of useful associations. The results of Chi-squared tests showed

1. Minsup and minconf can significantly cut down the number of rules generated but does not necessarily cut off those insignificant rules.
2. Approximately, one-third of association rules, discovered at minconf = 50% and minsup= 5% or 10%, failed to prove that there is relationship

Table 7. Chi-square Test on bi-directional relationship

Rule 1: T -> S					
	S	NO_S	T_ROW	SUP_L	CONF

(b) Rule 4: L -> NO_R

between the antecedent and the consequent in Chi-squared tests.

3. The relationship between minsup and minconf was not decisive. High level of minconf (70% above), in general, reflected significant relationship with either high or low minsup. Mid range of minconf mixed with either mid or high level of minsup can produce either significant or not-significant outcomes.

KEY TERMS

Chi-Squared (χ^2) Test: A non-parametric statistical method that can be used to test independence among attributes.

Confidence: Given a rule X->Y, the confidence of the rule is the conditional probability that a customer buys itemset Y, given that he/she buys itemset X.

Frequent Itemsets: Itemsets that satisfy the minsup threshold.

Itemset: A set of zero or more items.

Market Basket Data: customer purchase data collected at the checkout counters of stores.

Minconf: The given minimal confidence level to validate the association rule.

Minsup: The given minimal support ratio for an itemset to qualify as a frequent itemset.

Support (Ratio): The percentage of transactions that contain a given itemset.

Quantization of Continuous Data for Pattern Based Rule Extraction

Andrew Hamilton-Wright
University of Guelph, Canada, & Mount Allison University, Canada

Daniel W. Stashuk
University of Waterloo, Canada

INTRODUCTION

A great deal of interesting real-world data is encountered through the analysis of continuous variables, however many of the robust tools for rule discovery and data characterization depend upon the underlying data existing in an ordinal, enumerable or discrete data domain. Tools that fall into this category include much of the current work in fuzzy logic and rough sets, as well as all forms of event-based pattern discovery tools based on probabilistic inference.

Through the application of discretization techniques, continuous data is made accessible to the analysis provided by the strong tools of discrete-valued data mining. The most common approach for discretization is quantization, in which the range of observed continuous valued data are assigned to a fixed number of quanta, each of which covers a particular portion of the range within the bounds provided by the most extreme points observed within the continuous domain. This chapter explores the effects such quantization may have, and the techniques that are available to ameliorate the negative effects of these efforts, notably fuzzy systems and rough sets.

BACKGROUND

Real-world data sets are only infrequently composed of discrete data, and any reasonable knowledge discovery approach must take into account the fact that the underlying data will be based on continuous-valued or mixed mode data. If one examines the data at the UCI Machine-Learning Repository (Newman, Hettich, Blake & Merz, 1998) one will see that many of the data sets within this group are continuous-valued; the majority of the remainder are based on measurements of continuous valued random variables that have been pre-quantized before being placed in the database.

The tools of the data mining community may be considered to fall into the following three groups:

- minimum-error-fit and other gradient descent models, such as: support vector machines (Cristianini & Shawe-Taylor, 2000; Duda, Hart & Stork, 2001; Camps-Valls, Martínez-Ramón, Rojo-Álvarez & Soria-Olivas, 2004); neural networks (Rumelhart, Hinton & Williams, 1986); and other kernel or radial-basis networks (Duda, Hart & Stork, 2001; Pham, 2006)
- Bayesian-based learning tools (Duda, Hart & Stork, 2001), including related random-variable methods such as Parzen window estimation
- statistically based pattern and knowledge discovery algorithms based on an event-based model. Into this category falls much of the work in rough sets (Grzymala-Busse, & Ziarko, 1999; Pawlak, 1982,1992; Singh & Minz, 2007; Slezak & Wroblewski, 2006), fuzzy knowledge representation (Boyen & Wehenkel, 1999; Gabrys 2004; Hathaway & Bezdek 2002; Höppner, Klawonn, Kruse & Runkler, 1999), as well as true statistical methods such as "pattern discovery" (Wang & Wong, 2003; Wong & Wang, 2003; Hamilton-Wright & Stashuk, 2005, 2006).

The methods in the last category are most affected by quantization and as such will be specifically discussed in this chapter. These algorithms function by constructing rules based on the observed association of data values among different quanta. The occurrence of a feature value within particular quanta may be considered an "event" and thereby all of the tools of information theory may be brought to bear. Without

the aggregation of data into quanta, it is not possible to generate an accurate count of event occurrence or estimate of inter-event relationships.

MAIN FOCUS

The discretization of continuous-valued data can be seen as a clustering technique in which the ranges of observed values are assigned to a limited set of *Q* cluster labels (sometimes referred to as a Borel set). The success or failure of a quantization structure may therefore be evaluated in terms of how well each of the *Q* clusters represents a homogenous and useful grouping of the underlying data.

The action of quantization is performed as a first step towards the discovery of the data topology, and therefore must frequently be undertaken without a great deal of knowledge of the underlying structure of the data. For this reason, such discretization is usually done using the information available in a single feature. Two major strategies for this are feature value *partitioning* and *quantization*.

Feature Value Partitioning

Partitioning schemes, such as those described in ID3 and C4.5 (Quinlan, 1986; 1993) as well as those used in the WEKA project (Witten & Frank, 2000) rely upon an analysis of decisions to be made within a single feature to provide a classification specific means of dividing the observed data values between labels. Quinlan (1993) provides an excellent discussion of an information-theoretic based approach to the construction of per-feature partitioning schemes in the discussion of the C4.5 classifier. In any such partitioning scheme, the placement of the partition is chosen as a means to optimize a classification decision made based on a single feature.

Quinlan's (1993) discussion is particularly salient, as it is in such tree-based classifiers that this treatment is the most advantageous, because the primary feature of a partitioning mechanism is that each feature is treated independently. This supports classification algorithms that are based on a decision tree, but does not support the discovery of multi-feature, high-order events. Furthermore, note that a classifier label value must be known in advance in order to use this technique; all data is therefore viewed in terms of its ability to provide support for some particular label value.

Feature Value Quantization

Quantization, on the other hand, refers to the construction of a set of range-based divisions of the input feature space, where each distinct quantization "bin" represents a projection of an input feature through an aggregation scheme, independent of label value. By constructing such a quantization independently of class label values, it is therefore possible to support the discovery of data patterns independent of any potential classification structure. Feature value quantization underlies most fuzzy systems (Pedrycz, 1995; Pal & Mitra, 1999) as well as discrete information theoretic based approaches such as the "pattern discovery" algorithm (Wang & Wong, 2003; Wong & Wang, 2003; Hamilton-Wright & Stashuk, 2006).

It is through the introduction of uncertainty-management techniques that the "cost of quantization" may be ameliorated. This cost is inherent in the structure of the quantization resulting from a particular technique.

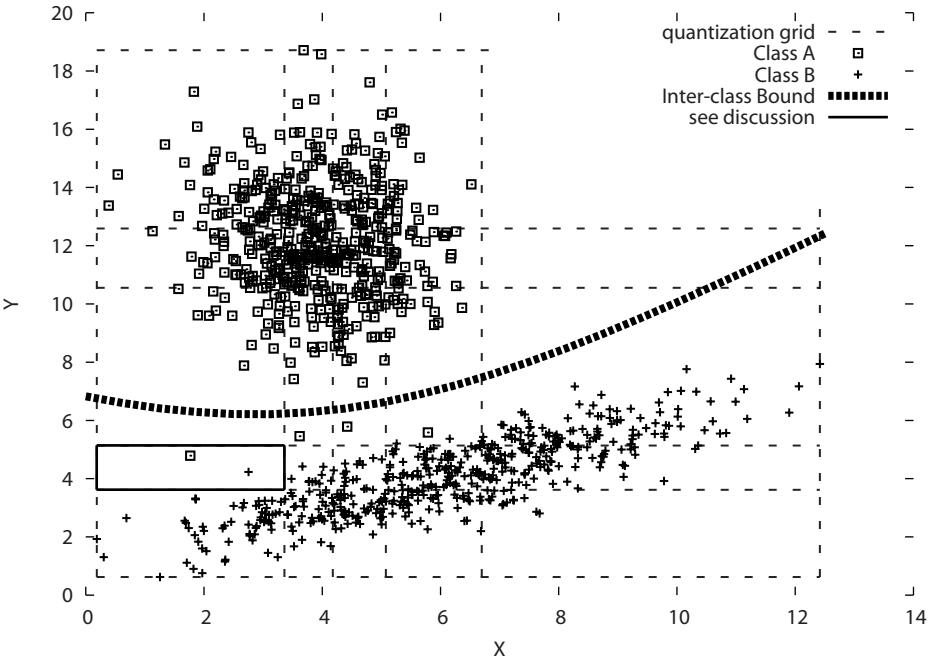
Properties of Quantization

The main strength of quantization is that by reducing a continuous domain problem to a discrete one, the powerful tools of event-based reasoning may be brought to bear. By taking a problem from the continuous domain to a discrete one, the random variables underlying the model of the continuous domain may be represented by discrete state variables, thereby allowing the representation of the data domain as a series of events with possible correlation (for an example, see Ross, 1985).

As an added benefit, such quantization provides protection against measurement noise (as analysis will be insensitive to perturbation in measurement value) provided such perturbation does not change the bin assignment. This simplifies the overall problem, reducing computational complexity, which in turn allows the application of algorithms that locate and analyze high-order patterns (*i.e.*; significant correlations between a large number of input features) such as the "pattern discovery" algorithm just mentioned.

All problems arising from the use of quantization stem from the fact that no quantization scheme can

Figure 1. Quantization example



accurately capture all of the underlying information in the continuous data representation. Consider the data in Figure 1; this data has been quantized into Q=5 quanta using the marginal maximum entropy quantization protocol (Gokhale, 1999; Chau, 2001), or "MME". The MME protocol functions by producing quantization bin boundaries that place an equal number of observed points into each bin for each feature in the input data. In Figure 1, it is clear that the data has been divided among 5 bins in each feature. The width of the bins varies inversely with point density, producing narrower bins where there is a higher density of data points, and wider bins elsewhere. This produces the optimal estimate of bin boundaries for the purpose of probabilistically based data mining; in other words, as each bin contains the same number of points, the statistical support that may be drawn from any bin is equivalent. It has been shown by Chau (2001) that this provides the optimal basis for the quantized representation of an unknown distribution topology from the point of view of observing statistical correlations between event-based bin values.

The choice of Q, the number of bins among which to divide the observed feature values, will be based on the rule discovery mechanism to be used. A mechanism to estimate the maximum possible value for Q based on event-based expectation is provided in Hamilton-Wright & Stashuk (2005); the methodology described in that work may easily be extrapolated to other statistically based classifiers.

Quantization Structure and Inter-Class Decision Boundaries

In cases where the purpose of quantization is to support prediction of a class label, MME quantization may pose a number of problems. For the data set displayed in Figure 1, using MME class-independent quantization the locations of the quantization bin boundaries are independent of the location of the optimal inter-class bound (constructed for Figure 1 as described in Duda, Hart & Stork (2001), pp. 41, for Gaussian "Normal" distributions). As such, the MME quantization bin structure shown in Figure 1 does not directly support

the discovery of the optimal inter-class bound. This is because the optimal inter-class boundary does not follow a neat straight-line path and also because the bins themselves were created without regard to class label.

In order to follow the optimal inter-class division for the data set shown all forms of regular quantization must be abandoned. If transparency (*i.e.*; the ability to directly explain classification decisions based on feature values) is not an objective, the reader is advised to turn to high-dimensional kernel methods such as support vector machines or radial-basis function based Bayesian methods (Duda, Hart & Stork, 2001) which can accurately model the optimal inter-class bound in a non-linear space, but they can not provide a direct explanation of their results in terms of feature values. Alternatively, assuming that transparency is a significant goal within the objectives of a data mining task, the transparent explanation of classification inference available through the use of a rule production scheme based on quantization may be preferable.

Imprecision in Quantization Bin Boundaries

A further issue requiring discussion is the lack of precise information regarding the construction of the bins themselves. Note that although the quantization grid has been constructed in order to place an equal number of points into each division *by feature*, this does not imply that there are an equal number of points in each multi-feature quantum. It is precisely this fact that allows us to produce an occurrence-based estimate of the importance of each quantum for purposes of rule discovery (Pawlak, 1992; Muresan, Lásló & Hirota, 2002; Tsumoto, 2002; Ziarko, 2002a,b; Wang & Wong, 2003; Hamilton-Wright & Stashuk, 2005). This irregularity drives rule production, as quanta that contain observed numbers of occurrences that are different from those expected may be directly assumed to be rules (Haberman, 1973, 1979; Gokhale, 1999). This also implies that the bounds of different quanta are defined with imperfect information.

Specific feature values used to define quantization bin boundaries. Each quantization bin boundary may be seen as a classifier in its own right. Therefore, the number of data values supporting each boundary provides a measure of precision (or imprecision) related to the definition of the bin bounds. Bin bounds supported by a small number of points are less precisely defined than those determined by a large number of points. This imprecision, or more accurately, *vagueness* in the bin bound definition leads to a desire to represent the bin bounds using one of the several mechanisms for computing with imprecise data. The two most common of these are fuzzy logic and rough sets.

Using fuzzy sets to define quantization bins and fuzzy membership for computing in event based spaces can be quite successful (Hamilton-Wright, Stashuk & Tizhoosh 2006), it is not only possible to improve a model's accuracy (as measured by classifier performance), but it is further possible to accurately represent points that cannot be represented using a crisp model.

Considering again the data shown in Figure 1, the box shown at the left of the figure directly below the optimal decision boundary contains only two observed points; one point from each class. No probabilistically based scheme for rule production will generate a rule for this for the purpose of class-based assignment, however by relaxing the bin boundaries using a fuzzy membership system, rules found for adjacent bins may be used to generate label assignments for these points at less than unity membership; in such an assignment the points will be assigned to the closest bin in the geometric system constructed through a fuzzy membership function.

FUTURE TRENDS

It is clear that the problems associated with quantization are not easily overcome. However, quantization brings with it highly attractive features, such as the high degree of transparency and the tractability of high-quality statistically based tools. Given these benefits quantization schemes are not easily abandoned.

It is therefore not surprising that a number of projects are continuing work on adaptation and application of fuzzy and/or rough sets in an effort to recover information from a quantized data domain (Singh & Minz, 2007; Slezak & Wroblewski, 2006). Further, class-dependent quantization, either by itself or in conjunction with the aforementioned works promises to provide assistance in classification problems. The major obstacle, however, remains: how does one best represent a limited number of continuous training data points so that they can best support high-level rule discovery.

CONCLUSIONS

Quantization based schemes seemingly discard important data by grouping individual values into relatively large aggregate groups; the use of fuzzy and rough set tools helps to recover a significant portion of the data lost by performing such a grouping. If quantization is to be used as the underlying method of projecting continuous data into a form usable by a discrete-valued knowledge discovery system, it is always useful to evaluate the benefits provided by including a representation of the vagueness derived from the process of constructing the quantization bins.

KEY TERMS

Borel Set: A division of a data space into non-overlapping (hyper) rectangular structures; a quantization scheme frequently forms by its quanta a collection of Borel sets covering the entire data space.

Data Value Partitioning: In contrast to "data value quantization" (below) this describes a technique in which a single partition point divides the range of a feature; this is performed in support of a related decision, which is optimized according to some metric. See Quinlan (1993) for a discussion of the construction of such partitions based on mutual information; Metz (1978) provides a random-variable analysis in the context of ROC decision threshold construction.

Data Value Quantization: The division of the observed feature range among several "quantization bins" for the purpose of providing a discrete representation of the values observed in a continuous valued feature; this representation is achieved by using the numeric bin index to represent all values in the given bin.

Event Based Learning: A specific type of statistically based machine learning in which the universe of

possible input values is drawn from a set of discrete events; each event may be represented by the intersection of several discrete variables, in which case it may be described as a Borel set.

Machine Learning: An algorithm that (a) modifies its output in accordance with reduced perceived error over time by observation of a series of inputs over time, or (b) constructs an output based on likely correspondences observed over a fixed training data set; these are frequently referred to as "online" and "offline" learning schemes. See also "statistically based learning" and "event based learning".

Parzen Windows: A technique for estimating the probability density function of a random variable by interpolating based on a few sample points. See Duda, Hart & Stork (2001) for an excellent description of this technique.

Pattern Discovery: The activity of discovering patterns in a training data set for the purpose of model building and data characterization; also a particular algorithm produced for this purpose that functions by locating events whose occurrence differs significantly from a predefined hypothetical model of noise (Wang & Wong, 2003; Hamilton-Wright, Stashuk & Tizhoosh, 2007).

Rule Discovery, Rule Extraction: A form of pattern discovery in which the patterns found are intended for use in a system in which a label or course of action is suggested by an evaluation of the best matching rule or rules. Decision support systems and data classification systems are common users of discovered rules.

Statistically Based Learning: A branch of machine learning in which the underlying model of the observed data is formed through statistical or probabilistic analysis of the input data. The two main branches of this field are Bayesian inference based systems and event-based inference systems. The first are characterized by a reliance on an underlying model describing the probability density function of all of the joint probabilities associated with each decision; the second by the use of an event-based (and therefore quantized) approach to achieve discrete events that may then be counted in crisp or fuzzy terms.

Realistic Data for Testing Rule Mining Algorithms

Colin Cooper
Kings' College, UK

Michele Zito
University of Liverpool, UK

INTRODUCTION

The association rule mining (ARM) problem is a well-established topic in the field of knowledge discovery in databases. The problem addressed by ARM is to identify a set of relations (associations) in a binary valued attribute set which describe the likely coexistence of groups of attributes. To this end it is first necessary to identify sets of items that occur frequently, i.e. those subsets F of the available set of attributes I for which the *support* (the number of times F occurs in the dataset under consideration), exceeds some threshold value. Other criteria are then applied to these item-sets to generate a set of association rules, i.e. relations of the form $A \rightarrow B$, where A and B represent disjoint subsets of a frequent item-set F such that $A \cup B = F$. A vast array of algorithms and techniques has been developed to solve the ARM problem. The algorithms of Agrawal & Srikant (1994), Bajardo (1998), Brin, et al. (1997), Han *et al.* (2000), and Toivonen (1996), are only some of the best-known heuristics.

There has been recent growing interest in the class of so-called *heavy tail* statistical distributions. Distributions of this kind had been used in the past to describe word frequencies in text (Zipf, 1949), the distribution of animal species (Yule, 1925), of income (Mandelbrot, 1960), scientific citations count (Redner, 1998) and many other phenomena. They have been used recently to model various statistics of the web and other complex networks Science (Barabasi & Albert, 1999; Faloutsos *et al.*, 1999; Steyvers & Tenenbaum, 2005).

BACKGROUND

Although the ARM problem is well studied, several fundamental issues are still unsolved. In particular the evaluation and comparison of ARM algorithms is a very difficult task (Zaiane, et al., 2005), and it is often tackled by resorting to experiments carried out using data generated by the well established QUEST program from the IBM Quest Research Group (Agrawal & Srikant, 1994). The intricacy of this program makes it difficult to draw theoretical predictions on the behaviour of the various algorithms on input produced by this program. Empirical comparisons made in this way are also difficult to generalize because of the wide range of possible variation, both in the characteristics of the data (the structural characteristics of the synthetic databases generated by QUEST are governed by a dozen of interacting parameters), and in the environment in which the algorithms are being applied. It has also been noted (Brin, et al., 1997) that data sets produced using the QUEST generator might be inherently not the hardest to deal with. In fact there is evidence that suggests that the performances of some algorithms on real data are much worse than those found on synthetic data generated using QUEST (Zheng, et al., 2001).

MAIN FOCUS

The purpose of this short contribution is two-fold. First, additional arguments are provided supporting the view that real-life databases show structural properties that are very different from those of the data generated by QUEST. Second, a proposal is described for an alternative data generator that is simpler and more realistic than QUEST. The arguments are based on results described in Cooper & Zito (2007).

Heavy-Tail Distributions in Market Basket Databases

To support the claim that real market-basket databases show structural properties that are quite

different from those of the data generated by QUEST, Cooper and Zito analyzed empirically the distribution of item occurrences in four real-world retail databases widely used as test cases and publicly available from http://fimi.cs.helsinki.fi/data/. Figure 1 shows an example of such a distribution (on a log-log scale) for two of these databases. Results concerning the other two datasets are in Cooper and Zito (2007).

The authors suggest that in each case the empirical distribution may fit (over a wide range of values) a heavy-tailed distribution. Furthermore they argue that the data generated by QUEST shows quite different properties (even though it has similar size and density). When the empirical analysis mentioned above is performed on data generated by QUEST (available from the same source) the results are quite different from those obtained for real-life retail databases (see Figure 2).

Differences have been found before (Zheng *et al.*, 2001) in the transaction sizes of the real-life vs. QUEST generated databases. However some of these differences may be ironed out by a careful choice of the numerous parameters that controls the output of the QUEST generator. The results of Cooper and Zito may point to possible differences at a much deeper level.

A Closer Look at QUEST

Cooper and Zito also start a deeper theoretical investigation of the structural properties of the QUEST databases proposing a simplified version of QUEST whose mathematical properties could be effectively analyzed. As the original program, this simplified version returns two related structures: the actual database

Figure 1. Log-log plots of the real-life data sets along with the best fitting lines

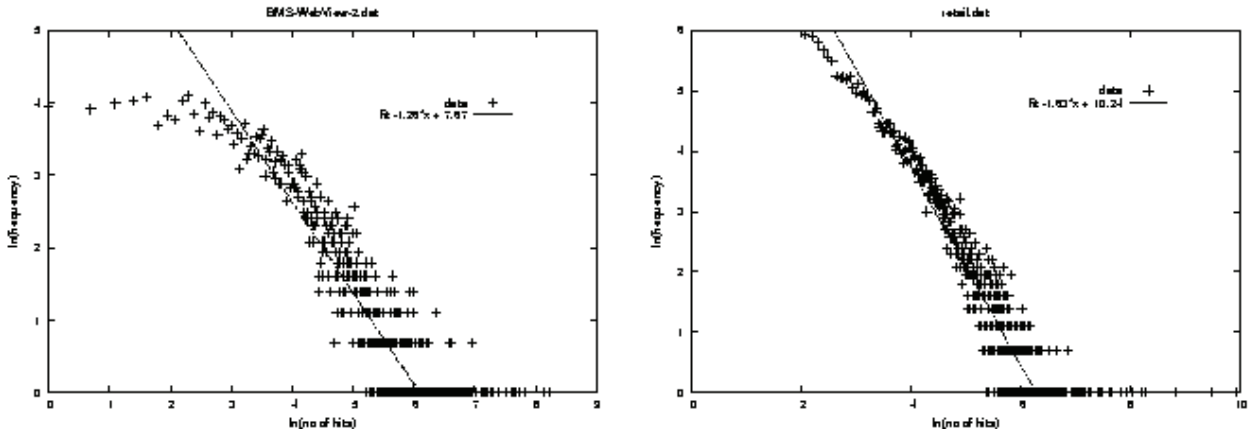

Figure 2. Log-log plots of the QUEST data sets along with the best fitting line

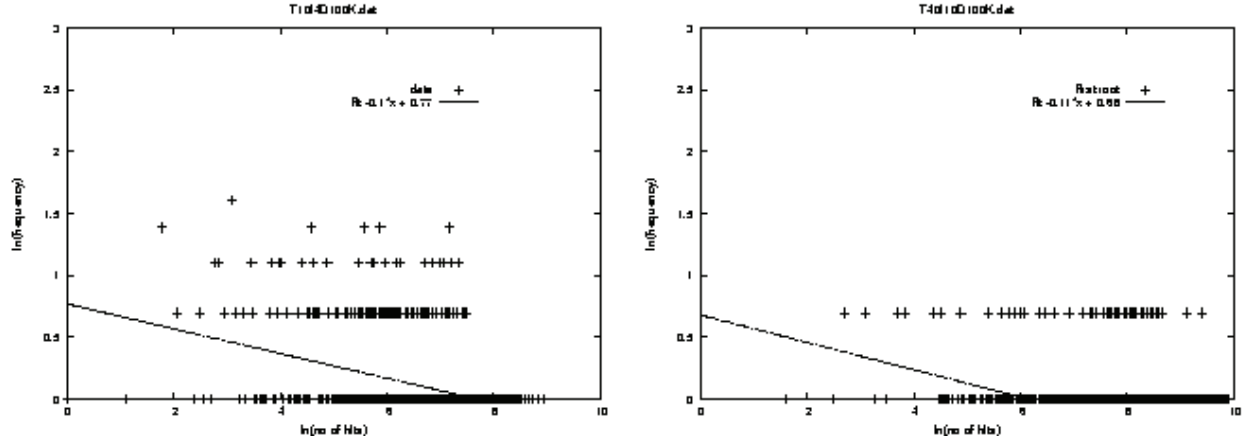

$\mathcal{D}$ and a collection $\mathcal{T}$ of *potentially large item-sets* (or *patterns*) that is used to populate $\mathcal{D}$. However in the simplified model, it is convenient to assume that each transaction is formed by the union of k elements of $\mathcal{T}$, chosen independently uniformly at random (with replacement). The patterns in $\mathcal{T}$ are generated by first selecting a random set of s items, and then, for each of the other patterns, by choosing (with replacement) ρ elements uniformly at random from those belonging to the last generated pattern and $s - \rho$ remaining elements uniformly at random (with replacement) from the whole set of items.

Let $\deg_D(v)$ (resp. $\deg_T(v)$) denote the number of transactions in $\mathcal{D}$ (resp. patterns in $\mathcal{T}$) containing item v. Assume that h, the total number of transactions, is a polynomial in n and $l \propto n$. It follows directly from the definition of the generation process given above that, for each item v, $\deg_D(v)$ has a binomial distribution with parameters h and $p_{k,l} = \sum_{i=1}^{k} \binom{k}{i} \frac{(-1)^{i+1}}{l^i} E(\deg_T(v)^i)$, and the expected value of N_r is $n \cdot \binom{h}{r} (p_{k,l})^r (1 - p_{k,l})^{h-r}$.

Moreover, at least in the restricted case when $s = 2$, by studying the asymptotic distribution of $\deg_T(v)$, it is possible to prove that, for constant values of k and large values of n, $p_{k,l}$ is approximately $2 \cdot n^{-1}$ and N_r is very close to its expected value. Hence for large r, the proportion of items occurring in r transaction decays much faster than r^{-z} for any fixed $z > 0$. For instance, if $k = 1$, then $\frac{N_r}{n} \to \binom{h}{r} (p_{k,l})^r (1 - p_{k,l})^{h-r}$.

An Alternative Proposal

Cooper and Zito's study of a synthetic database generator also points to possible alternatives to the IBM generator. In fact, a much more effective way of generating realistic databases is based on building the database sequentially, adding the transactions one at the time, choosing the items in each transaction based on their (current) popularity (a mechanism known as *preferential attachment*). The database model proposed by Cooper and Zito (which will be referred to as **CoZi** from now on) is in line with the proposal of Barabasi & Albert (1999), introduced to describe structures like the scientific author citation network or the world-wide web. Instead of assuming an underlying set of patterns $\mathcal{T}$ from which the transactions are built up, the elements of $\mathcal{D}$ are generated sequentially. At the start there is an initial set of e_0 transactions on n_0 existing items. **CoZi** can generate transactions based entirely on the n_0 initial items, but in general new items can also be added to newly defined transactions, so that at the end of the simulation the total number of items is $n > n_0$. The simulation proceeds for a number of steps generating groups of transactions at each step. For each group in the sequence there are four choices made by the simulation at step t:

1. The type of transaction. An `OLD` transaction (chosen with probability $1 - \alpha$) consists of items occurring in previous transactions. A `NEW` transaction (chosen with probability α) consists of a mix of new items and items occurring in previous transactions.
2. The number of transactions in a group, $m_0(t)$ (resp. $m_N(t)$) for `OLD` (resp. `NEW`) transactions. This can be a fixed value, or given any discrete distribution with mean $\overline{m_O}$ (resp. $\overline{m_N}$). Grouping corresponds to e.g. the persistence of a particular item in a group of transactions in the QUEST model.
3. The transaction size. This can again be a constant, or given by a probability distribution with mean $\overline{\pi}$.
4. The method of choosing the items in the transaction. If transactions of type `OLD` (resp. `NEW`) are chosen in a step we assume that each of them is selected using preferential attachment with probability P_0 (resp. P_N) and randomly otherwise.

The authors provide:

1. A proof that the **CoZi** model is guaranteed to generate heavy-tailed datasets, and
2. details of a simple implementation in Java, available from the authors web-sites.

More specifically, following Cooper (2006) they prove that, provided that the number of transactions is large, with probability approaching one, the distribution of item occurrence in $\mathcal{D}$ follows a power law distribution with parameter $z = 1 + \frac{1}{\eta}$, where $\eta = \frac{\alpha \overline{m_N}(\overline{\pi} - 1) P_N + (1 - \alpha)\overline{m_O}\,\overline{\pi} P_O}{(\alpha \overline{m_N} + (1 - \alpha)\overline{m_O})\,\overline{\pi}}$. In otherwords, the number of items occurring r times after t steps of the generation process is approximately Ctr^{-z} for large r and some constant $C > 0$.

Turning to examples, in the simplest case, the group sizes are fixed (say $m_N(t) = m_0(t) = 1$ always) and the preferential attachment behaviour is the same ($P_N = P_0 = P$). Thus $\eta = P - \frac{\alpha P}{\pi}$, and $z = 1 + \frac{\pi}{(\pi - \alpha P)}$. A simple implementation in Java of the **CoZi** generator, based on these settings (and the additional assumption that the transaction sizes are given by the absolute value of a normal distribution), is available at http://www.csc.liv.ac.uk/~michele/soft.html. Figure 3 displays item distribution plots obtained from running the program with P = 50% for different values of h and α.

While there are many alternative models for generating heavy tailed data (Mitzenmacher, 2004; Watts, 2004) and different communities may prefer to use alternative processes, we contend that synthetic data generators of this type should be a natural choice for the testing of ARM algorithms.

FUTURE TRENDS

Given the ever increasing needs to store and analyse large amounts of data, we anticipate that tasks like ARM or classification or pattern analysis will become increasingly important. In this context it will be desirable to have sound mathematical models that could be used to generate synthetic data or test cases. As a step in this direction, in our recent work, we looked at models for market-basket databases. Another interesting area one could look at is that of generators of classifier test cases. We believe that the theory of random processes, and, more generally, probability theory, could provide a range of techniques to devise realistic models and help discover interesting structural properties of the resulting data sets.

CONCLUSION

The association rule mining problem is a very important topic within the Data Mining research field. We provided additional evidence supporting the claim that, although a large array of algorithms and techniques exist to solve this problem, the testing of such algorithms is often done resorting to un-realistic synthetic data generators. We also put forward an alternative synthetic data generator that is simple to use, mathematically sound, and generates data that is more realistic than the one obtained from other generators.

KEY TERMS

Association Rule Mining: The problem addressed is to identify a set of relations in a binary valued attribute set which describe the likely coexistence of groups of attributes.

Best Fitting Line: On a data diagram, this is the line drawn as near as possible to the various points so as to best represent the trend being graphed. The sums of the displacements of the points on either side of the line should be equal.

Heavy-Tailed Distribution: A statistical distribution is said to have a heavy tail if the fraction of the population up to a certain value x decays more slowly than e^{-cx}, for some $c > 0$, as x tends to infinity.

Power-Law Distribution: A statistical distribution is said to follow a power law decay if the fraction of the population up to a certain value x decays like x^{-c}, for some $c > 0$, as x tends to infinity.

Preferential Attachment: In a system of numerical quantities, randomly modified as time goes by, it is a positive feedback mechanism by which larger increases tend to accumulate on already large quantities.

Random Process: A random process is a sequence of random variables. It may be used to model the dynamics of a certain system.

Random Variable: A random variable is a numerical or otherwise measurable quantity associated with an experiment involving a random outcome.

Real-Time Face Detection and Classification for ICCTV

INTRODUCTION

Data mining is widely used in various areas such as finance, marketing, communication, web service, surveillance and security. The continuing growth in computing hardware and consumer demand has led to a rapid increase of multimedia data searching. With the rapid development of computer vision and communication techniques, real-time multimedia data mining is becoming increasingly prevalent. A motivating application is Closed-Circuit Television (CCTV) surveillance systems. However, most data mining systems mainly concentrate on text based data because of the relative mature techniques available, which are not suitable for CCTV systems. Currently, CCTV systems rely heavily on human beings to monitor screens physically. An emerging problem is that with thousands of cameras installed, it is uneconomical and impractical to hire the required numbers of people for monitoring. An Intelligent CCTV (ICCTV) system is thus required for automatically or semi-automatically monitoring the cameras.

BACKGROUND

CCTV Surveillance Systems

In recent years, the use of CCTV for surveillance has grown to an unprecedented level. Especially after the 2005 London bombings and the 2001 terrorist attack in New York, video surveillance has become part of everyday life. Hundreds of thousands of cameras have been installed in public areas all over the world, in places such as train stations, airports, car parks, Automatic Teller Machines (ATMs), vending machines and taxis. Based on the number of CCTV units on Putney High Street, it is "guesstimated" (McCahill & Norris 2002) that there are around 500,000 CCTV cameras in the London area alone and 4,000,000 cameras in the UK. This suggests that in the UK there is approximately one camera for every 14 people. However, currently there is no efficient system to fully utilize the capacity of such a huge CCTV network. Most CCTV systems rely on humans to physically monitor screens or review the stored videos. This is inefficient and makes proactive surveillance impractical. The fact that police only found activities of terrorists from the recorded videos after the attacks happened in London and New York shows that existing surveillance systems, which depend on human monitoring, are neither reliable nor timely. The need for fully automatic surveillance is pressing.

Challenges of Automatic Face Recognition on ICCTV Systems

Human tracking and face recognition is one of the key requirements for ICCTV systems. Most of the research on face recognition focuses on high quality still face images and achieves quite good results. However, automatic face recognition under CCTV conditions is still on-going research and many problems still need to be solved before it can approach the capability of the human perception system. Face recognition on CCTV is much more challenging. First, image quality of CCTV cameras is normally low. The resolution of CCTV cameras is not as high as for still cameras and the noise levels are generally higher. Second, the environment control of CCTV cameras is limited, which introduces large variations in illumination and

the viewing angle of faces. Third, there is generally a strict timing requirement for CCTV surveillance systems. Such a system should be able to perform in near real-time — detecting faces, normalizing the face images, and recognizing them.

MAIN FOCUS

Face Detection

Face detection is a necessary first step in all of the face processing systems and its performance can severely influence on the overall performance of recognition. Three main approaches are proposed for face detection: feature based, image based, and template matching.

Feature based approaches attempt to utilize some priori knowledge of human face characteristics and detect those representative features such as edges, texture, colour or motion. Edge features have been applied in face detection from the beginning (Colmenarez & Huang 1996), and several variations have been developed (Froba & Kublbeck 2002; Suzuki & Shibata 2004). Edge detection is a necessary first step for edge representation. Two edge operators that are commonly used are the Sobel Operator and Marr-Hildreth operator. Edge features can be easily detected with a very short time but are not robust for face detection in complex environments. Others have proposed texture-based approaches by detecting local facial features such as pupils, lips and eyebrows based on an observation that they are normally darker than the regions around them (Hao & Wang 2002). Color feature based face detection is derived from the fact that the skin color of different humans (even from different races) cluster very closely. Several color models are normally used, including RGB (Satoh, Nakamura & Kanade 1999), normalized RGB (Sun, Huang & Wu1998), HSI (Lee, Kim & Park 1996), YIQ (Wei & Sethi 1999), YES (Saber & Tekalp 1996), and YUV (Marques & Vilaplana 2000). In these color models, HSI is shown to be a very suitable when there is a large variation in feature colors in facial areas such as the eyes, eyebrows, and lips. Motion information is appropriate to detect faces or heads when video sequences are available (Espinosa-Duro, Faundez-Zanuy & Ortega 2004; Deng, Su, Zhou & Fu 2005). Normally frame difference analysis or moving image contour estimation is applied for face region segmentation. Recently, researchers tend to focus more on multiple feature methods which combine shape analysis, color segmentation, and motion information to locate or detect faces (Qian & Li 2000; Widjojo & Yow 2002).

The Template matching approach can be further divided into two classes: feature searching and face models. Feature searching techniques first detect the prominent facial features, such as eyes, nose, mouth, then use knowledge of face geometry to verify the existence of a face by searching for less prominent facial features (Jeng, Liao, Liu & Chern 1996). Deformable templates are generally used for face models for face detection. Yuille et al. (1989) extends the snake technique to describe features such as eyes and the mouth by a parameterized template. The snake energy comprises a combination of valley, edge, image brightness, peak, and internal energy. In Cootes and Taylor's work (1996), a point distributed model is described by a set of labeled points and Principal Component Analysis is used to define a deformable model.

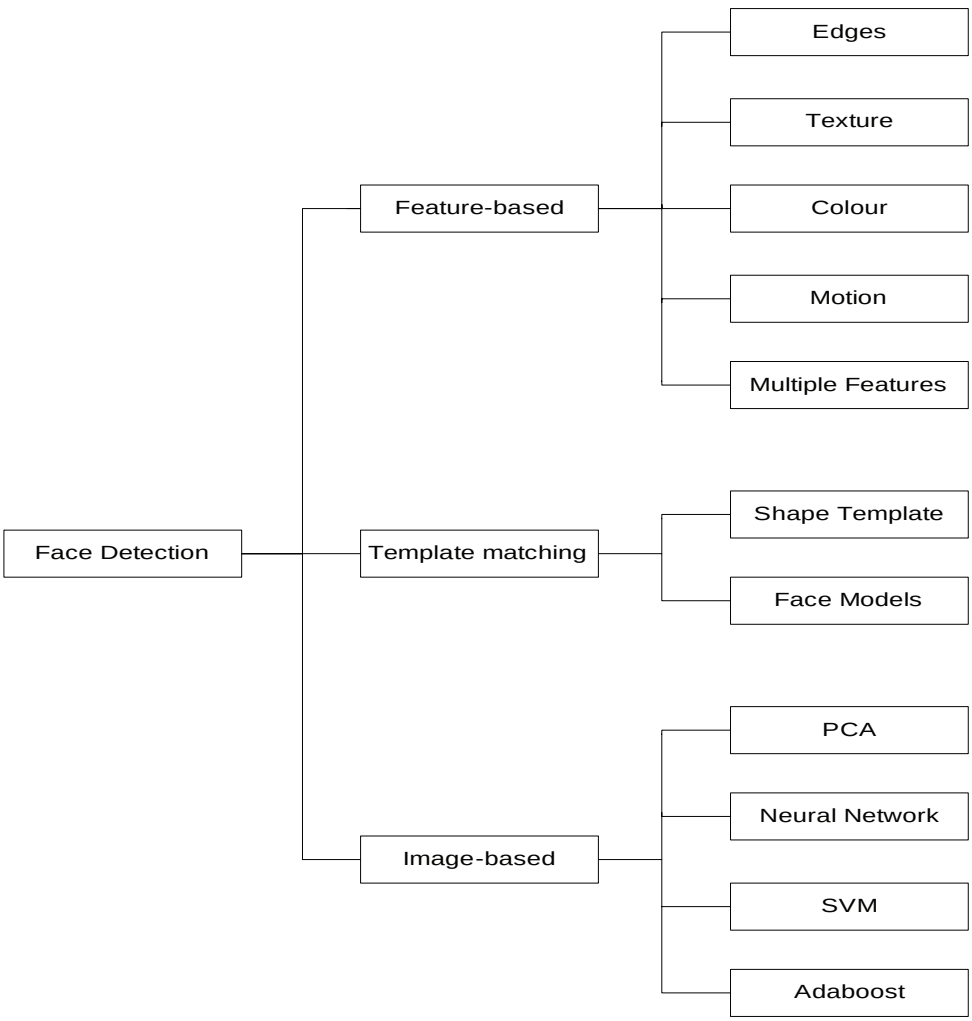
Image-based approaches treat face detection as a two class pattern recognition problem and avoid using *a priori* face knowledge. It uses positive and negative samples to train a face/non-face classifier. Various pattern classification methods are used, including Eigenfaces (Wong, Lam, Siu, & Tse 2001), Neural Network (Tivive & Bouzerdoum 2004), Support Vector Machine (Shih & Liu 2005), and Adaboost (Hayashi & Hasegawa 2006).

In summary, there are many varieties of face detection methods and to choose a suitable method is heavily application dependent. Figure 1 shows various face detection techniques and their categories. Generally speaking, feature-based methods are often used in real-time systems when color, motion, or texture information is available. Template-matching and image-based approach can attain superior detection performance than feature-based method, but most of the algorithms are computationally expensive and are difficult to apply in a real-time system.

Pose Invariant Face Recognition

Pose invariant face recognition can be classified into two categories: 2D based approaches and 3D based approaches. Although 3D face models can be used to describe the appearance of a human face under different pose changes accurately and can attain good recognition results for face images with pose variation, there

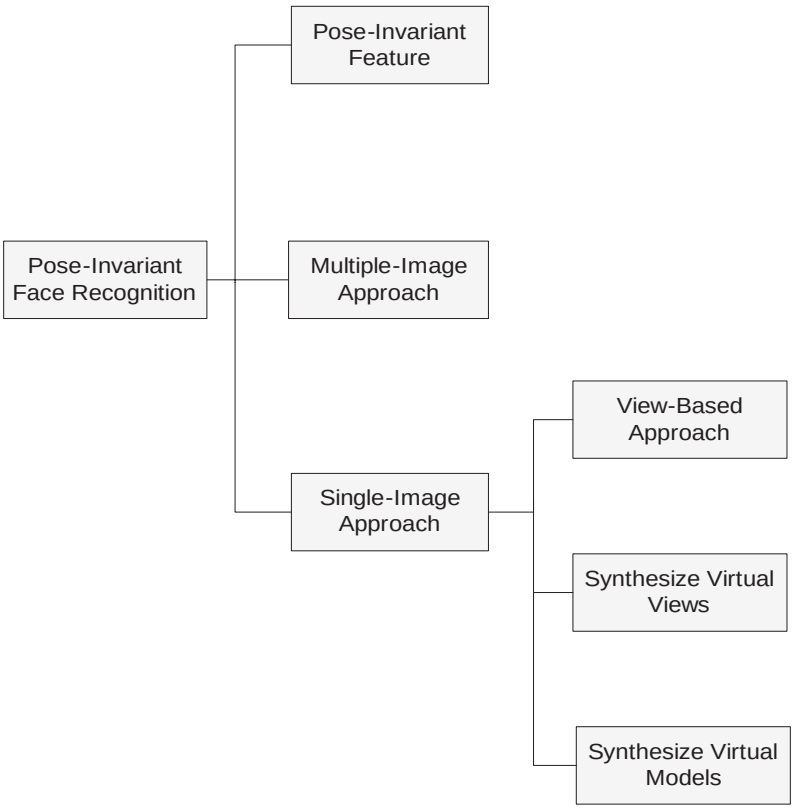
Figure 1. Various face detection techniques



are several disadvantages that limit its application to the CCTV scenario (Bowyer, Chang & Flynn 2004). First, to construct a 3D face model, 3D scanners have to be installed to replace existing cameras in the CCTV system, which is very expensive. Second, to acquire 3D data, the depth of field of the scanners has to be well controlled and this leads to the limitation on the range of data acquisition. Third, using 3D scanners to obtain 3D data is time consuming and cannot be done in real-time. Most researchers thus focus on 2D approaches for dealing with pose variation.

The 2D based approaches can be categorized into three classes: pose invariant features, multiple image, and single image as shown in Figure 2. Wiskott et al. (Wiskott, Fellous, Kuiger & Malsburg 1997) proposed Elastic Bunch Graph Matching for face recognition, which applied Gabor filters to extract pose invariant features. Beymer (1996) used multiple model views to cover different poses from the viewing sphere. Sankaran and Asari (2004) proposed a multi-view approach on Modular PCA (Pentland, Moghaddam & Starner 1994) by incorporating multiple views of the subjects as separate sets of training data. In 2001, Cootes, Edwards and Taylor (2001) proposed "View-based Active Appearance Models," based on the idea that a small number of 2D statistical models are sufficient to capture the shape and appearance of a face from any viewpoint. Sanderson *et al* (2006, 2007) addressed the pose mismatch problem by extending each frontal face model with artificially synthesized models for non-frontal views.

Figure 2. 2D based pose invariant face recognition techniques



Towards Real-Time Trials on ICCTV

The authors developed Adaptive Principal Component Analysis (APCA) to improve the robustness of PCA to nuisance factors such as lighting and expression (Chen & Lovell, 2003 and 2004). They extended APCA to deal with face recognition under variant poses (Shan, Lovell & Chen 2006) by applying an Active Appearance Model to perform pose estimation and synthesize the frontal view image. However, similar to most face recognition algorithms, the experiments were performed on some popular databases that contain only still camera images with relatively high resolution. Very few tests are done on video databases (Aggarwal 2004, Gorodnichy 2005).

We recently constructed a near real-time face detection and classification system and tested it on operational surveillance systems installed in a railway station. The system is composed of four modules: the communication module exchanges data with the surveillance system; the face detection module uses AdaBoost based cascade face detectors to detect multiple faces inside an image; the face normalization module detects facial features such as eyes and the nose to align and normalize face images; the face classification module uses the APCA method to compare face images with gallery images inside the face database. The system is implemented in C++ and runs at 7 to 10 frames per second on an Intel Dual-Core PC. Figure 3 illustrates the system structure. Our system works well in a controlled environment. If we manually align the face images of size 50 by 50 pixels or larger, it can achieves recognition rate up to 95%. But in fully automatic tests in complex uncontrolled environment, the recognition rate drops significantly. This is due to the combined effects of variations in lighting, pose, expression, registration error and image resolution etc. Figure 4 shows the real-time recognition results on two frames from a video sequence obtained from the railway station.

Figure 3. Real-time face detection and classification system structure

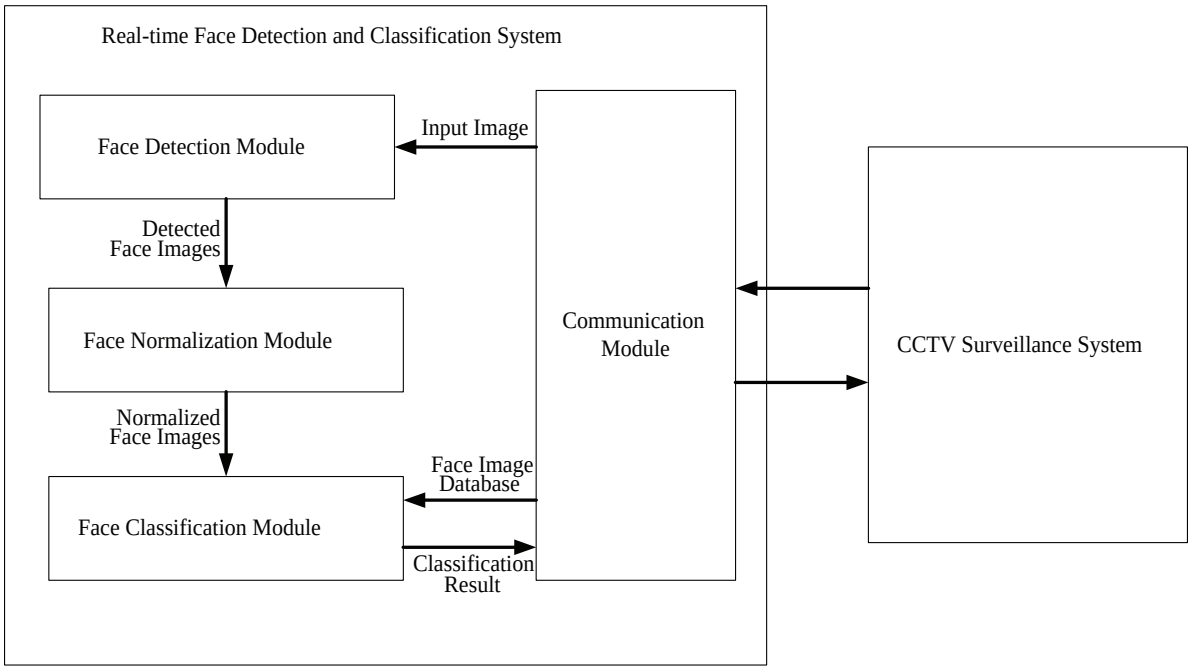


Figure 4. Real-life trial of face recognition on ICCTV. The boxes in the images show detection of the faces and the labels indicate the identity of the person from Shan et. al.(2007)

FUTURE TRENDS

Modern surveillance systems produce enormous video archives and their rate of growth is accelerating as video resolution and the number of cameras increases due to heightened security concerns. At present these archives are often erased after a few weeks due to cost of storage, but also because the archive have diminished value because there is no automatic way to search for events of interest. Face recognition provides one means to search these data for specific people. Identification reliability will be enhanced if this can be combined with, say, human gait recognition, clothing appearance models, and height information. Moreover human activity recognition could be used to detect acts of violence and suspicious patterns of behavior. Fully

integrated automatic surveillance systems are certainly the way of the future.

CONCLUSION

With the increasing demands of security, multimedia data mining techniques on CCTV, such as face detection and recognition, will deeply affect our daily lives in the near future. However, current surveillance systems which rely heavily on human operators are not practical, scalable, nor economical. This creates much interest in ICCTV systems for security applications. The challenge is that existing computer vision and pattern recognition algorithms are neither reliable nor fast enough for large database and real-time applications. But the performance and robustness of such systems will increase significantly as more attention is devoted to these problems by researchers.

KEY TERMS

Active Appearance Model: Active appearance model (AAM) is a method to represent the shape and appearance variations of objects. A statistical shape model and an appearance model are learned from landmarks of the sample data and then correlated by applying Principal Component Analysis on the training data.

Adaboost: Adaboost is a short for Adaptive Boosting. It is a boosting learning algorithm to combine many weak classifiers into a single powerful classifier. It adaptively changes the weight for weak classifiers from the misclassified data sample. It is mainly used to fuse many binary classifiers into a strong classifier.

Close-Circuit Television: Close-Circuit Television (CCTV) is a system that transmits signals from video cameras to specific end users, such as monitors and servers. Signals are transmitted securely and privately over the network. CCTV is mainly used for surveillance applications.

Face Detection: To determine whether or not there are any faces in the image and return the corresponding location of each face.

Intelligent CCTV: Intelligent CCTV (ICCTV) is a CCTV system that can automatically or semi-automatically implement surveillance functions. Some advanced techniques of computer vision, pattern recognition, data mining, artificial intelligence and communications etc. are applied into CCTV to make it smart.

Pose: In face recognition, pose means the orientation of the face in 3D space including head tilt, and rotation.

Pose Estimation: To estimate the head pose orientation in 3D space. Normally estimate angles of the head tilt and rotation.

Reasoning about Frequent Patterns with Negation

Marzena Kryszkiewicz
Warsaw University of Technology, Poland

INTRODUCTION

Discovering of frequent patterns in large databases is an important data mining problem. The problem was introduced in (Agrawal, Imielinski & Swami, 1993) for a sales transaction database. Frequent patterns were defined there as sets of items that are purchased together frequently. Frequent patterns are commonly used for building association rules. For example, an association rule may state that 80% of customers who buy fish also buy white wine. This rule is derivable from the fact that fish occurs in 5% of sales transactions and set {fish, white wine} occurs in 4% of transactions. Patterns and association rules can be generalized by admitting negation. A sample association rule with negation could state that 75% of customers who buy coke also buy chips and neither beer nor milk. The knowledge of this kind is important not only for sales managers, but also in medical areas (Tsumoto, 2002). Admitting negation in patterns usually results in an abundance of mined patterns, which makes analysis of the discovered knowledge infeasible. It is thus preferable to discover and store a possibly small fraction of patterns, from which one can derive all other significant patterns when required. In this chapter, we introduce first lossless representations of frequent patterns with negation.

BACKGROUND

Let us analyze sample transactional database D presented in Table 1, which we will use throughout the chapter. Each row in this database reports items that were purchased by a customer during a single visit to a supermarket.

As follows from Table 1, items *a* and *b* were purchased together in four transactions. The number of transactions in which set of items $\{x_1, ..., x_n\}$ occurs is called its *support* and denoted by $sup(\{x_1, ..., x_n\})$. A set of items is called a *frequent pattern* if its support exceeds a user-specified threshold (*minSup*). Otherwise, it is called an *infrequent pattern*. In the remainder of the chapter, we assume *minSup* = 1. One can discover 27 frequent patterns from D, which we list in Figure 1.

One can easily note that the support of a pattern never exceeds the supports of its subsets. Hence, subsets of a frequent pattern are also frequent, and supersets of an infrequent pattern are infrequent.

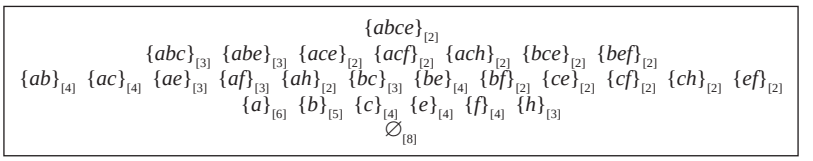
Aside from searching for only statistically significant sets of items, one may be interested in identifying frequent cases when purchase of some items (presence of some symptoms) excludes purchase of other items (presence of other symptoms). A pattern consisting of items $x_1, \ldots, x_m$ and negations of items $x_{m+1}, \ldots, x_n$ will be denoted by $\{x_1, \ldots, x_m, -x_{m+1}, \ldots, -x_n\}$. The *support of pattern* $\{x_1, \ldots, x_m, -x_{m+1}, \ldots, -x_n\}$ is defined as the number of transactions in which all items in set $\{x_1, \ldots, x_m\}$ occur and no item in set $\{x_{m+1}, \ldots, x_n\}$) occurs. In particular, $\{a(-b)\}$ is supported by two transactions in D, while $\{a(-b)(-c)\}$ is supported by one transaction. Hence, $\{a(-b)\}$ is frequent, while $\{a(-b)(-c)\}$ is infrequent.

From now on, we will say that *X* is a *positive pattern*, if *X* does not contain any negated item. Otherwise, *X* is called a *pattern with negation*. A pattern obtained from pattern *X* by negating an arbitrary number of items in *X* is called a *variation of X*. For example, {*ab*} has four

Table 1. Sample database D

Id	Transaction
T_1	{*abce*}
T_2	{*abcef*}
T_3	{*abch*}
T_4	{*abe*}
T_5	{*acfh*}
T_6	{*bef*}
T_7	{*h*}
T_8	{*af*}

Figure 1. Frequent positive patterns discovered from database D. Values provided in square brackets in the subscript denote supports of patterns.



distinct variations (including itself): {*ab*}, {*a*(–*b*)}, {(–*a*)*b*}, {(–*a*)(–*b*)}.

One can discover 109 frequent patterns in D, 27 of which are positive, and 82 of which have negated items. In practice, the number of frequent patterns with negation is by orders of magnitude greater than the number of frequent positive patterns.

A first trial to solve the problem of large number of frequent patterns with negation was undertaken by Toivonen (1996), who proposed a method for using supports of positive patterns to derive supports of patterns with negation. The method is based on the observation that for any pattern X and any item x, the number of transactions in which X occurs is the sum of the number of transactions in which X occurs with x and the number of transactions in which X occurs without x. In other words, $sup(X) = sup(X \cup \{x\}) + sup(X \cup \{(-x)\})$, or $sup(X \cup \{(-x)\}) = sup(X) - sup(X \cup \{x\})$ (Mannila and Toivonen, 1996). Multiple usage of this property enables determination of the supports of patterns with an arbitrary number of negated items based on the supports of positive patterns. For example, the support of pattern {*a*(–*b*)(–*c*)}, which has two negated items, can be calculated as follows: $sup(\{a(-b)(-c)\}) = sup(\{a(-b)\}) - sup(\{a(-b)c\})$. Thus, the task of calculating the support of {*a*(–*b*)(–*c*)}, which has two negated items, becomes a task of calculating the supports of patterns {*a*(–*b*)} and {*a*(–*b*)*c*}, each of which contains only one negated item. We note that $sup(\{a(-b)\}) = sup(\{a\}) - sup(\{ab\})$, and $sup(\{a(-b)c\}) = sup(\{ac\}) - sup(\{abc\})$. Eventually, we obtain: $sup(\{a(-b)(-c)\}) = sup(\{a\}) - sup(\{ab\}) - sup(\{ac\}) + sup(\{abc\})$. The support of {*a*(–*b*)(–*c*)} is hence determinable from the supports of {*abc*} and its proper subsets.

It was proved in (Toivonen, 1996) that for any pattern with negation its support is determinable from the supports of positive patterns. Nevertheless, the knowledge of the supports of only frequent positive patterns may be insufficient to derive the supports of all patterns with negation (Boulicaut, Bykowski & Jeudy, 2000), which we illustrate beneath.

Let us try to calculate the support of pattern $\{bef(-h)\}$: $sup(\{bef(-h)\}) = sup(\{bef\}) - sup(\{befh\})$. Pattern {*bef*} is frequent (see Figure 1), so it is stored altogether with its support. To the contrary, {*befh*} is not frequent, so the information about {*befh*} and its support is not stored. Thus, we are unable to calculate the support of {*bef*(–*h*)} based on the frequent positive patterns.

The problem of large amount of mined frequent patterns is widely recognized. Within the last decade, a number of lossless representations of frequent positive patterns have been proposed. Frequent closed itemsets were introduced in (Pasquier et al., 1999); the generators representation was introduced in (Kryszkiewicz, 2001). Other lossless representations are based on disjunction-free sets (Bykowski & Rigotti, 2001), disjunction-free generators (Kryszkiewicz, 2001), generalized disjunction-free generators (Kryszkiewicz & Gajek, 2002), generalized disjunction-free sets (Kryszkiewicz, 2003), non-derivable itemsets (Calders & Goethals, 2002), and *k*-free sets (Calders & Goethals, 2003). All these models allow distinguishing between frequent and infrequent positive patterns and enable determination of supports for all frequent positive patterns. Although the research on concise representations of frequent positive patterns is advanced, there are few papers in the literature devoted to representing of all frequent patterns with negation.

MAIN THRUST OF THE CHAPTER

We define a *generalized disjunction-free literal set model* (GDFLR) as a concise lossless representation of all frequent positive patterns and all frequent patterns with negation. Without the need to access the database, GDFLR enables distinguishing between all frequent and infrequent patterns, and enables calculation of the supports for all frequent patterns. We also define a *k-generalized disjunction-free literal set model* (*k*-GDFLR) as a modification of GDFLR for more concise lossless representing of all frequent positive patterns and all frequent patterns with at most *k* negated items.

Both representations may use the mechanism of deriving supports of positive patterns that was proposed in (Kryszkiewicz & Gajek, 2002). Hence, we first recall this mechanism. Then we examine how to use it to derive the supports of patterns with negation and introduce a respective naive representation of frequent patterns. Next we examine relationships between specific patterns and supports of their variations. Eventually, we use the obtained results to offer GDFLR as a refined version of the naive model, and *k*-GFLDR as a generalization of GDFLR which coincides with GDFLR for $k = \infty$.

Reasoning about Positive Patterns Based on Generalized Disjunctive Patterns

Let us observe that whenever item *a* occurs in a transaction in database D, then item *b*, or *f*, or both also occur in the transaction. This fact related to pattern {*abf*} can be expressed in the form of implication $a \Rightarrow b \vee f$. Now, without accessing the database, we can derive additional implications, such as $ac \Rightarrow b \vee f$ and $a \Rightarrow b \vee f \vee c$, which are related to supersets of {*abf*}. The knowledge of such implications can be used for calculating the supports of patterns they relate to. For example, $ac \Rightarrow b \vee f$ implies that the number of transactions in which {*ac*} occurs equals the number of transactions in which {*ac*} occurs with *b* plus the number of transactions in which {*ac*} occurs with *f* minus the number of transactions in which {*ac*} occurs both with *b* and *f*. In other words, *sup*({*ac*}) = *sup*({*acb*}) + *sup*({*acf*}) – *sup*({*acbf*}). Hence, *sup*({*abcf*}) = *sup*({*abc*}) + *sup*({*acf*}) – *sup*({*ac*}), which means that the support of pattern {*abcf*} is determinable from the supports of its proper subsets. In general, if there is an implication related to a positive pattern, then the support of this pattern is derivable from the supports of its proper subsets (please, see (Kryszkiewicz & Gajek, 2002) for proof). If there is such an implication for a pattern, then the pattern is called a *generalized disjunctive set*. Otherwise, it is called a *generalized disjunction-free set*. We will present now a lossless *generalized disjunction-free set representation* (GDFSR) of all frequent positive patterns, which uses the discussed mechanism of deriving supports. The GDFSR representation is defined as consisting of the following components (Kryszkiewicz, 2003):

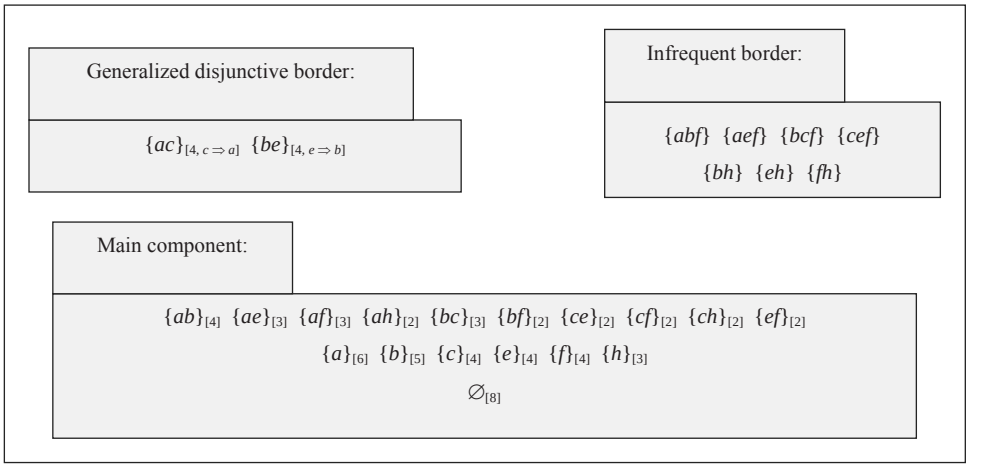
- The main component containing all frequent generalized disjunction-free positive patterns stored altogether with their supports;
- The infrequent border consisting of all infrequent positive patterns all proper subsets of which belong to the main component;
- The generalized disjunctive border consisting of all minimal frequent generalized disjunctive positive patterns stored altogether with their supports and/or respective implications.

Figure 2 depicts the GDFSR representation found in D. The main component consists of 17 elements, the infrequent border of 7 elements, and generalized disjunctive border of 2 elements.

Now, we will demonstrate how to use this representation for evaluating unknown positive patterns:

- Let us consider pattern {*abcf*}. We note that {*abcf*} has a subset, e.g. {*abf*}, in the infrequent border. This means that all supersets of {*abf*}, in particular {*abcf*}, are infrequent.
- Let us consider pattern {*abce*}. It does not have any subset in the infrequent border, but has a subset, e.g. {*ac*}, in the generalized disjunctive border. Property $c \Rightarrow a$, which is associated with {*ac*} implies property $bce \Rightarrow a$ related to {*abce*}. Hence, *sup*({*abce*}) = *sup*({*bce*}). Now, we need to determine the support of {*bce*}. We observe that {*bce*} has subset {*be*} in the generalized disjunctive border. Property $e \Rightarrow b$ associated with {*be*} implies property $ce \Rightarrow b$ related to {*bce*}. Hence, *sup*({*bce*}) = *sup*({*ce*}). Pattern {*ce*} belongs to the main component, so its support is known (here: equals 2). Summarizing, *sup*({*abce*}) = *sup*({*bce*}) = *sup*({*ce*}) = 2.

Figure 2. The GDFSR representation found in D



Naive Approach to Reasoning About Patterns with Negation based on Generalized Disjunctive Patterns

One can easily note that implications, we were looking for positive patterns, may exist also for patterns with negation. For instance, looking at Table 1, we observe that whenever item *a* occurs in a transaction, then item *b* occurs in the transaction and/or item *e* is missing in the transaction. This fact related to pattern $\{ab(\neg e)\}$ can be expressed as implication $a \Rightarrow b \vee (\neg e)$. Hence, $sup(\{a\}) = sup(\{ab\}) + sup(\{a(\neg e)\}) - sup(\{ab(\neg e)\})$, or $sup(\{ab(\neg e)\}) = sup(\{ab\}) + sup(\{a(\neg e)\}) - sup(\{a\})$. Thus, the support of pattern $\{ab(\neg e)\}$ is determinable from the supports of its proper subsets. In general, the support of a generalized disjunctive pattern with any number of negated items is determinable from the supports of its proper subsets.

Having this in mind, we conclude that the GDFSR model can easily be adapted for representing all frequent patterns. We define a *generalized disjunction-free set representation of frequent patterns admitting negation* (GDFSRN) as holding all conditions that are held by GDFSR except for the condition restricting the representation's elements to positive patterns. GDFSRN discovered from database D consists of 113 elements. It contains both positive patterns and patterns with negation. For instance, $\{bc\}_{[3]}$, $\{b(\neg c)\}_{[2]}$, and $\{(\neg b)(\neg c)\}_{[2]}$, which are frequent generalized disjunction-free, are sample elements of the main component of this representation, whereas $\{a(\neg c)\}_{[2,\ \varnothing \Rightarrow a \vee (\neg c)]}$, which is a minimal frequent generalized disjunctive pattern, is a sample element of the generalized disjunctive border. Although conceptually straightforward, the representation is not concise, since its cardinality (113) is comparable with the number of all frequent patterns (109).

Generalized Disjunctive Patterns vs. Supports of Variations

Let us consider implication $a \Rightarrow b \vee f$, which holds in our database. The statement that whenever item *a* occurs in a transaction, then item *b* and/or item *f* also occurs in the transaction is equivalent to the statement that there is no transaction in which *a* occurs without both *b* and *f*. Therefore, we conclude that implication $a \Rightarrow b \vee f$ is equivalent to statement $sup(a(\neg b)(\neg f)) = 0$. We generalize this observation as follows:

$x_1 \ldots x_m \Rightarrow x_{m+1} \vee \ldots \vee x_n$ is equivalent to $sup(\{x_1, \ldots, x_m\} \cup \{\neg x_{m+1}, \ldots, \neg x_n\}) = 0$.

Let us recall that $x_1 \ldots x_m \Rightarrow x_{m+1} \vee \ldots \vee x_n$ implies that pattern $\{x_1, \ldots, x_n\}$ is generalized disjunctive, and $sup(\{x_1, \ldots, x_m\} \cup \{\neg x_{m+1}, \ldots, \neg x_n\}) = 0$ implies that pattern $\{x_1, \ldots, x_n\}$ has a variation different from itself that does not occur in any transaction. Hence, we infer that a positive pattern is generalized disjunctive if and only if it has a variation with negation the support of which equals 0.

Effective Approach to Reasoning About Patterns with Negation based on Generalized Disjunctive Patterns

In order to overcome the problem of possible small conciseness ratio of the GDFSRN model, we offer a new representation of frequent patterns with negation. Our intention is to store in the new representation at most one pattern for a number of patterns occurring in GDFSRN that have the same positive variation.

We define a *generalized disjunction-free literal representation* (GDFLR) as consisting of the following components:

- the main component containing each positive pattern (stored with its support) that has at least one frequent variation and all its variations have non-zero supports;
- the infrequent border containing each minimal positive pattern all variations of which are infrequent and all proper subsets of which belong to the main component;
- the generalized disjunctive border containing each minimal positive pattern (stored with its support and, eventually, implication) that has at least one frequent variation and at least one variation with zero support.

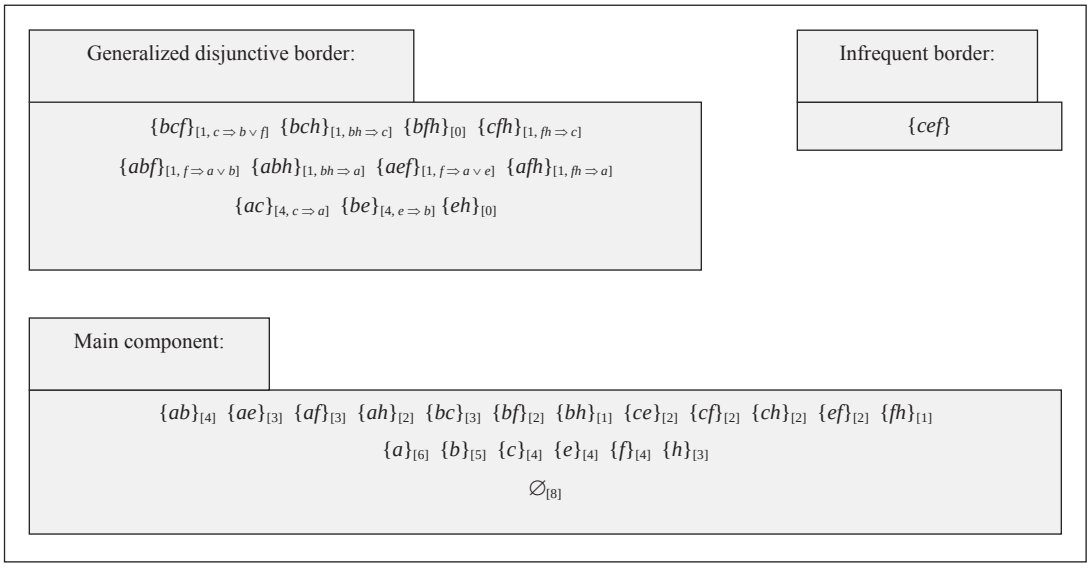
Please note that each element in the main component is generalized disjunction-free since all its variations have non-zero supports. On the other hand, each element in the generalized disjunctive border is generalized disjunctive or has support equal to zero.

Figure 3 depicts GDFLR discovered in D. The main component consists of 19 elements, the infrequent border of 1 element, and generalized disjunctive border of 11 elements.

Now we will illustrate how to use this representation for evaluating unknown patterns:

- Let us consider pattern $\{a(\neg c)(\neg e)f\}$. We note that $\{acef\}$, which is a positive variation of the evaluated pattern, has subset $\{cef\}$ in the infrequent border. This means that both $\{cef\}$ and all its variations including $\{(\neg c)(\neg e)f\}$ are infrequent. Hence, $\{a(\neg c)(\neg e)f\}$, which is a superset of $\{(\neg c)(\neg e)f\}$, is also infrequent.
- Let us consider pattern $\{bef(\neg h)\}$. The positive variation $\{befh\}$ of $\{bef(\neg h)\}$ does not have any subset in the infrequent border, so $\{bef(\neg h)\}$ has a chance to be frequent. Since, $sup(\{bef(\neg h)\}) = sup(\{bef\}) - sup(\{befh\})$, we need to determine the supports of two positive patterns $\{bef\}$ and $\{befh\}$. $\{bef\}$ has subset $\{be\}$ in the generalized disjunctive border, the implication of which is $e \Rightarrow b$. Hence, $ef \Rightarrow b$ is an implication for $\{bef\}$.

Figure 3. The GDFLR representation found in D



Thus, $sup(bef) = sup(ef) = 2$ (please, see the main component for pattern $\{ef\}$). Pattern $\{befh\}$ also has a subset, e.g. $\{eh\}$, in the generalized disjunctive border. Since $sup(\{eh\}) = 0$, then $sup(\{befh\})$ equals 0 too. Summarizing, $sup(\{bef(-h)\}) = 2 - 0 = 2$, and thus $\{bef(-h)\}$ is a frequent pattern.

GDFLR is a lossless representation of all frequent patterns. It can be proved that a pessimistic estimation of the length of a longest element in GDFLR depends logarithmically on the number of records in the database. A formal presentation of this model and its properties, as well as an algorithm for its discovery and experimental results can be found in (Kryszkiewicz, 2004b). The experiments carried out on real large data sets show that GDFLR is by several orders of magnitude more concise than all frequent patterns. Further reduction of GDFLR (and GDFSRN) can be achieved by applying techniques for reducing borders (Calders & Goethals, 2003; Kryszkiewicz, 2003; Kryszkiewicz, 2004a) or a main component (Kryszkiewicz, 2004c).

In (Kryszkiewicz & Cichon, 2005), we discuss the complexity of evaluating candidate elements of the representation. We observe that the calculation of the support of a pattern with n negated items from the supports of positive patterns requires the knowledge of the support of the positive variant P of that pattern and the supports of $2^n - 1$ proper subsets of pattern P. In order to alleviate this problem, we offer a special ordering of candidate elements in (Kryszkiewicz & Cichon, 2005). The introduced ordering enables calculation of the support of a pattern with n negated items as the difference of the supports of only two patterns, possibly with negation, the supports of which were calculated earlier. The proposed algorithm using this method of calculating supports performs much faster (by up to two orders of magnitude for low support threshold values). Nevertheless, in each iteration l, it requires storing all variants of all candidates of length l and all variants of all elements of the main component of length l-1.

Reasoning about Patterns with at Most k-Negated Items

An important part of data mining is discovering patterns conforming user-specified constraints. It is natural to expect that the derivation of a part of all frequent patterns instead of all of them should take less time and should produce less number of patterns than unrestricted data mining. One can also anticipate that a representation of a part of all frequent patterns should be more concise than the representation of all frequent patterns. In this section, we define a generalized disjunction-free literal representation of frequent patterns with at most k negated items (k-GDFLR). The new representation consists of the following components (Kryszkiewicz, 2006):

- the main component containing each positive pattern (stored with its support) that has at least one frequent variation with at most k negated items and is neither generalized disjunctive nor has support equal 0;
- the infrequent border containing each positive pattern whose all variations with at most k negated items are infrequent and whose all proper subsets belong to the main component;
- the generalized disjunctive border containing each minimal positive pattern (stored with its support and/or implication) that has at least one frequent variation with at most k negated items and at least one variation with zero support.

Please note that for $k = 0$ (no negation allowed) k-GDFLR represents all frequent positive patterns, whereas for $k = \infty$ (unrestricted number of negations) it represents all frequent patterns: both positive ones and with negation.

It was proved in (Kryszkiewicz, 2006) that the k-GDFLR representation losslessly represents all frequent patterns with at most k negated items. The conducted experiments show that k-GDFLR is more concise and faster computable than GDFLR especially for low support values and low k.

FUTURE TRENDS

Development of different representations of frequent patterns with negation and algorithms for their discovery can be considered as a short-term trend. As a long-term trend, we envisage development of representations of patterns satisfying user imposed constraints and representations of other kinds of knowledge admitting negation, such as association rules, episodes, sequential patterns and classifiers. Such research should stimulate positively the development of inductive databases, where queries including negation are common.

CONCLUSION

The set of all positive patterns can be treated as a lossless representation of all frequent patterns, nevertheless it is not concise. On the other hand, the set of all frequent positive patterns neither guarantees derivation of all frequent patterns with negation, nor is concise in practice. The GDFSRN and GDFLR representations, we proposed, are first lossless representations of both all frequent positive patterns and patterns with negation. GDFLR consists of a subset of only positive patterns and hence is more concise than analogous GDFSRN, which admits the storage of many patterns having the same positive variation. We have proposed the *k*-GDFLR representation for even more concise, lossless representing of all frequent patterns with at most *k* negated items. In (Kryszkiewicz & Cichon, 2005), we have offered a method for fast calculation of the supports of the candidate elements of the generalized disjunction-free representations, which is based on a special ordering of the candidate patterns.

KEY TERMS

Frequent Pattern: Pattern the support of which exceeds a user-specified threshold.

Generalized Disjunction-Free Pattern: Pattern the support of which is not determinable from the supports of its proper subsets.

Generalized Disjunctive Pattern: Pattern the support of which is determinable from the supports of its proper subsets.

Item: 1) sales product; 2) feature, attribute.

Literal: An item or negated item.

Lossless Representation of Frequent Patterns: Fraction of patterns sufficient to distinguish between frequent and infrequent patterns and to determine the supports of frequent patterns.

Pattern with Negation: Pattern containing at least one negated item.

Positive Pattern: Pattern with no negated item.

Reasoning about Patterns: Deriving supports of patterns without accessing a database.

Support of a Pattern: The number of database transactions in which the pattern occurs.

Receiver Operating Characteristic (ROC) Analysis

Nicolas Lachiche
University of Strasbourg, France

INTRODUCTION

Receiver Operating Characteristic (ROC curves) have been used for years in decision making from signals, such as radar or radiology. Basically they plot the hit rate versus the false alarm rate. They were introduced recently in data mining and machine learning to take into account different misclassification costs, or to deal with skewed class distributions. In particular they help to adapt the extracted model when the training set characteristics differ from the evaluation data. Overall they provide a convenient way to compare classifiers, but also an unexpected way to build better classifiers.

BACKGROUND

ROC analysis mainly deals with binary classifiers, models associating each entry to the positive or to the negative class. The performance of a given classifier is collected in a confusion matrix (also known as a contingency table) counting the number of training examples in each of the four cells depending on their actual classes and on their predicted classes (see Table 1).

The True Positive Rate (TPR) is the fraction of positive examples correctly classified, TP/P and the False Positive Rate (FPR) is the fraction of negative examples incorrectly classified, FP/N.

MAIN FOCUS

ROC Space

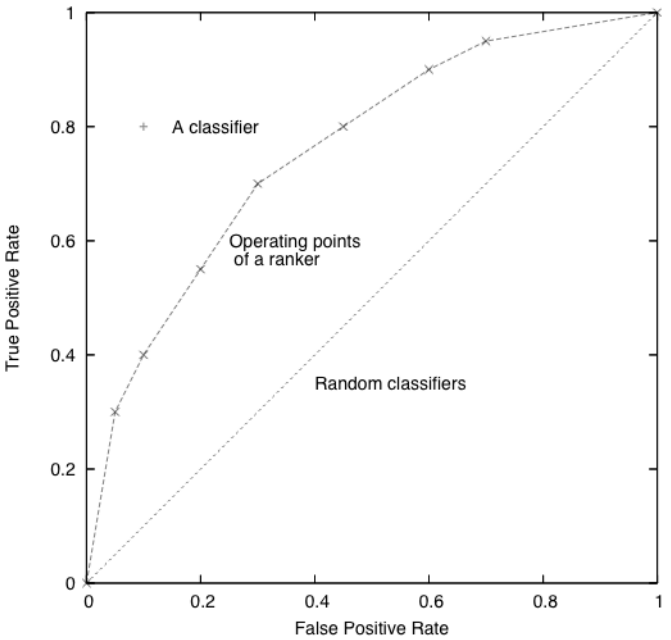
A ROC curve plots the True Positive Rate (TPR, aka recall or sensitivity) versus the False Positive Rate (FPR, equals to 1 – specificity). The performance of a binary classifier corresponds to a single point in the ROC space, cf. A classifier on Figure 1.

A ranker is a model associating a score to each entry, e.g. the naive bayesian classifier. Intuitively this score represents the "probability" that the entry is positive, even if it is not always a proper probability. Overall it provides a ranking of all examples. A threshold can be chosen and all examples whose score is above (respectively below) that threshold are predicted as positive (resp. negative). This is a called an Operating Point. It turns a ranker into a classifier. Different operating points lead to different classifiers. Therefore a ranker leads to a whole ROC curve, cf. Operating points of a ranker on Figure 1. Actually the curve is not continuous, only the operating points make sense. The number of operating points is the number of different ways of splitting the ranking of the examples. It is the number of examples if there are no tie, less otherwise. An efficient algorithm (Fawcett, 2004) to build the ROC curve is:

Table 1.

	Real Positive	Real Negative
Predicted Positive	True Positive (TP) aka Hit	False Positive (FP) aka False Alarm aka Type I Error
Predicted Negative	False Negative (FN) aka Miss aka Type II Error	True Negative (TN) aka Correct Rejection
	Total Number of Positive (P)	Total Number of Negative (N)

Figure 1. A classifier and a ranker in the ROC space



1. start in (0,0) with a score equals to the infinity
2. for each example ordered by decreasing scores
    1. if its score is different from the current score, plot a point in the current position and store its score as the current one
    2. if the example is positive, move up by 1/P, if it is negative move by 1/N

The ROC space contains several well-known landmarks:

- the top left corner corresponds to a perfect classifier, predicting correctly all positive and all negative examples,
- the bottom left corresponds to the constantly negative classifier, always predicting negative,
- the top right corner corresponds to the constantly positive classifier,
- the bottom-left to top-right diagonal denotes the performances of random classifiers, indeed any point can be obtained by a classifier randomly predicting positive a constant proportion of the entries, e.g. (0.3,0.3) corresponds to a classifier randomly predicting positive 30% of the entries.

Selection Of The Best Model According To The Operating Conditions Independently Of The Training Conditions

A ROC curve is first useful to select an operating point for a ranker or to select one among different classifiers. It should be noted that a ROC curve is insensitive to the class distribution because TPR and FPR do not depend on it. Whatever the class distribution and misclassification costs were on the training set, it is possible to select the best model according to their values on the new population to predict. Indeed once the expected number of positive P', the expected number of negative N', and the cost of misclassifying a positive (resp. negative) example C(-/+) (resp. C(+/-)) are known, it is easy to select the classifier:

- either maximizing the accuracy = P' * TPR + N' * (1 – FPR)
- or minimizing the cost = C(+/-) * FPR + C(-/+) * (1 - TPR).

Global Comparison Of Models

Classifiers are usually compared using simple measures such as the accuracy. However the accuracy depends on each operating point for a ranker. The ROC space allows to compare rankers before and independently of the final operating conditions.

- If a classifier is above and on the left-hand side of another classifier, the former dominates the latter, e.g. Classifier A dominates Classifier B on Figure 2.
- The Area Under the ROC Curve (AUC) summarizes the performances of a ranker over all possible operating points. Actually the AUC is equivalent to the Wilcoxon rank-sum test (aka Mann-Whitney U test). It measures the probability that a randomly chosen positive example will be assigned a greater rank than a randomly chosen negative example. Still one ranker can dominate another, e.g. Ranker X dominates Rankers Y and Z on Figure 2, but rankers can also be not comparable, e.g. Rankers Y and Z on Figure 2.

Improvement Of Current Models

Last but not least ROC analysis allows to build new classifiers.

- First any point between two classifiers can be reached, e.g. On Figure 3 Point C on the segment between Classifiers A and B can be reached by randomly choosing the prediction of Classifier A for 20% of the entries and the prediction of the classifier B otherwise.
- Therefore any classifier below and on the right-hand side of a segment joining two classifiers is dominated, e.g. Classifier D on Figure 3, and only the ROC convex hull is considered, cf. Figure 3.
- ROC analysis can also lead to new, better models. First, a bad (worse than random) classifier can be turned into a good classifier, by negating its predictions, e.g. Classifier A' is the negation of A on Figure 4. Flach & Wu (2005) show that a similar correction can also be applied to any classifiers B, C, D such that TPR(B) < TPR(C) < TPR(D) and FPR(B) < FPR(C) < FPR(D) and classifier C' can be built that agrees with B and D when B and D do agree, and predicts the negation of C when B and D disagree, cf. Figure 4. Those conditions are trivially satisfied if B, C and D are different operating points of a same ranker.
- If two classifiers are independent, in particular when they do not correspond to two operating points of the same ranker, Fawcett (2004) shows that their logical conjunction and disjunctions cor-

Figure 2. Comparison of models

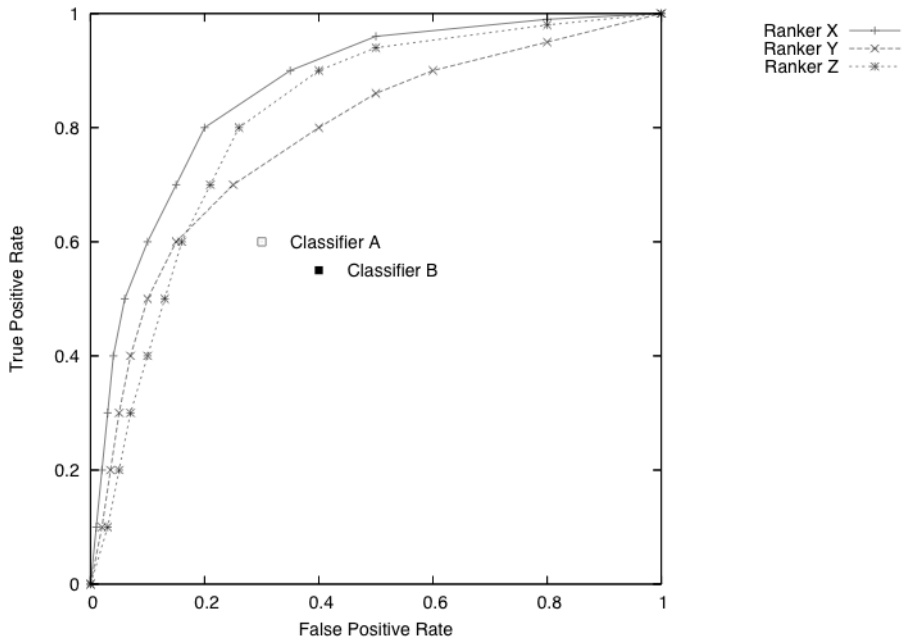


Figure 3. Interpolating classifiers and the ROC convex hull

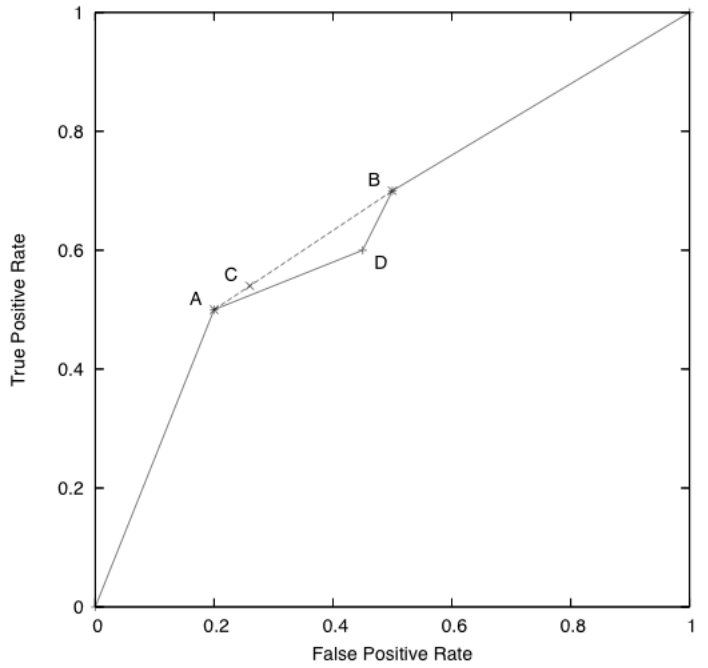

Figure 4. Improving models

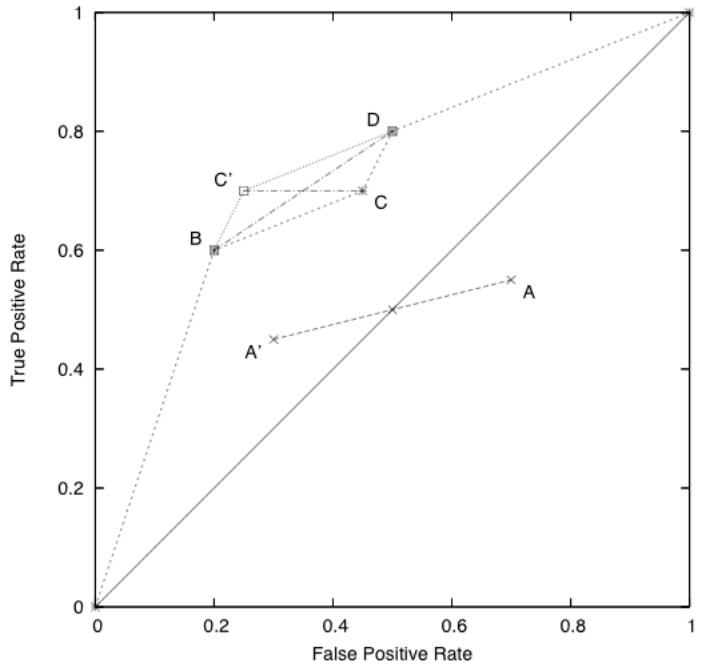

Figure 5. Logical combination of independent classifiers

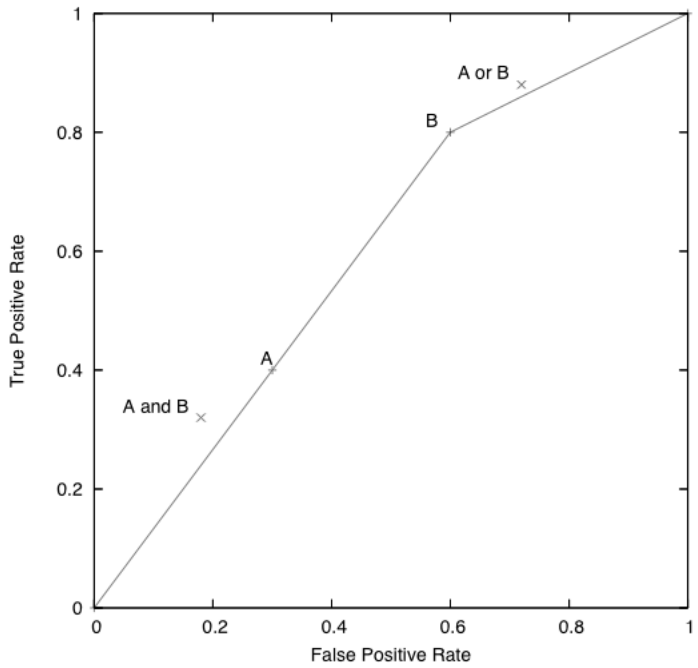

respond to new classifiers whose true positive and false positive rates can be approximated by:

- $TPR(A \otimes B) = TPR(A)*TPR(B)$
- $FPR(A \otimes B) = FPR(A)*FPR(B)$
- $TPR(A \oplus B) = TPR(A) + TPR(B) - TPR(A)*TPR(B)$
- $FPR(A \oplus B) = FPR(A) + FPR(B) - FPR(A)*FPR(B)$

Those new classifiers lie outside the ROC convex hull of classifiers A and B, cf. Figure 5.

Averaging ROC Curves

First of all, a k-fold cross-validation produces k classifiers or rankers. Their results can be averaged, as their accuracies usually are, but their variance should be measured and represented too. The most frequent methods are:

- Vertical averaging: for each FPR, the average and standard deviation of the TPR on the k curves are computed,
- Threshold averaging: for each threshold, the averages and standard deviations of the TPR and FPR are computed.

Vertical averaging is practical only if the FPR can be easily tuned, and it only measures variations on the TPR dimension. Threshold averaging solves both problems. However it requires to compare the scores produced by different rankers, which may not be calibrated (Fawcett, 2004). Macskassy and Provost (2004) survey more sophisticated ways of providing confidence bands to ROC curves.

FUTURE TRENDS

ROC curve have a clear meaning since they display the hit rate versus the false alarm rate. Though alternative have been suggested that present different and useful points of view. For instance, DET (Detection Error Trade off) curves (Martin et al, 1997) plot false negative versus false positive in log scale in order to zoom on the lower left part of the graph. Indeed this part corresponds to the upper left part of the corresponding ROC curve and so helps to distinguish classifiers performances. Cost curves (Drummond & Holte, 2006) have a complementary point of view. They display the error rate in function of the proportion of positive instances, respectively the cost in function of the probability times cost.

ROC curve are primarily defined for binary classes. However lots of domains involve either multiple classes or continuous classes. Different approaches have been suggested to address multi-class problems, ranging from turning the multi-class problem into several pairwise problems (Hand & Till, 2001) to exploring a N dimensional ROC surface (Lachiche & Flach, 2003). Regression Error Curves (REC) were proposed to deal with numerical targets. Bi and Bennet (2003) prove statistical properties of the REC curve. However their usefulness is limited to graphically comparing models until now.

CONCLUSION

ROC curves have quickly become part of the standard data mining toolbox. While most people are only aware of the AUC to replace the accuracy in comparing models, ROC analysis offers other benefits: from adapting a model to different operating conditions, to building better classifiers. ROC analysis has also been used to enlight most machine learning metrics (Flach, 2003), (Fürnkranz & Flach, 2003) or to prove the equivalence between the Pool Adjacent Violators (PAV) algorithm and the ROC convex hull (Niculescu-Mizil & Fawcett, 2007). ROC analysis has still lots to offer to data mining practitioners.

KEY TERMS

Accuracy: The fraction of examples correctly classified, i.e. the number of positive examples classified as positive plus the number of negative examples

classified as negative divided by the total number of examples.

AUC: The Area Under the ROC Curve.

Classifier: A model associating a class to each entry, and more generally the learning system that extracts that model from the training data.

Cost-Sensitive: Taking into account different costs associated to different misclassifications, for instance the loss associated to granting a credit to a faulty customer compared to rejecting a good customer.

Operating Point: One point of a ROC curve, corresponding to one threshold of a ranker, i.e. to one classifier. The threshold can be expressed in terms of the corresponding respective prior probabilities of positive and negative.

Ranker: A model associating a rank to each entry, and more generally the learning system that extracts that model from the training data.

ROC Curve: The Receiver Operating Characteristic curve plots the hit rate in function of the false alarm rate, and was first used with Radars.

ROC Convex Hull: The convex envelop of the ROC curve.

Reflecting Reporting Problems and Data Warehousing

Juha Kontio
Turku University of Applied Sciences, Finland

INTRODUCTION

Reporting is one of the basic processes in all organizations. Reports should offer relevant information for guiding the decision-making. Reporting provides information for planning and on the other hand it provides information for analyzing the correctness of the decisions made at the beginning of the processes. Reporting is based on the data the operational information systems contain. Reports can be produced directly from these operational databases, but an operational database is not organized in a way that naturally supports analysis. An alternative way is to organize the data in such a way that supports analysis easily. Typically this leads to the introduction of a data warehouse.

In summer 2002 a multiple case study research was launched in six Finnish organizations. The research studied the databases of these organizations and identified the trends in database exploitation. One of the main ideas was to study the diffusion of database innovations. In practice this meant that the present database architecture was described and the future plans and present problems were identified. The data was mainly collected with semi-structured interviews and altogether 54 interviews were arranged.

The research processed data of 44 different information systems. Most (40 %) of the analyzed information systems were online transaction processing systems like order-entry systems. Second biggest category (30 %) was information systems relating to decision support and reporting. Only one pilot data warehouse was among these, but on the other hand customized reporting systems was used for example in SOK, SSP and OPTI. Reporting was anyway commonly recognized as an area where interviewees were not satisfied and improvements were hoped.

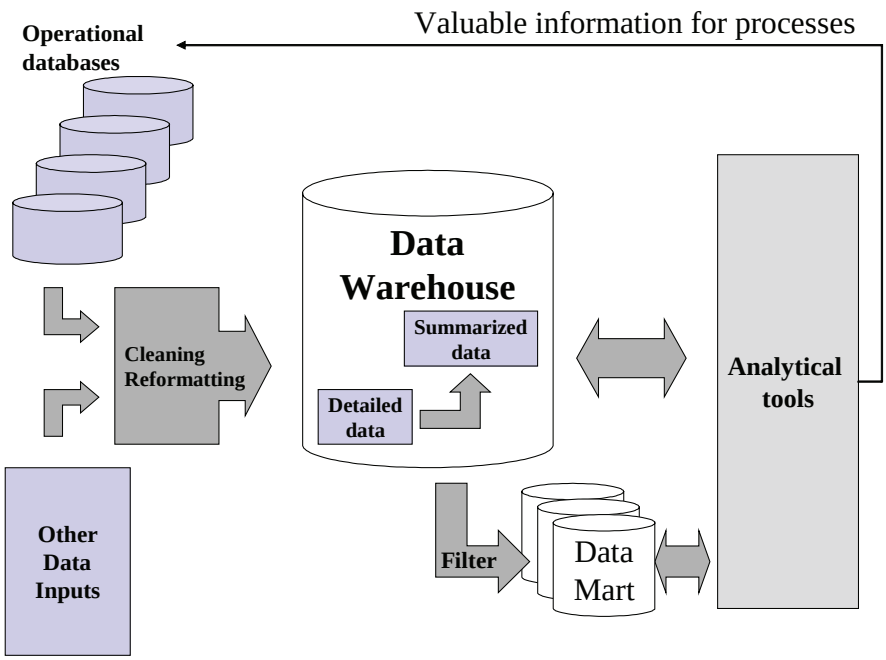
Turku University of Applied Sciences is one of the largest of its kind in Finland with almost 9000 students and 33 Degree Programs. Our University is organized in six units of education that promote multidisciplinary learning. In autumn 2005 an enterprise resource planning system was introduced at Turku University of Applied Sciences. At the heart of this information system is a data warehouse collecting necessary information from the operational databases.

This paper concentrates on briefly describing the identified problems in reporting in the earlier research and how a data warehouse might help overcoming these problems (a more thorough description is provided at (Kontio 2005)). These ideas are benchmarked with usage experiences of the data warehouse based ERP at Turku University of Applied Sciences resulting to some generalizations and confirmation.

BACKGROUND

The term data warehouse was first introduced as a subject-oriented, integrated, non-volatile, and time variant collection of data in support of management's decisions (Inmon 1992). A simpler definition says that a data warehouse is a store of enterprise data that is designed to facilitate management decision-making (Kroenke 2004). A data warehouse differs from traditional databases in many points. The structure of a data warehouse is different than traditional databases and different functionalities are required (Elmasri and Navathe 2000). The aim is to integrate all corporate information into one repository where the information is easily accessed, queried, analyzed and used as basis for the reports (Begg and Connolly 2002). A data warehouse provides decision support to organizations with the help of analytical databases and On Line Analytical Processing (OLAP) tools (Gorla 2003). A data warehouse (see Figure 1.) receives data from the operational databases on regular basis and new data is added to the existing data. This process is called an ETL-process letters standing for extract, transform and load (Simitsis 2005). A data warehouse contains both detailed aggregated data and also summarized data to

Figure 1. Data Warehousing



speed up the queries. A data warehouse is typically organized in smaller units called data marts that support the specific analysis needs of a department or a business unit (Bonifati, Cattaneo et al. 2001).

In the case organizations the idea of the data warehouse had been discussed but so far no data warehouses existed although in one case a data warehouse pilot was in use. The main reason for these discussions was that the reporting and the analyzing possibilities are not serving the organizations very well. The research actually identified many problems in reporting. The reporting and analyzing problems played also a role in starting the ERP design at our University.

The case organizations of the 2002 study introduced several problems in reporting and analyzing (Table 1).

These cases proposed alternative solutions to overcome the presented problems in reporting and analyzing. In case A centralization of the data has been discussed to overcome the challenges. In case B the organization has discussed a data warehouse solution for three

Table 1. Identified problems in reporting and analyzing.

Organization	Problems in reporting and analyzing
A	The data is distributed in numerous information systems and building a comprehensive view of the data is difficult. Financial reporting gives conflicting results, because data is not harmonized and processed similarly.
B	The major information system is somehow used inconsistently leading to data that is not consistent. The reporting system has capacity limitations and users are incapable to define own reports. Analyzing customer data is also difficult, because the collection of relevant data is very hard.
C	The case organization gathers and analyzes a large amount of data, but no special data management tools were not in use. The analysis task is a very burdensome task.
D	Reporting was not identified as a major problem at the moment, but a DW might offer extra value in data analysis.
E	A DW pilot existed, but the distribution and the format of the reports should be solved. Due to some compatibility problems the usage of the system is not widely spread.
F	Reports are generated directly from operational databases that are not designed for reporting purposes.

reasons: a) to get rid of the capacity problems, b) to provide a user friendlier system where definition of reports is easier and c) to gain more versatile analysis possibilities. In case F a data warehouse solution was justified with the possibility to define customized reports. In addition, the ability to serve customers better was named as a rationale.

Before 2005, we used balanced scorecards to define our goals. We had separate Excel sheets for defining BSC numeric goals. Unfortunately, these goals remained partly irrelevant and distant from the operational level. Reliable analysis of our success was difficult to achieve, because exact data was not easily available. This influenced our reporting as well. Our reporting and analysis was unformulated and random and it seldom had direct effects on our operation. In addition, there were certain mandatory reports that required a plenty of manual work. We had to give regular reports to the Ministry of Education, City of Turku and some other public organizations as well.

At 2005, an ERP system was introduced for management and resource planning in our institute. The introduction of this system was an effort to link operational and strategic management. Resource planning is here understood as setting goals, planning actions for the goals, resourcing the actions and follow-up and analysis of the results. A central part of our ERP system is a data warehouse where operational data is extracted, transformed and loaded. This data is used for analysis, action planning and reporting.

MAIN THRUST OF THE CHAPTER

Before introducing a data warehouse the organization has to do a lot of careful design. A requirement analysis is needed to successfully design and represent the desired information needs in the data warehouse (Mazon, Trujillo et al. 2007). Designing a data warehouse requires quite different techniques than the design of an operational database (Golfarelli and Rizzi 1998). Modeling a data model for a data warehouse is seen as one of the most critical phases in the development process of a data warehouse (Bonifati, Cattaneo et al. 2001). This data modeling has specific features that distinguish it from normal data modeling (Busborg, Christiansen et al. 1999). At the beginning the content of the operational information systems, the interconnections between them and the equivalent entities should be understood (Blackwood 2000). It is crucial to obtain a consistent reconciliation of data sources and information needs (Mazon, Trujillo et al. 2007). In practice this means studying the data models of the operational databases and developing an integrated schema to enhance data interoperability (Bonifati, Cattaneo et al. 2001).

The data modeling of a data warehouse is called dimensionality modeling (DM) (Golfarelli and Rizzi 1998; Begg and Connolly 2002). Dimensional models were developed to support analytical tasks (Loukas and Spencer 1999). Dimensionality modeling concentrates on facts and the properties of the facts and dimensions connected to facts (Busborg, Christiansen et al. 1999). Facts are numeric and quantitative data of the business and dimensions describe different dimensions of the business (Bonifati, Cattaneo et al. 2001). In other words, facts are used to memorize quantitatively business situations and dimension are used to analyze these situations (Schneider 2007). Fact tables contain all business events to be analyzed and dimension tables define how to analyze fact information (Loukas and Spencer 1999). The result of the dimensionality modeling is typically presented in a star model or in a snowflake model (Begg and Connolly 2002). multi dimensional schema (MDS) is a more generic term that is used to collectively refer to both schemas (Martyn 2004). When a star model is used the fact-tables are normalized, but dimension-tables are not. When dimension-tables are normalized too, the star-model turns into snowflake-model. (Bonifati, Cattaneo et al. 2001)

Ideally an information system like a data warehouse should be correct, fast and friendly (Martyn 2004). Correctness is especially important in data warehouses to ensure that decisions are based on correct information. In principal data warehouse is used for strategic decisions, hence the quality of data warehouse is crucial (Serrano, Trujillo et al. 2007). However, it is estimated that 30 to 50 percent of information in a typical database is missing or incorrect (Blackwood 2000). This emphasizes the need to pay attention to the quality of the source data in the operational databases (Finnegan and Sammon 2000). A problem with MDS is that when the business environment changes the evolution of MD schemas is not as manageable as normalized schemas (Martyn 2004). It is also said that any architecture not based on third normalized form can cause the failure of a data warehouse project (Gardner 1998). On the other hand however a dimensional model provides a

better solution for a decision support application than a pure normalized relational model (Loukas and Spencer 1999). All the above is actually related to efficiency since a large amount of data is processed during analysis. Typically this is a question about needed joins in the database level. Usually a star schema is the most efficient design for a data warehouse since the denormalized tables require fewer joins (Martyn 2004). However recent developments in storage technology, access methods (like bitmap indexes) and query optimization are indicating that the performance with the third normalized form should be tested before moving to multi dimensional schemas (Martyn 2004). From this 3NF schema a natural step toward MDS is to use denormalization and this will support both efficiency and also flexibility issues (Finnegan and Sammon 2000). Still, there is a possibility to define necessary SQL views on top of the 3NF schema without denormalization (Martyn 2004). Finally, during the design, the issues of physical and logical design should be separated: physical is about performance and logical is about understandability (Kimball 2001).

The OLAP tools access data warehouse for complex data analysis and decision support activities (Kambayashi, Kumar et al. 2004). OLAP tools are based on MDS views. These tools include typically assessing the effectiveness of a marketing campaign, product sales forecasting and capacity planning. The architecture of the underlying database of the data warehouse categorizes the different analysis tools. (Begg and Connolly 2002) Depending on the schema type terms relational OLAP (ROLAP), multidimensional OLAP (MOLAP) and Hybrid OLAP (HOLAP) are used (Kroenke 2004). ROLAP is a preferable choice when a) the information needs change frequently, b) the information should be as current as possible and c) the users are sophisticated computer users (Gorla 2003). The main differences between ROLAP and MOLAP are in currency of data and in data storage processing capacity. MOLAP populates an own structure of the original data when it is loaded from the operational databases (Dodds, Hasan et al. 2000). In MOLAP the data is stored in a special-purpose MDS (Begg and Connolly 2002). ROLAP analyzes the original data and the users can drill down to the unit data level (Dodds, Hasan et al. 2000). ROLAP uses a meta-data layer to avoid the creation of a MDS. ROLAP typically utilize the SQL extensions like CUBE and ROLLUP in Oracle DBMS (Begg and Connolly 2002).

FUTURE TRENDS

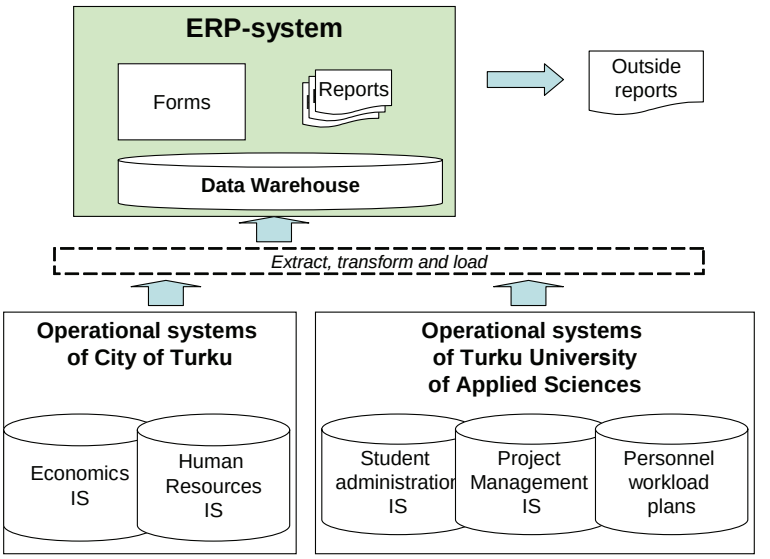
Several future steps were identified in the 2002 case study (Table 2). The presented cases reflect probably quite well the overall situation in different organizations and we might give predictions what is happening in the future. The cases show that organizations have clear problems in analyzing operational data. They have developed own applications to ease the reporting, but still they are living with inadequate solutions. data warehousing has been identified as a possible solution for the reporting problems and the future will show whether data warehouses diffuse in the organizations.

In our university our main operational systems are integrated into the data warehouse of our ERP system (Figure 2). Our future with the ERP system and the data warehouse concentrates on learning the new way of working and learning to utilize the new possibilities in a reasonable manner. There are for example differ-

Table 2. Future of reporting and analyzing in the cases.

Organization	Future steps
A	A comprehensive view of the corporation data needs to be built i.e. an enterprise data model.
B	A major concern is correctness of the data and the way users work with the information systems. The consistency of the data has to be improved before starting a data warehouse project.
C	At first a suitable tool/system is needed for managing the operational data. This provides possibilities to truly benefit from data analysis.
D	A data warehouse could define standard formats for the reports and it could also solve the report distribution problems.
E	A data warehouse could solve slowness problems in reporting. Introduction necessary OLAP tools will improve the situation even further.
F	A data warehouse might offer extra value in data analysis when it is introduced - if at all.

Figure 2. ERP and DW at Turku University of Applied Sciences.



ent levels of planning and analyzing in the system and the lowest levels are learning while higher levels are fully utilizing the system and the data offered from the data warehouse. Furthermore, in the future additional features like more detailed reporting possibilities will be introduced.

CONCLUSION

The case organization recognized the possibilities of a data warehouse to solve the problems in reporting. In our organization we are much longer in our implementation process than the cases were at the time of the research. Now we will compare the findings of the 2002 case study and our experiences with a real life data warehouse implementation.

The data warehouse initiatives of the case organizations based on business requirements, which is a good starting point because to success a data warehouse should be a business-driven initiative, but in partnership with the IT department (Gardner 1998; Finnegan and Sammon 2000). However the first step should be the analysis of the real needs of a data warehouse. Our case also started from business needs: to connect strategic and operational management. This required an environment were necessary data is available for analysis and reporting purposes. The success of the system confirms the essential starting point: business needs.

To really support reporting the operational data should be organized more like in a data warehouse. In practice this means studying and analyzing the existing operational databases. As a result, a data model describing the necessary elements of the data warehouse should be achieved. A suggestion is that first an enterprise level data model is produced to describe all the data and the interconnections of it. This enterprise level data model will be the basis for the data warehouse design. As the theory suggested at the beginning a normalized data model with SQL views should be produced and tested. This can further be denormalized into snowflake or into star model when performance requirements are not met with the normalized schema. Our case pretty much confirms also these ideas. At the beginning a lot of work was done with defining the data, defining the entities and their properties. A database of our data and their definitions was created. A data model was also designed describing the data that is needed in the future data warehouse. Finally, a data warehouse schema was defined with fact and dimension tables.

Producing a data model for the data warehouse is only one part. In addition special attention should be taken in designing data extraction from operational databases to the data warehouse. The enterprise level data model helps understanding the data in these databases and thus eases the development of data extraction solutions. When the data warehouse is in use there should be automated tools that speed up the loading the operational data into the data warehouse (Finnegan and Sammon

2000). Our case confirms that one of the biggest challenges is the ETL-process. It also emphasizes careful planning and design which operational information systems are connected and which are not.

Before loading data into the data warehouse the organizations should also analyze the correctness and the quality of the data in the operational databases. In our case a series of careful test were done and the correctness of the data has been checked over an over. Our case also highlights the importance of the correct use of the operational systems. The data in operational systems must be clean and correct. The more variants and problems there are with the data in operational databases the more difficult it becomes to design the ETL-process successfully. It is essential that the data received from data warehouse is reliable. At the beginning we had some problems with this data. This caused additional problems and extra work thus resulting in just opposite consequences than a data warehouse was supposed to result. Nowadays most of these problems of dirty data are solved. As our experiences show this phase is very important. The technical ETL process might be free of errors, but when the operational data is dirty you cannot be delighted.

Finally, as the paper showed, a data warehouse is a relevant alternative for solving the problems in reporting that the case organizations are currently working with. After the implementation of a Data Warehouse organizations must ensure that the possible users of the system are educated to fully take advantage of the new possibilities that the DW offers. During our implementation process many education sessions had been organized. The system was built and implemented in phases and the users were trained at the same pace. This made the adoption of the system easier. Quite often the training sessions concentrated on the technical features and how to do different single things. The overall management process and the relationship of these different single things were difficult to figure out at the beginning. Still, we see that the implementation of the ERP system has been successful and the training of the user has been sufficient. However, organizations should remember that there is no quick jump to data warehouse exploitation rather all steps takes time and patience, but as this study confirms it is all worth of it.

KEY TERMS

Data Extraction: A process where data is transferred from the operational databases to the data warehouse. Also term ETL (extract-transform-load) -process is used to give a more realistic picture of the process that needs to be done to move data from operational databases to a data warehouse.

Dimensionality Modeling: A logical design technique that aims to present data in a standard, intuitive form that allows for high-performance access.

Normalization/Denormalization: A technique for producing a set of relations with desirable properties, given the data requirements of an enterprise. Denormalization is a step backward in normalization process for example to improve performance.

OLAP: The dynamic synthesis, analysis, and consolidation of large volumes of multi-dimensional data.

Snowflake Model: A variant of the star schema where dimensions tables do not contain denormalized data.

Star Model: A logical structure that has a fact table containing factual data in the center, surrounded by dimension tables containing reference data.

Robust Face Recognition for Data Mining

NICTA, Australia

INTRODUCTION

While the technology for mining text documents in large databases could be said to be relatively mature, the same cannot be said for mining other important data types such as speech, music, images and video. Multimedia data mining attracts considerable attention from researchers, but multimedia data mining is still at the experimental stage (Hsu, Lee & Zhang, 2002). Nowadays, the most effective way to search multimedia archives is to search the metadata of the archive, which are normally labeled manually by humans. This is already uneconomic or, in an increasing number of application areas, quite impossible because these data are being collected much faster than any group of humans could meaningfully label them — and the pace is accelerating, forming a veritable explosion of non-text data. Some driver applications are emerging from heightened security demands in the 21st century, postproduction of digital interactive television, and the recent deployment of a planetary sensor network overlaid on the internet backbone.

BACKGROUND

Although they say a picture is worth a thousand words, computer scientists know that the ratio of information contained in images compared to text documents is often much greater than this. Providing text labels for image data is problematic because appropriate labeling is very dependent on the typical queries users will wish to perform, and the queries are difficult to anticipate at the time of labeling. For example, a simple image of a red ball would be best labeled as sports equipment, a toy, a red object, a round object, or even a sphere, depending on the nature of the query. Difficulties with text metadata have led researchers to concentrate on techniques from the fields of Pattern Recognition and Computer Vision that work on the image content itself. Although pattern recognition, computer vision, and image data mining are quite different fields, they share a large number of common functions (Hsu, Lee & Zhang, 2002).

An interesting commercial application of pattern recognition is a system to semi-automatically annotate video streams to provide content for digital interactive television. A similar idea was behind the MIT MediaLab Hypersoap project (The Hypersoap Project, 2007; Agamanolis & Bove, 1997). In this system, users touch images of objects and people on a television screen to bring up information and advertising material related to the object. For example, a user might select a famous actor and then a page would appear describing the actor, films in which they have appeared, and the viewer might be offered the opportunity to purchase copies of their other films. In the case of Hypersoap, the metadata for the video was created manually. Automatic face recognition and tracking would greatly simplify the task of labeling video in post-production — the major cost component of producing such interactive video.

With the rapid development of computer networks, some web-based image mining applications have emerged. SIMBA (Siggelkow, Schael, & Burkhardt, 2001) is a content-based image retrieval system performing queries based on image appearance from an image database with about 2500 images. RIYA (RIYA Visual Search) is a visual search engine that tries to search content relevant images from the context input. In 2007, Google added face detection to its image search engine (Google Face Search). For example, the URL *http://images.google.com/images?q=bush&imgtype=face* will return faces associated with the name "Bush" including many images of recent US presidents. While

the application appears to work well, it does not actually identify the face images. Instead it relies on the associated text metadata to determine identity.

None of the above systems support the input of face images as a query to retrieve similar images of the same person. A robust face recognition method is needed for such kind of systems. Now we will focus on the crucial technology underpinning such a data mining service—automatically recognizing faces in image and video databases.

MAIN FOCUS

Challenges for Face Recognition
